TEXT-BOOK OF ZOOLOGY

TEXT-BOOK OF ZOOLOGY

FOR JUNIOR STUDENTS.

BY

HENRY ALLEYNE NICHOLSON,

M. D., D. Sc., Ph. D. (GöTT.), F. L. S., F. G. S.,

REGIUS PROFESSOR OF NATURAL HISTORY IN THE UNIVERSITY OF ABERDEEN.

FOURTH EDITION,

REVISED AND ENLARGED.

NEW YORK :: CINCINNATI :: CHICAGO
AMERICAN BOOK COMPANY.

Printed by
D. Appleton & Company
New York, U. S. A.

PREFACE TO THE FOURTH EDITION.

WITH regard to the present Edition of this work, the Author has only to say that he has submitted it to a thorough revision, and, to the best of his ability, has brought it up to the present standard of our knowledge. As the work is strictly elementary, and is intended solely for the use of Junior Students, it has not been deemed advisable to make fundamental alterations in its general plan, or to materially change the classification followed in previous Editions, save in those instances in which there is now a general *consensus* of opinion. The more important recent additions to our acquaintance with the existing or extinct fauna of the world have, however, been noticed in the text, and fresh illustrations have been introduced where this appeared to be desirable.

UNIVERSITY, ABERDEEN,
December 1885.

CONTENTS.

INTRODUCTION.

	PAGE
Definition of Biology and Zoology—Characters of dead and unorganised bodies—Characters of living and organised bodies—Differences between animals and plants—Conditions of Life—Principles of Zoological classification—The great Physiological Functions—Homology and Analogy—General divisions of the Animal Kingdom—Invertebrata and Vertebrata—Distribution in Space—Distribution in Time,	1-17

CHAPTER I.

General characters of the Protozoa—Classification of the Protozoa—Gregarinida,	18-23
--	-------

CHAPTER II.

General characters and orders of the Rhizopoda—Monera—Anatomy of the Amœbea—Foraminifera—Distribution of the Foraminifera in space and in time—Radiolaria—Acanthometræ—Polycystina—Thalassicollida—Heliozoa,	24-36
--	-------

CHAPTER III.

General characters of the Infusoria—Ciliated Infusoria—Anatomy of Paramœcium—Vorticella—Flagellated Infusorians,	37-42
--	-------

CHAPTER IV.

General characters of the Porifera—Structure of a typical Sponge—Reproduction of Spongilla—Distribution of Sponges in space,	43-49
--	-------

CHAPTER V.

General characters of the Cœlenterata—Divisions of the Cœlenterata—General characters of the Hydrozoa—General terminology of the Hydrozoa,	50-57
--	-------

CHAPTER VI.

Divisions of the Hydrozoa—Hydroida—Hydrida—Anatomy of Hydra—Corynida—Reproduction in the Corynida and in the Hydroid Zoophytes generally—Alternation of generations—Sertularida—Campanularida—Medusidæ,	58-71
---	-------

CHAPTER VII.

Siphonophora or Oceanic Hydrozoa—Calycephoridae—Physophoridae,	72-75
--	-------

CHAPTER VIII.

Lucernarida—Hidden-eyed Medusæ—Development of Lucernarida—Rhizostomidae—Ceratolithidae—Hydrocorallinae,	76-82
---	-------

CHAPTER IX.

General characters of the Actinozoa—Zoantharia—Anatomy of a Sea-anemone—Zoantharia sclerodermata—Sclerodermic and Sclerobasic Corals—Coral-reefs—Zoantharia sclerobasica—Alcyonaria—Gorgonidae—Red Coral—Helioporidæ—Rugose Corals—Ctenophora—Anatomy of Pleurobrachia,	83-96
---	-------

CHAPTER X.

General characters of the Echinodermata—Divisions of the Echinodermata—Echinoidea—Anatomy of Echinus—Asteroidea—Ophiuroidea—Crinoidea—Cystoidea and Blastoidea—Holothuroidea,	97-111
---	--------

CHAPTER XI.

General characters and divisions of the Annulosa—General characters of the Scolecida—Divisions of the Scolecida—Taniada—Development of a Tape-worm—Cystic worms—Trematoda—Turbellaria—Acanthocephala—Gordiacea—Nematoda—Rotifera,	112-126
---	---------

CHAPTER XII.

General characters of the Anarthropoda—Gephyrea—Annelida—Divisions of the Annelida—Hirudinea—Oligochaeta—Polychæta,	127-135
---	---------

CHAPTER XIII.

General characters of the Arthropoda—Divisions of the Arthropoda—General characters of the Crustacea—Decapoda—Macrura—Anomura—Brachyura—Stomapoda—Isopoda—Amphipoda—Læmodipoda—Merostomata—Trilobita—Phyllo- lopoda—Cladocera, Copepoda, and Ostracoda—Ichthyoph- thira—Cirripedia—Rhizocephala,	136-150
--	---------

CHAPTER XIV.

General characters of the Arachnida—Podosomata—Acarina— Pedipalpi—Araneida,	151-156
--	---------

CHAPTER XV.

General characters of the Myriapoda—Centipedes—Millipedes— Paupoda—Onychophora,	157-159
--	---------

CHAPTER XVI.

General characters and anatomy of Insects—Metamorphosis of Insects,	160-167
--	---------

CHAPTER XVII.

Orders of Insects—Anoplura—Mallophaga—Collembola—Thy- sanura—Hemiptera—Orthoptera—Neuroptera—Aphanip- tera—Diptera—Lepidoptera—Hymenoptera—Strepsiptera— Coleoptera,	168-182
---	---------

CHAPTER XVIII.

General characters of the Mollusca—Primary divisions of the Mollusca,	183-186
--	---------

CHAPTER XIX.

Molluscoida—General characters of the Polyzoa—General charac- ters of the Tunicata—General characters of the Brachiopoda,	187-195
--	---------

CHAPTER XX.

Classes of the Mollusca proper—General characters of the Lamel- libranchiata—General characters of the Gasteropoda—Nudi- branchiata—Heteropoda—Air-breathing Gasteropods—Pter- opoda,	196-207
--	---------

CHAPTER XXI.

- General characters of the Cephalopoda—Reproductive process in the Cuttle-fishes—Shell of the Cephalopoda—Dibranchiata—Tetrabranchiata—Orthocerata Ammonites, 208-217

CHAPTER XXII.

- General characters of the Vertebrata—Skeleton of Vertebrates—Structure of a vertebra—Vertebral column—Limbs of Vertebrates—Digestive system—Circulatory system—Respiratory system—Nervous system—Reproduction—Primary divisions—Ichthyopsida—Sauropsida—Mammalia, 218-227

CHAPTER XXIII.

- General characters of the Fishes Scales—Endoskeleton—Limbs—Tail—Digestive system—Circulation—Respiration—Nervous system—Organs of hearing and smell—Reproduction, 228-236

CHAPTER XXIV.

- Orders of Fishes—Pharyngobranchii—Marsipobranchii—Teleostei—Sub-orders of the Teleostei—Ganoidei—Elasmobranchii—Sub-orders of the Elasmobranchii—Dipnoi, 237-248

CHAPTER XXV.

- General characters of the Amphibia—Orders of the Amphibia—Ophiomorpha—Urodela—Anoura—Labyrinthodontia, 249-256

CHAPTER XXVI.

- General characters of the Reptilia—Circulatory and Respiratory systems—Divisions, 257-260

CHAPTER XXVII.

- Orders of Reptilia—Chelonia—Ophidia—Lacertilia—Crocodilia—Ichthyopterygia—Sauroptrygia—Pterosauria—Anomodontia—Deinosauria—Theriodontia, 261-277

CHAPTER XXVIII.

- General characters of the class Aves—Feathers—Vertebral column—Anterior extremity and pectoral arch—Posterior extremity and pelvic arch—Digestive system—Respiration—Circulatory system—Nervous system—Organs of the senses—Migrations of Birds, 278-289

CHAPTER XXIX.

Divisions of Aves—Cursorcs—Natatores—Grallatores—Rasores —Scansores—Insessores—Raptores—Odontornithes, .	290-308
---	---------

CHAPTER XXX.

General characters of the class Mammalia—Skeleton—Teeth— Dental formula—Digestive system—Heart—Lungs—Ner- vous system—Integumentary appendages—Development— Primary divisions,	309-318
---	---------

CHAPTER XXXI.

Orders of Mammalia—Monotremata—Marsupialia—Edentata— Sirenia—Cetacea—Ungulata—Dinocerata—Tillodontia— Toxodontia—Hyracoides—Proboscidea—Carnivora—Roden- tia—Cheiroptera—Insectivora—Quadrumania—Bimana, .	319-360
---	---------

ZOOLOGY.

INTRODUCTION.

1. DEFINITION OF BIOLOGY AND ZOOLOGY

ALL natural objects may be roughly divided into three groups constituting the so-called Mineral, Animal, and Vegetable kingdoms. The objects comprised in the mineral kingdom are all devoid of life, and they exhibit the following characters: *a.* Their chemical composition is simple. They consist of either a single element, as is the case, for instance, with native gold; or, if combined, they almost always occur in nature in the form of simple compounds, composed of no more than two or three elements—as, for example, common salt, limestone, plaster of Paris, and many others. *b.* Mineral bodies are, when unmixed, composed of similar particles, which have no definite relations to one another; or, in other words, they are *homogeneous*. *c.* The form of mineral bodies is either altogether indefinite, when they are said to be “amorphous”; or, if they have a definite shape, they are crystalline, in which case they are usually bounded by plane surfaces and straight lines. *d.* When mineral bodies increase in size, as crystals may do, the increase is produced simply by the addition of particles from the outside (technically called “accretion”). *e.* Mineral bodies exhibit no phenomena which are not purely physical and chemical, and they show no tendency to periodic changes of any kind.

All the bodies which exhibit these characteristics properly belong to the mineral kingdom, and fall to be treated of by the sciences of Geology, Mineralogy, Chemistry, and Physics. It should be borne in mind, however, that in the case of what are called “fossils” or

"petrifications," we have mineral bodies which owe their existence and characters to living beings which existed at former periods in the history of the earth. For this reason, fossils, though composed of mineral matter, cannot be said properly to belong to the mineral kingdom.

On the other hand, the objects which belong to the animal and vegetable kingdoms differ from those which are comprised in the mineral kingdom in the following points: *a.* They are composed of few chemical elements, of which carbon, hydrogen, oxygen, and nitrogen are the most important; and these elements are combined to form complex organic compounds, which always contain a large proportion of water, are very unstable, and are prone to spontaneous decomposition. *b.* They are composed of diverse or *heterogeneous* parts, which have usually more or less definite relations to one another. These heterogeneous but related parts are termed "organs," and the objects possessing them are said to be "organised." Some of the lowest forms of animals have bodies composed of so uniform a substance that they cannot be said to be organised, as they exhibit no definite organs. This exception, however, does not affect the general value of this distinction. *c.* They are always more or less definite in shape, presenting concave and convex surfaces, and being bounded by curved lines. *d.* When they increase in size, or "grow," they do so, not by the addition of particles from the outside, but by the reception of foreign matter into their interior and its assimilation there (technically called "intussusception"). *e.* Lastly, they invariably pass through certain periodic changes in a definite and discoverable order,—these changes constituting *life*.

All the objects, then, which fulfil these conditions, are said to be alive; and they all belong either to the animal or to the vegetable kingdom. The study of living objects of all kinds, irrespective of which kingdom they belong to, is conveniently called by the general name of *Biology* (Gr. *bios*, life; and *logos*, discourse). As all living objects, however, may be referred to one or other of these two kingdoms, so Biology may be divided into the two sciences of *Botany*, which treats of plants, and *Zoology* (Gr. *zōōn*, animal; *logos*, discourse), which treats of animals. The term Natural History, again, is generally understood nowadays as being equivalent to Zoology alone, though originally it was applied to the study of all natural objects indiscriminately.

2. DIFFERENCES BETWEEN ANIMALS AND PLANTS.

It now becomes necessary to inquire into the differences which subsist between animals and plants, and which enable us to separate

the kindred sciences of Zoology and Botany. It might have been thought that nothing could be easier than to determine the animal or vegetable nature of any given organism ; and such, indeed, was the almost universal belief of older observers. In point of fact, however, no hard-and-fast line can be drawn, in the present state of our knowledge, between the animal and vegetable kingdoms, and it is often a matter of extreme difficulty, or even wholly impossible, to decide positively whether we are dealing with an animal or a plant. In the case of the higher members of the two kingdoms there is no difficulty in arriving at a decision. The higher animals are readily separated from the higher plants by the possession of a distinct nervous system, of locomotive power which can be voluntarily exercised, and of an internal cavity fitted for the reception and digestion of solid food. The higher plants, on the other hand, possess no nervous system or organs of sense, are incapable of voluntary changes of place, and are not provided with any definite internal cavity, their food being wholly fluid or gaseous.

The lower animals (*Protozoa*) cannot, however, be separated in many cases from the lower plants (*Protophyta*) by these distinctions, since many of the former have no digestive cavity, and are destitute of a nervous system, and many of the latter possess the power of active locomotion. In determining, therefore, the nature of these ambiguous organisms, the following are the chief points to be attended to:—

Firstly, As to mere *form* or external configuration, no certain rules can be laid down for separating animals and plants. Many of the lower plants, either in their earlier stages of existence or when grown up, are exactly similar in form to some of the lower animals. This is the case, for example, in some of the *Algæ*, which closely resemble some of the Infusorian animalcules. Many undoubted animals, again, are rooted to solid objects in their adult state, and are so plant-like in appearance as to be always popularly regarded as vegetables. This is the case with many of the so-called Hydroid Zoophytes, such as the Sea-firs, and also with the much more highly organised Sea-mats (*Fuſtra*), all of which are usually regarded as sea-weeds by seaside visitors. This is also, but less strikingly, the case with the Corals and Sea-anemones, of which the latter are often spoken of as “sea-flowers.”

Secondly, No decided distinction can be drawn between animals and plants as to their minute *internal structure*. Both alike consist essentially of minute solid particles (molecules or granules), of cells, or of fibres.

Thirdly, As regards *chemical composition*, there are some decided, though not universal, differences between plants and animals. As a general rule, it may be stated that plants exhibit a decided predominance of what are known to chemists as “ternary compounds”—that is to say, compounds which, like sugar, starch, and cellulose, are composed of the three elements, carbon, hydrogen, and oxygen. They are, comparatively speaking, poorly supplied with “quaternary” compounds, which contain the fourth element, nitrogen, in addition to the three first mentioned. Animals, on the other hand, are rich in quaternary nitrogenised compounds, such as albumen or fibrin. Still, in both kingdoms we find nitrogenised and non-nitrogenised compounds, and it is only

in the proportion which these bear to one another in the organism that animals differ in any way from plants. The most characteristic of all vegetable compounds is the one known as *cellulose*, very nearly allied in its chemical composition to ordinary starch. As a general rule, it may be stated that the presence of an external envelope of cellulose in any organism raises a strong presumption as to its vegetable nature. Still cellulose is not exclusively confined to plants, as was at one time believed. It is now well known that the outer covering of the so-called Sea-squirts or Ascidian Molluscs contains a large quantity of cellulose (as much as 60 per cent in some cases). Another highly characteristic vegetable product is *chlorophyll*, the green colouring-matter of plants. Any organism which exhibits chlorophyll in any quantity as a proper element of its tissues is most probably vegetable. In this case also, however, the presence of chlorophyll cannot be regarded as a certain test, since it occurs regularly in some undoubted animals (*e.g.*, *Stentor* amongst the *Infusoria*, and the *Hydra viridis*, or green Fresh-water Polype, amongst the *Cœlenterata*).

Fourthly, As regards *locomotive power*, or the ability to effect changes of place at will, the results of observation are singularly at variance with our preconceived notions. Before the invention of the microscope, no instances of independent voluntary movements were known in plants, if we except the voluntary opening and closure of flowers and their turning towards the sun, the drooping of the leaves of sensitive plants under irritation, and some other phenomena of a like nature. Now, however, we know of many plants which are endowed, either when young or throughout life, with the power of effecting voluntary movements apparently as spontaneous and independent as those exhibited by the lower animals. In some cases the movements are brought about by means of little vibrating hairs or cilia, with which a part or the whole of the surface is furnished. When it is added that many animals are permanently fixed and rooted to solid objects in their fully-grown condition, it will be seen that no absolute distinction can be drawn between animals and plants merely on the ground of the presence or absence of independent locomotive power.

Fifthly, We have shortly to consider one of the most reliable of all the tests by which an animal may be separated from a plant—namely, the *nature of the food*, and the products which are formed out of the food within the body.

The differences between animals and plants in this respect may be roughly stated as follows:—

1. Plants live upon purely inorganic substances, such as water, carbonic acid, and ammonia—and they have the power of making, out of these, true organic substances, such as starch, cellulose, sugar, &c. Plants, therefore, take as food very simple bodies, and manufacture them into much more complex substances, so that plants are the great producers in nature.

2. All plants which contain green colouring-matter (chlorophyll) in the process of digestion break up carbonic acid into the two elements of which it is composed—namely, carbon and oxygen, keeping the carbon and setting free the oxygen. As carbonic acid occurs always in the air in small quantities, the result of this is that plants remove carbonic acid from the atmosphere and give out oxygen.

3. Animals, on the other hand, have no power of living on inorganic matters, such as water, carbonic acid, and ammonia. They have no power of converting these into the complex organic substances of which their bodies are composed. On the contrary, animals require to be supplied with ready-made organic com-

pounds if their existence is to be maintained. These they can only get in the first place from plants, and therefore animals are all dependent upon plants for food either directly or indirectly. Animals, therefore, differ from plants in requiring as food complex organic bodies which they ultimately reduce to very much simpler inorganic bodies. Whilst plants, then, are the great manufacturers in nature, animals are the great consumers. Another distinction arising from the nature of their food is, that whilst plants decompose carbonic acid, keeping the carbon and setting free the oxygen, animals absorb oxygen and give out carbonic acid, so that their reaction upon the atmosphere is the reverse of that of plants. It should be added, however, that there are organisms which are genuine plants so far as concerns their nutritive processes, but which, nevertheless, exhibit other characters which would place them among animals. Examples of such organisms are found in *Volvox* and its allies.

As regards these general distinctions between plants and animals, there are two points which should be remembered:—

1. That even if universally true, these distinctions can often not be applied in practice to the ambiguous microscopic organisms about which alone any doubt can be entertained.

2. These general laws are certainly not of universal application in the case of plants. Thus, plants which do not contain chlorophyll (*e.g.* Fungi) do not possess the power of decomposing carbonic acid under the influence of sunlight, but are like animals in requiring organic compounds for their food.

3. CONDITIONS OF LIFE.

Certain conditions are necessary for the manifestation of life or vitality, as, indeed, is the case with every known force. Some of these conditions, though very generally present, are not absolutely indispensable; but there is one condition which appears to be essential, and that is, that the living body must be composed of a certain material. This material forms the essential and fundamental parts of every living being, whether vegetable or animal, and it is usually known by the technical name of “protoplasm” (Gr. *protos*, first; and *plasso*, I mould). Living beings may, and often do, contain in their bodies many other substances besides “protoplasm,” but it is in this substance that vitality seems alone to be inherent; and we are consequently justified in saying that life is only found in connection with protoplasm. It is, however, still a matter of opinion whether the protoplasm of all animals and plants is precisely the same, and under any circumstances we may believe that this substance is simply the medium or vehicle through which vital force manifests itself. Using the term in its general sense, “protoplasm” is chemically related in its nature to *albumen* or white-of-egg, and generally has the character of a jelly-like, semi-fluid, transparent material, which does not in itself exhibit any definite structure. When heated to a certain temperature, it solidifies or “coagulates,” just as the white of an egg does when

boiled. In its living state also, protoplasm appears invariably to have the power of movement. Thus, any little mass of living protoplasm, if free to do so, has the power of throwing out processes of its own substance, and thus of moving and changing its place. It has, also, the power of increasing in size or of maintaining its existence by "assimilating" fresh and foreign material; and it may detach portions of its own substance which may become developed into fresh masses of protoplasm.

In some cases, though protoplasm be present, there is no external and visible manifestation of life, as is the case with eggs and seeds, which exhibit what is called a "dormant" vitality. This condition may remain for a long time unchanged, until the external circumstances are altered, and then the organism passes from a state of *dormant* into one of *active* life.

As a general rule, therefore, it is necessary for certain external conditions to be present before any external vital phenomena can be manifested; and usually life itself, even in a dormant state, cannot be maintained in the absence of these conditions. Thus, the presence of atmospheric air (or rather of free oxygen) is in an ordinary way essential to active life. The higher manifestations of vitality, again, are only possible between certain limited ranges of temperature, varying from near the freezing-point to about 120° Fahr. Water, again, is an essential constituent of protoplasm in its living state, and is therefore absolutely essential to the carrying on of vital processes of all kinds. Hence the mere drying of an animal or plant will in most cases kill it outright, and will always suspend all visible vital phenomena.

Lastly, the great majority of living beings are *organised*—that is to say, they are composed of different parts, or *organs*, which hold certain relations with one another, and which discharge different functions. It is not the case, however, that organisation is a *necessary* accompaniment of vitality, or that *all* living beings are organised. Many of the lower forms of life exhibit absolutely no visible structure, and cannot, therefore, be said to be "organised"; but they nevertheless discharge all their vital functions just as well as if they possessed special organs set apart for the performance of each. Animals, therefore, are organised, or possess structure, because they are alive; they do not live because they are organised.

4. CLASSIFICATION.

By the term classification is understood the arrangement of a number of dissimilar objects of any kind into larger or smaller groups according as they exhibit more or less likeness to one an-

other. The number of different animals is so enormous, that it was long ago perceived that some classification of them, or method of arranging them into groups, was absolutely indispensable. Without some such arrangement it would have been utterly impossible to have ever acquired a clear notion of the animal kingdom as a whole. In forming such a classification, we might take some one character, such as the possession of wings, the number of legs, or the like ; just as we might divide mankind into groups according to the colour of the hair, the shape of the nose, or some other trivial feature. Classifications of this kind, however, are "artificial," and do not express the real relationships of animals ; hence they are now universally discarded by naturalists. The true method of forming a classification is to compare different animals with one another as regards *all* the features which they present ; and in this way we obtain what is called a "natural" classification. It is to be remembered, however, that a thoroughly natural classification of animals would imply that our knowledge of all their characters was complete ; and as that is not the case, no known classification can be regarded as more than approximately true.

A natural classification, then, is founded upon a comparison of different animals with one another as regards all their essential characters ; and these characters are of two kinds. *Firstly*, we have to look to the laws, form, and arrangement of the *structures* of the organism. This constitutes what is called "Morphology," or the science of form and structure (from the Greek words *morphe*, shape or form ; and *logos*, a discourse). *Secondly*, we have to study the vital actions performed by the living organism, and the *functions* discharged by each portion of the body. This constitutes the science of "Physiology."

MORPHOLOGY.—As we have just seen, Morphology, as a general science, deals with the mere form and structure of the organism, irrespective of *function* or *use* ; but it admits of a more or less artificial division into subordinate departments. Thus the study of the form and structure of living beings in their fully developed condition constitutes the science of *Anatomy*. The term *Human Anatomy* is given to the morphology of man, and the term *Comparative Anatomy* is applied to the study of the structure of animals in general, as compared with one another and with man.

Morphology, again, not only deals with the organism as a fully developed whole, but is also concerned with the changes through which every living being has to pass in reaching its mature or fully-grown condition. This constitutes a special branch of the subject to which the term "*Development*" is applied.

Finally, a separate department of the subject is sometimes consti-

tuted under the name of "*Minute Anatomy*," to designate those morphological studies which are specially concerned with the investigation of the minute or microscopic structures and tissues of which living beings are composed, apart from the grosser and more palpable features of form and structure.

PHYSIOLOGY.—In its broadest sense, Physiology may be stated to be the *science of life and vital phenomena*,—understanding by "science," knowledge methodised and reduced to its principles. In other words, Physiology deals with the *functions* exercised by living bodies, or by the various definite parts or "organs" of which most living beings are made up. *Morphology* teaches us the structure of the animated machine; *Physiology* shows us what the machine can do, and what are the use and purpose of the various parts of which the machine is composed.

The study of the functions discharged by the human organism constitutes a distinct branch of Physiology to which the name of *Human Physiology* is applied; whilst *Comparative Physiology* is concerned with the study of the vital phenomena exhibited by the lower animals.

All the vital actions of the organism—in other words, all physiological phenomena—may be roughly divided into the following three groups:—

1. *Functions of nutrition*, comprising the various functions by which the organism is enabled to live, grow, and maintain its existence as an *individual*.

2. *Functions of reproduction*, comprising those functions whereby fresh individuals are produced, and the perpetuation of the *species* is secured, whilst the original individual perishes.

3. *Functions of relation*, comprising all those functions (such as sensation and the power of voluntary movement) whereby the outer world is brought into *relation* with the organism, and the organism in turn is enabled to react upon the outer world.

The functions of nutrition and reproduction are essential to bare existence, and are sometimes spoken of collectively as the "vegetative" functions, as being common to animals and plants alike. On the other hand, the functions of relation are often spoken of as the "animal" functions, since they are most highly developed in animals. Various plants, however, are endowed with the power of movement, and exhibit sensibility equal in amount and apparently similar in kind to that manifested by many of the lower animals; so that the functions of relation, though more characteristic of animals than of plants, are not peculiar to animals.

It should also be borne in mind, that though the above grouping of the physiological functions is convenient, it is to a certain extent

arbitrary, and that the groups of functions run into one another, and are most intimately connected. Thus, for example, in the higher animals, some or all of the functions of relation are secondarily functions of nutrition, and *vice versâ*, since the integrity of both groups is essential to the working of either. If the animal be deprived of the powers of vision and locomotion, it cannot obtain food; and if its nutrition be interfered with, its functions of relation will be destroyed.

HOMOLOGY AND ANALOGY.—These are two terms which are employed to express, respectively, the morphological and physiological likenesses between the organs and parts of different animals.

When we find the same morphological structure or organ in two different animals, however much altered or disguised in form, then we have to deal with a case of *homology*; the two organs are *homologous*; and the one is said to be the *homologue* of the other. And

Fig. 1.—A, Arm of Man. B, Fore-leg of Dog. C, Wing of Bird. *h* Humerus, or bone of upper arm; *r* and *u* Radius and Ulna, or bones of the fore-arm; *c* Carpus, or bones of the wrist; *m* Metacarpus, or bones of the root of the hand; *p* Phalanges, or bones of the fingers.

it is not in the least degree necessary that the two homologous organs should perform the same *function* or discharge the same work. On the contrary, they may be fitted for very different purposes, and it is simply necessary that they should be formed on the same fundamental plan of structure. For example, the arm of man, the fore-leg of the dog, and the wing of a bird, are constructed upon the same morphological type, and are therefore *homologous*—as will readily be seen by referring to the annexed illustration, where cor-

responding parts are lettered with corresponding letters. They perform, however, totally different functions, the first being an organ of prehension, the second being devoted to terrestrial progression, and the third being an organ of flight.

On the other hand, whenever we find in different animals organs fulfilling the same purpose and doing the same work, then we have to deal with a case of *analogy*—the organs are *analogous*, and the one is said to be the *analogue* of the other. In other words, those parts or organs are *analogous* which resemble one another physiologically and discharge the same *functions*, wholly irrespective of what their fundamental *structure* may be. In most cases the organs which would ordinarily be called “analogous” are such as differ from one another in structure, at the same time that they discharge the same duties. Thus the wings of a bird and the wings of an insect are analogous organs, since they are both organs of flight, and serve to sustain their possessor in the air. They are, however, in no way similar to one another except when regarded from this physiological point of view; and they differ altogether from a morphological aspect, being in no way formed on the same fundamental plan. It often happens, however, that “analogous” organs have the deeper relation to one another of being constructed upon the same morphological plan, in which case they are *both* analogous and homologous. Thus, the leg of man and the hind-leg of a dog are both analogous and homologous, since they are constructed upon the same plan and discharge similar functions.

It need only be added in this connection that sound classification depends on a correct discrimination between likenesses of homology and likenesses of analogy. Likenesses of analogy—that is, likenesses dependent solely upon the possession of organs discharging the same physiological function—are to be disregarded. Thus, the Bird and the Butterfly are not to be grouped together simply because both possess organs of flight. On the other hand, likenesses of homology—that is to say, likenesses dependent on identity of structural plan—are a safe guide to real affinity, enabling us to trace the genuine relationships which may subsist between animals outwardly very dissimilar, and affording to us the foundation of a common type capable of almost endless modification. Whilst the *theory* of philosophical classification is thus clear, it may be further said that great difficulties attend the carrying out of the admitted theory into actual *practice*. This arises chiefly from the difficulty which is met with when we come to disentangle the homological from the merely analogical likenesses of animals; and it is in overcoming this difficulty that a great portion of the labours of the philosophical zoologist consists.

GENERAL DIVISIONS OF THE ANIMAL KINGDOM.

Acting upon the principles above indicated, and by a careful comparison of the morphological and physiological differences between different animals, naturalists have divided the entire animal kingdom into a number of divisions, the general arrangement of which may be very briefly indicated. Firstly, the whole animal kingdom may be divided into two great sections, known respectively as "Invertebrate Animals" or *Invertebrata*, and "Vertebrate Animals" or *Vertebrata*. The leading characters which distinguish these two great sections are exhibited in the subjoined diagram, and may be shortly stated as follows: In all Invertebrate animals, the body, if divided transversely or cut in two, shows only a single tube containing all the vital organs (fig. 2, A). These organs in the higher *Invertebrata* consist of a digestive or alimentary tube; a circulatory system, by which the vital fluids are distributed through

Fig. 2.—A, Diagrammatic section of one of the higher *Invertebrata*. B, Section of one of the *Vertebrata* (slightly altered from Huxley): *a* Wall of the body; *b* Alimentary canal; *c* Circulatory system; *n* Nervous system; *n'* Brain and spinal cord of the *Vertebrata*, enclosed in a separate tube; *ch* Notochord or chorda dorsalis.

the body; and a nervous system, by which the animal is brought into relation with the outer world. Any or all of these vital organs, however, may be wanting, or may be imperfect or rudimentary. When there is any skeleton, this is usually *external*, and is mostly nothing more than a hardening of the skin, produced by the deposition in it of horny matter, of lime, or of flint. The limbs, when present, are turned towards that side of the body upon which the main portions of the nervous system are situated. In the *Vertebrata*, on the other hand, the body, if transversely divided, exhibits *two* tubes (fig. 2, B). In the one is placed the main mass of the nervous system (the brain and spinal cord). In the other tube are the alimentary canal, the main organs of the circulatory system, and certain other portions of the nervous system, which are

known as the "sympathetic" system of nerves. Further, in the *Vertebrata* there is always an *internal* skeleton, the central stem of which is usually constituted by a true backbone or "vertebral column." When this is not present, there is a structure which will be afterwards described as the "notochord" or "chorda dorsalis." Lastly, the limbs of Vertebrate animals, when present, are never more than four in number, and they are always turned away from that side of the body on which the main masses of the nervous system are placed.

The subdivision of the Invertebrate animals is divided into five great groups or "morphological types," which are known as *sub-kingdoms*.¹ These primary types of structure are known to naturalists under the technical names of the *Protozoa*, *Cœlenterata*, *Echinodermata*, *Annulosa*, and *Mollusca*. Their distinguishing characters and more important subdivisions will be spoken of hereafter, and need not, therefore, be noticed here. The division of the Vertebrate animals constitutes by itself a sixth sub-kingdom, which is simply known under the name of *Vertebrata*. There are, therefore, *six* primary types of structure or sub-kingdoms, to one or other of which all known animals may be referred. The highest of these forms alone the division of the "Vertebrate Animals," whilst the five lower sub-kingdoms are grouped together under the collective name of "Invertebrate Animals."

Each *sub-kingdom*, therefore, comprises a group of animals which are constructed upon a common plan or type, however greatly this type may be modified; and each is, in turn, broken up into subdivisions which are termed "*classes*." Each "class," again, is divided into "*orders*," each "order" into "*families*," each "family" into "*genera*," and each "genus" into "*species*." To *define* the term "species," which is the smallest definite division accepted by naturalists, is, in the light of recent researches, no easy matter. We may, however, consider that each "species," or, as we should commonly say, "kind," of animals consists of such individuals as resemble one another in all the essential characters of their structure, and are able, directly or indirectly, to produce other fertile individuals like themselves. Even in the above definition, we must recollect that the individuals of a species are not *precisely* alike, and it commonly happens that a number of the individuals of a species have some special peculiarity or peculiarities, by which they can readily be separated from the rest. When this is the case, the individuals thus distinguishable constitute what is called a "*variety*,"

¹ Many naturalists regard the Sponges as forming a sixth division, to which the name of *Porifera* is often given; but this division is hardly equivalent in rank to a sub-kingdom.

and if their peculiarities are permanent, and are handed down constantly by inheritance, then we get a "*race*." Thus we may suppose (though some doubt it) that all known dogs belong to and constitute one species. But we know that individual dogs, such as the greyhound, the mastiff, the terrier, the bull-dog, and the like, differ from one another so greatly that we can always recognise them with certainty. These, therefore, constitute so many *varieties* of the dog. It need only be added that the greatest of all difficulties which the practical naturalist has to confront is the difficulty of determining precisely what constitutes a *species* as distinguished from a *variety*. In other words, there are innumerable cases in which it is almost impossible to tell whether we are dealing with two closely allied species, or with a species and its variety; and in no case can any definite rule of guidance be laid down by which this difficulty can be got rid of.

The classification now adopted by naturalists will perhaps be better understood if we take an actual example, and see how it is applied in practice. If we regard the domestic dog, with all its subordinate varieties, as a single *species*, we have to notice, in the first place, that it is known technically by a *double* name, and is called the *Canis familiaris*. All species are thus known by "binomial" designations, the *second* name being like a man's Christian name, and being distinctive of the *individual*, whilst the *first* name is like a man's surname, and indicates the *group*, or, technically, "*genus*," to which the individual belongs. The dog, then, whilst individually recognised by the epithet "*familiaris*," belongs to the "*genus*" *Canis*, in which are included other related species, such as the Wolf (*Canis lupus*) and the Jackal (*Canis aureus*). The genus *Canis*, again, belongs to the "*family*" *Canidæ*, including other genera, such as the Foxes (*Vulpes*). The family *Canidæ*, again, is one of a number of families, such as the Lions, Tigers, and Cats (*Felidæ*), the Bears and Racoons (*Ursidæ*), the Hyænas (*Hyænidæ*), &c., which together constitute the "*order*" of the *Carnivora* or Beasts of Prey. The *Carnivora*, again, constitute one of many orders of Quadrupeds, which are distinguished by suckling their young and by other common characters, and which collectively constitute the "*class*" *Mammalia*. Finally, the class *Mammalia* is united with the classes of the Birds, Reptiles, Amphibians, and Fishes, to constitute the great primary division of *Vertebrata* or "Vertebrate Animals;" since all these classes agree with one another in the fundamental character of possessing a backbone or "vertebral column," or an equivalent structure.

Condensing the above, the zoological position of the Dog, expressed in full, would be as follows:—

Sub-kingdom, VERTEBRATA.

Class, *Mammalia*.

Order, *Carnivora*.

Family, *Canidæ*.

Genus, *Canis*.

Species, *Canis familiaris*.

In an ordinary way, however, it is quite unnecessary to employ in practice any of the above names except the last or *specific* name, since that implies all the others.

The remainder of this work will be occupied with the consideration of the chief characters of the more important groups into which the animal kingdom has been divided, omitting those which are not of paramount interest; but it will be necessary first to say a few words as to the distribution of animals in space and in time.

5. DISTRIBUTION OF ANIMALS IN SPACE AND IN TIME.

DISTRIBUTION IN SPACE.—The distribution of animals in *space*, or their *geographical distribution*, is a department of zoology which is concerned with determining the limits within which each species of animal is at the present day confined. Save man, and his faithful attendant the dog, no species of animal can be said to have anything like a *universal* distribution; and each species, as is a matter of common observation, belongs to a certain region, and is confined within wider or narrower limits. Thus the Giraffe, for example, is not known to exist out of Africa; the Kangaroos belong to Australia; the Armadillos do not occur out of South America,—and so on. Further than this, it is possible to divide the earth's surface into a certain number of geographical regions or "*zoological provinces*," each of which is characterised by the occurrence in it of certain associated forms of animal life. Under the head, therefore, of "distribution in space," come two different but allied branches of inquiry. Firstly, we have to inquire as to the geographical range enjoyed by each individual *species* of animal; and secondly, we have to determine what *general assemblages* of animals characterise certain large areas or provinces, and this alone demands a brief consideration here.

The geographical distribution of land animals is conditioned partly by the existence of suitable surroundings, and partly by the presence of barriers preventing migrations. Thus, certain contiguous regions might be equally suitable for the existence of the same animals, but they might belong to different zoological provinces if separated by any impassable barrier, such as a lofty chain of mountains. Owing to their power of flight, the geographical distribution of birds is much less limited than that of Mammals; and many migratory birds may

be said to belong to two zoological provinces. In spite of their powers of locomotion, however, birds are limited by the necessities of their life to definite areas, and a zoological province may be marked by its birds just as well as by its quadrupeds.

The geographical distribution of an animal at the present day by no means necessarily coincides with its former extension in space. Many species are known which now occupy a much more restricted area than they did formerly, owing to changes in climate, the agency of man, or other causes. Similarly, there are species whose present area is much wider than it was originally.

At the present day, naturalists usually adopt the arrangement of the dry land into zoological provinces, which was originally proposed by Mr Sclater. In this arrangement the earth's surface is divided into the following six provinces, each of which is characterised partly by the presence of a particular "fauna," or characteristic assemblage of animals, and partly by the absence of certain other characteristic animals :—

I. The *Palaearctic Province*, including Europe, Africa north of the Atlas Mountains, and Northern Asia. Among the more characteristic animals of this province are Bears, Sheep, Goats, Catarrhine Monkeys, and Pheasants.

II. The *Ethiopian Province*, including Africa south of the Atlas Mountains, and Southern Arabia. Among the more characteristic animals are the African Elephant, the Hippopotamus, Giraffe, Hyrax, Aardvark, numerous Antelopes, Baboons, the Lion, and the Ostrich. There is a characteristic absence of Bears, Deer, Goats, and Sheep.

III. The *Oriental or Indian Province*, including Asia south of the Himalaya Mountains, Burmah, Siam, Southern China, and the Indian Archipelago (Java, Sumatra, Borneo, &c.) Characteristic animals are the Chevrotains, Indian Buffalo, Indian Elephant, Tiger, Hornbills, Pea-fowl, and Jungle-fowl.

IV. The *Australian Province*, including Australia, Tasmania, New Guinea, New Zealand, and most of the islands of the Pacific Ocean. Characteristic animals are the Duck-mole and Spiny Ant-eater (*Echidna*), numerous Marsupials, Birds of Paradise, Cockatoos, and the Australian Mud-fish (*Ceratodus*). There is a remarkable absence of most orders of the Placental Mammals, of Vultures, Woodpeckers, and Tailed Amphibians. New Zealand is peculiar in not having any Marsupials nor Monotremes; in having no Reptiles except Lizards; and in the possession of the curious *Apteryx* and the extinct *Dinornis*.

V. The *Nearctic Province*, including North America down to the centre of Mexico. Characteristic animals are the Prongbuck, the

Musk-rat, the American Buffalo, Tree-Porcupines, and the Turkey. The Beaver, Reindeer (Caribou), Sheep, and Bears are types common to this and the Palæarctic Region.

VI. The *Neotropical Province*, including the whole of South America, Central America, and Southern Mexico, together with the Antilles. Characteristic animals are the Platyrrhine Monkeys, Llamas, Peccaries, Cavies, Sloths, Ant-eaters, Armadillos, Trogons, and Curassows. There is an absence of Insectivorous Mammals, Goats, Antelopes, Oxen, Cranes, &c. The Opossums are common to this and to the Nearctic Province.

Leaving the dry land, we find that even in the ocean animals are not distributed at random, but have, on the contrary, a more or less definite range. Without entering at length into this very interesting subject, two or three of the more important facts connected with the distribution of marine life may be stated here. In the first place, certain marine animals affect that portion of the sea-shore which lies between tide-marks, and is therefore more or less completely uncovered twice a-day by the retirement of the tide. Technically, naturalists call the tract between tide-marks the "Littoral Zone" (Latin, *litus*, the shore). In the second place, we find other animals which do not like to be uncovered by the retiring tide, and which live, therefore, just below the limit of low water, and usually extend their range till the sea becomes about fifteen fathoms in depth. Within these limits the great Tangle (*Laminaria*) flourishes in profusion, and hence this is called the "Laminarian Zone." Beyond the Laminarian Zone are other regions of different depths, which can usually be recognised more or less distinctly by the animals which inhabit them. Finally, by the researches of Carpenter, Wyville Thomson, Gwyn Jeffreys, Wallich, Sars, Pourtales, Agassiz, and other observers, we know that the "deep sea" properly so called, extending from a depth of 300 fathoms up to at least 3000 or 4000 fathoms, is tenanted by a vast number of animals, constituting a very remarkable and peculiar life-assemblage. We also know now, that, except in very limited depths, the distribution of marine animals is conditioned not by the *depth* of the water, but by its *temperature*. Similar forms of marine life are therefore found inhabiting areas in which the bottom-temperature is the same, irrespective of what the depth of the water may be. And it may happen that two neighbouring areas of the sea-bottom may be inhabited by different assemblages of animals, in spite of their being close together, provided one area is swept by a current of warm water, whilst the other has its temperature lowered by the influx of a cold current.

DISTRIBUTION IN TIME.—The distribution of animals in past

time, or their "geological distribution," belongs to the science of "*Palæontology*" (Gr. *palaios*, ancient; *onta*, beings; *logos*, a discourse), and constitutes a subject so vast that nothing more can be done here than to indicate one or two of the most elementary considerations relating thereto. In the first place, Geology shows us that a very large portion of the crust of the earth is composed of rocks which existed originally in the form of sand, mud, clay, or ooze, and which formed the floor of the ocean. Other rocks can be shown to have been originally formed by lakes or rivers, and sometimes we find what may be regarded as old land-surfaces or soils. These various kinds of rock, in the second place, often contain in their interior what are called "fossils" or "petrifications,"—in other words, the remains or traces of animals and plants which lived at the time when the rocks were in actual process of formation. In rocks which have been formed in the sea, the fossils consist chiefly of the skeletons of shell-fish, corals, sea-urchins, and other marine animals; in rocks which have been formed in lakes or rivers, we have chiefly fresh-water shells and the skeletons of fresh-water fishes; and in ancient soils we find the remains of plants, along with air-breathing animals, such as insects, spiders, or quadrupeds.

We see, then, that animals existed upon the earth for a long period before the appearance of such forms as are now familiar to us; and we have to note, in the third place, that not only are existing animals in many cases different from those which immediately preceded them, but that the globe has really passed through a succession of *periods*, during each of which there flourished an assemblage of animals more or less peculiar to the period. In the later periods of the earth's history, the animals which lived in the sea or in lakes and rivers, or which roamed upon the land or disported themselves in the air, present a general likeness to the animals now in existence, though not identically the same. In the earlier periods, again, the animals are not only "extinct," or, in other words, no longer existent, but they are very unlike any animals which we see at the present day, and the older the period the greater is this unlikeness.

We have, finally, to remember, that though many extinct animals are so peculiar that we have to place them in distinct families or orders, there is at present no known fossil which cannot be referred to one or other of the existing *sub-kingdoms*. We have therefore, so far as our present knowledge goes, no proof of the former existence and disappearance of any "morphological type."

INVERTEBRATE ANIMALS.

SUB-KINGDOM I. PROTOZOA.

CHAPTER I.

1. GENERAL CHARACTERS OF THE PROTOZOA. 2. CLASSIFICATION.
3. GREGARINIDA.

THE sub-kingdom *Protozoa* (Gr. *protos*, first ; and *zoön*, an animal), as the name implies, is the lowest division of the animal kingdom, and its limits are therefore necessarily not yet strictly defined. The *Protozoa* comprise an enormous number of animals, which are mostly so small as to be invisible to the naked eye, and can only be satisfactorily examined under pretty high powers of the microscope. For this reason, and because they are almost universally found in water, these creatures, often popularly called “animalcules,” are almost unknown to the majority of people. The microscopical forms of the *Protozoa* swarm in most stagnant pools, and in all waters charged with organic matter so as to afford them food. Every worker with the microscope is familiarly acquainted with them, and they exhibit phenomena which in many cases render them objects of the highest interest. From their low position in the animal scale, it arises that the *Protozoa* are mainly characterised by the absence of organs and structures which occur in higher beings, and they possess few positive characters by which they can be distinguished.

The *Protozoa* may be defined as *animals, generally of a very minute size, and composed of unmodified or slightly modified protoplasm. The typical members of the group are “unicellular,” the primitive mass of protoplasm developing a “nucleus,” and thus becoming a “cell.” The “nucleus” may, however, be absent ; and it is only in the Sponges*

that the protoplasm becomes converted into an aggregate of cells. There is no definite internal cavity ("body-cavity"), and no nervous system is developed. Definite digestive organs are wanting, or present only in rudimentary form.

If we except the Sponges—which many naturalists regard as a separate division—the *Protozoa* do not rise, morphologically, above the condition of which is called a "cell." That is to say, a typical *Protozoön* consists of a mass of protoplasm, surrounded by a thickened layer or "wall," and enclosing a central solid or vesicular body or "nucleus," often containing in its interior, or attached to its exterior, a still smaller body or "nucleolus." The outer layer of the protoplasm may, however, remain unchanged, not becoming differentiated into a "wall," and the "nucleus" and "nucleolus" may be wanting. In such cases, the organism constitutes what is usually called a "cytode," rather than a "cell."

On the other hand, in the Sponges the organism becomes "multicellular," the primitive protoplasm becoming ultimately divided into a larger or smaller number of separate "cells." For this reason it is not unusual to associate the sponges with the whole series of animals higher than the *Protozoa*, and to speak of them collectively as the *Metazoa*.

The substance of which the body of any *Protozoön* is composed is of the nature of protoplasm, usually very slightly differentiated or altered in any way, and commonly known as "sarcode" (Gr. *sarx*, flesh; *eidos*, form). Viewed under the microscope, the sarcode appears as a transparent, colourless, or variously coloured viscid substance, exhibiting numerous minute darker particles or granules scattered through it, these being probably of a fatty nature. Along with these dark granules and molecules there can generally be observed a larger or smaller number of variously sized round clear spaces, which are known by the name of "vacuoles." Some of these "vacuoles" seem to be constantly present; but many are of mere temporary occurrence, and these seem to be merely little drops of water included in the soft protoplasm, and sometimes surrounding a particle of food. Often one of the vacuoles is not only permanent and fixed in position, but is much larger than the rest, and is "contractile," having the power of dilating and contracting at definite intervals. This is known as the "contractile vesicle" (fig. 3, A), and may, perhaps, be looked upon as a rudimentary organ of circulation. Sometimes there are two or more contractile vesicles.

Very commonly the external layer of sarcode composing the body of a *Protozoön* is comparatively dense and free from granules, while the internal protoplasm is softer and more fluid, and is charged with granules and vacuoles. Thus the protoplasm may be distinguished

in many cases into an "ectosarc" and "endosarc." In the endosarc in most *Protozoa* is found the solid or hollow body, known as the "nucleus" (fig. 3, A), and this may have a still smaller body, the "nucleolus," attached to its external surface, or embedded in its interior. The "nucleus" and "nucleolus" have often been supposed to have a reproductive function; but there appears to be insufficient evidence for this conjecture.

Fig. 3.—A, *Amoeba proteus*, with the pseudopodia protruded, enlarged 200 diameters (after Leidy): *n*, Nucleus; *c*, Contractile vesicle; *v*, One of the larger food-vacuoles; *en*, The granular endosarc; *ec*, The transparent ectosarc; *a*, A cell of an Alga taken in as food (other cells of the same Alga are obliquely shaded). B, *Amoeba radiosa*, enlarged 500 diameters (after Leidy). The body shows two large vacuoles, but no nucleus or contractile vesicle. The long and delicate pseudopodia are protruded.

In one division of the *Protozoa* (the *Infusoria*) there is a permanent mouth and a short gullet, but in all the others there are no definite organs connected with the process of digestion. In no *Pro-*

tozoön, however, without exception, have any traces of a nervous system been hitherto detected; and in none, even in those which possess a mouth, is there any distinct and definite cavity or chamber within the body in which the particles of food are received. No organs of sense (except, perhaps, occasionally very rudimentary ones) exist in any of the *Protozoa*—that is to say, there are no distinct organs fitted for the reception of impressions produced by light or sound; but the general surface of the body appears capable of receiving the impressions produced by contact with foreign bodies, and therefore acts as an organ of touch. The power of active locomotion is enjoyed by most of the *Protozoa*; but in some cases this is very limited, and in other cases the animal is permanently fixed in the adult condition. The apparatus of locomotion in the *Protozoa* is of a varied nature. In many cases, especially in the higher forms, movements are effected by means of little hair-like processes, which are called “*cilia*” (Lat. *cilium*, an eyelash), and which have the power of vibrating or lashing to and fro with great rapidity. In other cases the *cilia* are accompanied or replaced by one or more long whip-like bristles, which act in the same fashion, and are known as “*flagella*.” Amongst the lower *Protozoa* the most characteristic organs of locomotion are the so-called “*pseudopodia*” (Gr. *pseudos*, falsity; *podes*, feet). These consist of variously shaped filaments, threads, or finger-like processes of sarcode (fig. 3), which the animal can thrust out from any or every part of its body. They are not, however, definite and permanent organs like the *cilia*, for they can be produced at will, and when they are again withdrawn they simply melt into the sarcode of the body, and leave no traces of their existence.

The three principal groups of the *Protozoa* are known as the *Gregarinida*, the *Rhizopoda*, and the *Infusoria*. The Sponges will be here regarded as a special division of the Animal Kingdom, to which the name of *Porifera* may be applied.

CLASS I. GREGARINIDA.—The *Gregarinida* may be defined as *parasitic Protozoa which have no mouth, and have no power of giving out pseudopodia*. They are usually looked upon as forming the lowest class of the *Protozoa*; but in all probability much of their degraded character, as we shall see in other cases, is due to the fact that they are mostly internal parasites, and are therefore not dependent on their own exertions for food. They vary in size from less than the head of a small pin up to nearly half an inch in length, when they look something like small worms; and they are found living in the interior of various animals, especially the cockroach and the earth-worm.

In anatomical structure a *Gregarina* usually presents the appear-

ance of a single cell, consisting of an ill-defined membranous envelope, filled with a more or less granular sarcode containing fatty granules, and having in it a little central bladder or vesicle—the “nucleus”—which in turn encloses a solid particle or “nucleolus” fig. 4, *a* and *b*). The outer covering or cuticle with which the

Fig. 4.—Morphology and development of *Gregarinida* (after Stein and Lieberkühn). *a* *Stylorhynchus oligacanthus*, a “dicystidean” Gregarine; *b* Gregarine of the earth-worm (“monoecystidean”); *c* The same encysted; *d* Further stage of the same, with the contents divided into “pseudonavicellae”; *e* Free “pseudonavicellae”; *f* Amœbiform mass of protoplasm liberated from a pseudonavicella; *g* and *h* Active forms of *f*. All the figures are greatly enlarged.

protoplasmic body is enclosed may be quite smooth, or it may be furnished with bristles or spines, and in some cases even cilia have been observed. Beyond the nucleus and nucleolus no definite organs have been detected in the *Gregarinæ*; and all the processes of assimilating food and getting rid of waste or injurious products must be effected by the general surface of the body. As we shall see, however, this is common in internal parasites, which are not necessitated to live upon solid food, but which are enabled to subsist simply by imbibing the nutritive juices of their hosts.

The following is a brief outline of the process of reproduction, as it has been observed in the *Gregarinæ*, sometimes in a single individual, sometimes in two individuals which have come together and completely coalesced and melted into one another. The *Gregarina* becomes completely motionless, assumes a globular form, and develops round itself a thick structureless coat or envelope,

when it is said to be "encysted" (fig. 4, *c*). The nucleus then disappears, and the sarcode of the body breaks up into little masses, which are at first rounded, but afterwards become pointed at both ends, when they are called "pseudonavicellæ" (fig. 4, *d*). The cyst then breaks and the pseudonavicellæ escape, when they give origin to little masses of sarcode, which have the power of active movement and of throwing out pseudopodia, thus coming closely to resemble the animalcule which will be directly described as the *Amœba* (fig. 4, *g* and *h*). These little amœba-like masses, if they find a suitable locality, are finally developed into new *Gregarinæ*.

CHAPTER II.

RHIZOPODA.

THE next class of the *Protozoa* which we have to consider comprises the most characteristic and typical forms of the whole sub-kingdom. The name of *Rhizopoda*, or "root-footed" animalcules (from the Greek, *rhiza*, root; and *podes*, feet), is derived from the fact that they all possess the power of throwing out at will from various parts of the body the processes of sarcode which have been already spoken of as pseudopodia, and by which they both move and obtain food. In fact, the *Rhizopoda* may be shortly defined as *Protozoa which have no mouth, and which possess the power of giving out pseudopodia*. The pseudopodia vary a good deal in shape and in other characters in

Fig. 5.—Morphology of Monera. a *Protomaba porrecta*; b *Protomyxa aurantiaca*; c The same in an encysted condition. Greatly magnified.

different orders of the *Rhizopoda*, but they have invariably the character of being nothing more than temporary threads or finger-like

processes of sarcode, which can be thrust out at will, and which melt again into the substance of the body when they are withdrawn.

Four principal types of structure are known in the *Rhizopoda*, and these constitute as many distinct orders, which are known by the names of the *Monera*, *Amœbea*, *Foraminifera*, and *Radiolaria*.

ORDER I. MONERA.

This name has been proposed for a small group of organisms which are not only the lowest types of the Rhizopods, but may be regarded as the most elementary forms of animal life known to us. The *Monera* are minute protoplasmic organisms in which the sarcode-body is neither defended by a thickened external envelope, nor furnished with the structures known as the "nucleus" and "contractile vesicle." Vacuoles and granules are present in the sarcode, and the pseudopodia emitted by the soft and mutable protoplasm of the body are delicate and thread-like, or may be ramified and variously interlaced (fig. 5). No hard covering or shell is ever developed. The *Monera* inhabit water, and are mostly marine.

ORDER II. AMŒBEA.

This order is characterised by the fact that *the pseudopodia are mostly blunt and finger-like in shape, and that the sarcode of the body contains the structures known as the "nucleus" and "contractile vesicle."*

As the *type* of the order may be taken the *Amœba* or Proteus-animalcule, so called because of the incessant and varied changes of form which it exhibits (Gr. *amoibos*, changing). The *Amœba* is a little microscopical creature which may commonly be detected in stagnant water, especially where there is decaying vegetable matter. When examined under the microscope, all that would probably be seen at first would be a shapeless or irregularly spherical mass of gelatinous, jelly-like sarcode, containing scattered granules. Soon the creature might be observed to push out a finger-shaped prolongation of its own substance; and it would soon be found that similar processes or pseudopodia could be pushed out at will from almost any point of the body and again retracted within it without leaving any trace behind. As a result of this, the form of the animal is constantly changing, and hence its common name of Proteus-animalcule (fig. 3 and fig. 6 B). By means of these temporary processes of sarcode, the *Amœba* both moves and obtains food. Locomotion is effected in a kind of creeping manner, the animal pushing out the pseudopodia in one direction and then

pulling the body in the same direction. In the same way, when any minute particle of food, such as a microscopic plant, comes within its reach, the *Amœba* wraps a pseudopodium round it, and then withdrawing the pseudopodium, lodges the nutrient particle securely in the substance of the body. It follows from this that the *Amœba* has no permanent mouth—no aperture, that is, which is especially employed in the admission of food. Any part of the surface can be pushed out into a pseudopodium, and therefore any

Fig. 6. — *Amœba*. A, Small *Amœba* developed in organic infusions, greatly magnified. B, *Amœba princeps*: n Nucleus; c Contractile vesicle; v Region of the body where indigestible matters are thrust out.

part of the surface can be extemporised into a mouth. The process of taking food, in fact, in the *Amœba*, has been aptly compared to thrusting a stone or any other solid body into a lump of dough. The central portion of the body of the animal is softer and more fluid than the outer layers, and the particles of food, on reaching this point, undergo a sort of digestion, and are subjected to a species of movement or rotation in the interior of the animal. Each particle of food, in the process of being taken into the body, usually carries with it a little drop of water; and in this way a number of clear spaces are formed, which are usually quite round, and look like distinct cavities. These spaces are called “vacuoles”; but they are not distinct organs of any kind, though formerly regarded as distinct stomachs. Having undergone digestion, any portions of food which may be indigestible or insoluble are simply thrust out again through the walls of the body. This appears to be effected at one particular part of the body; but there is no permanent aperture for the purpose. There are no distinct vessels which serve to convey the nutritive fluid derived from the digestion; but there does appear to be a rudimentary organ by which this fluid is driven through

the body. If we watch an *Amæba* (fig. 6, B) carefully, there is usually no difficulty in observing that every now and again there appears at one particular place a clear spot, "like a window," which slowly expands to its full extent, and then usually contracts slowly till it disappears altogether. This process of gradual expansion and contraction is what is called "rhythmical"—that is to say, it is repeated at tolerably regular intervals, perhaps twice a-minute. In some cases the vesicle, when contracted, remains so for a long time, but it always reappears in the same place. It is known as the "contractile vesicle"; and there can be little doubt that it is a permanent organ. It is, in fact, a little clear space or cavity in the substance of the body, filled probably with the nutritive fluid derived from the digestion, and no doubt serving by its contraction to drive this fluid to various parts of the body. In its function, then, the contractile vesicle of the *Amæba* is to be looked upon as the first indication which we have in the entire animal kingdom of that most important organ, the heart.

The *Amæba* possesses no breathing-organs of any kind, and no excretory organs, so that these functions must be performed by the general surface of the body in a manner somewhat the same as the exhalation from the skin which takes place in the higher animals. There are, also, no traces of a nervous system, and no organs of sense, and the only other structure of any kind is what is known as the nucleus. The nucleus (fig. 3 and fig. 6 n) is simply a small rounded or oval, granular mass, and there may be more than one in the same individual. Its function, however, is quite unknown, though it is probably connected with reproduction. The means employed by the *Amæba* to perpetuate the species are various, but the only one which need be mentioned is the process by self-division. This is what is technically called "fission" (Lat. *findo*, I cleave), and it consists in a gradual division or cleavage of the body into two parts, each of which then becomes a separate and independent individual. In some cases this process is slightly varied, a single pseudopodium alone being cast off and becoming a fresh *Amæba*, but this does not differ essentially from the former.

Regarding the *Amæba* from a physiological point of view, we see that, though the animal nourishes itself and maintains its existence perfectly, the process of nutrition is carried on in the simplest possible manner, and with the simplest possible apparatus. There is no permanent mouth, no stomach or alimentary canal of any kind, no respiratory or excretory organs, and even no distinct aperture for the extrusion of indigestible food. The only distinct structure which is at all concerned in nutrition is a rudimentary contractile cavity, the first foreshadowing of the heart in the higher animals.

As regards the functions of relation, it is questionable how far the *Amæba* can be said to have distinct perceptions or sensations of any kind. It has no nervous system or organs of sight or hearing, and in all probability it has nothing more than a general sensibility to light. It appears, however, to be fully aware when any object comes in contact with a pseudopodium, and even to have some idea

whether this is fit for food. Locomotion, as we have seen, is entirely effected by the temporary processes of sarcode, or pseudopodia, and there are no permanent organs set aside either for locomotion or for prehension—that is, for seizing external objects.

Many other Rhizopods, more or less closely related to the *Amæba*, have been described. Some of these, though resembling the *Amæba* in general structure, and in the form of the pseudopodia, have the soft protoplasmic body enclosed in a kind of shell or “test.” A good example of these shelled *Amæbeæ* is the little *Diffugia* (fig. 7), a not uncommon inhabitant of fresh water. In this form the body is enclosed in a sort of shell, composed of sand-grains and other foreign particles cemented together by a kind of horny secretion. The animal can retire within its shell, one end of which is open, so as to allow of the protrusion of the pseudopodia. In walking, the animal creeps about “head-downwards,” so to speak—that is to say, with the closed end of the

shell elevated above the surface on which it is moving.

Fig. 7. — *Diffugia pyriformis*, greatly enlarged. (Altered slightly from Carter.) The case is composed of angular grains of transparent quartz, within which is the transparent outer layer of the body, lined by the finely granular inner layer; *n* Nucleus; *c c* Contractile vesicles.

ORDER III. FORAMINIFERA.

The next order of the *Rhizopoda* is that of the *Foraminifera*, comprising animals which at first sight appear to be highly complex, but which are really less highly organised than the *Amæba*. The *Foraminifera* may be defined as *Rhizopoda* in which the body is protected by a shell or “test”; a nucleus and contractile vesicle are usually present; and the pseudopodia are extremely long and thread-like, and interlace with one another so as to form a network.

The most obvious and striking character of the *Foraminifera* is

the possession of an outer case or shell, and for a long time they were known to naturalists by their shells alone. As the shell or test is usually very beautiful and often very complex, the *Foraminifera* were consequently placed at first amongst the true shell-fish (*Mollusca*), very much in advance of their true position. When, however, the anatomical structure of the group came to be investigated, it was soon found that they were really referable to the *Protozoa*, and that

Fig. 8.—Foraminifera. *a* The animal of *Nonionina*, after the shell has been removed by a weak acid; *b* *Gromia* (after Schultze), showing the shell surrounded by a network of filaments derived from the body-substance.

in point of fact they even occupy a low position in this sub-kingdom. However elaborate and complicated the shell may be, the body of the contained animal is composed simply of granular gelatinous sarcodine, highly elastic and contractile, and usually reddish or yellowish in colour (fig. 8, *a*). This sarcodine not only fills the shell, but also in many cases gains the exterior by means of little perforations in its walls, and forms a thin film over its outer surface. Wherever

the sarcode is exposed, whether this be only at the mouth of the shell, as in *Miliola* (fig. 9, *b*), or whether it be over the whole surface, as in *Discorbina* (fig. 9, *c*), it has the power of giving off pseudopodia. The pseudopodia, however, differ greatly from those of the *Amœba*, and they show some remarkable characters. They are extremely long thread-like processes, instead of being blunt and finger-shaped (fig. 8, *b*), and they have the curious property that they run into one another and interlace towards their extremities, so as to form a network which has been aptly compared to an "animated spider's web." Lastly, the microscope reveals in the pseudopodia

Fig. 9.—Morphology of Foraminifera. *a* *Lagena vulgaris*, a monothalamous Foraminifer; *b* *Miliola* (after Schultze), showing the pseudopodia protruded from the oral aperture of the shell; *c* *Discorbina* (after Schultze), showing the nautiloid shell with foramina in the shell-walls, giving exit to pseudopodia; *d* Section of *Nodosaria* (after Carpenter); *e* *Nodosaria hi-pida*; *f* *Globigerina bulloides*.

a very curious circulation of minute solid particles or granules, which travel in all directions through the pseudopodial network. Internally, the sarcode-body of the *Foraminifera* is of a very simple structure; but a nucleus and contractile vesicle are usually, if not invariably, present.

Simple as is the sarcode-body of the *Foraminifera*, it has in all cases the power of secreting a skeleton or shell, which is technically called the "test" (Lat. *testa*, a shell). The shell is usually "calcareous"—that is to say, composed of carbonate of lime; but it is sometimes "arenaceous," or composed of particles of sand united together

firmly by a horny cement, and it is in some cases simply membranous. In rare cases, the shell may be siliceous. In any case, the shell may exhibit one or other of two very distinct types of structure. In the one type (as in *Miliola*, fig. 9, *b*), the shell-walls are not perforated with holes, and the pseudopodia are therefore all emitted from the mouth or "oral aperture" of the shell. In the other type (as in *Discorbina*, fig. 9, *c*), the shell-walls are perforated with a number of little apertures or "foramina," from which the order derives its name. These foramina are the mouths of tubes which pierce the walls of the shell, and thus establish a free communication between the interior and exterior. In this way the sarcode which fills the inside of the shell is enabled to reach the outer surface, so as to form a film, from any part of which the pseudopodia may be given off. The presence or absence of foramina is believed to constitute a true structural distinction, and the *Foraminifera* may be thereby divided into two great and natural groups (*Perforata* and *Imperforata*).

According to the form of the shell, also, the *Foraminifera* may be conveniently, though arbitrarily, divided into two sections. The simplest form of shell is seen in such an example as *Lagena* (fig. 9, *a*), where the shell consists of but a single chamber; and the animal, in fact, is nothing more than a little mass of sarcode, surrounded by a calcareous envelope. *Lagena*, then, may be taken as the type of what are called the "monothalamous" *Foraminifera* (Gr. *monos*, single; *thalamos*, a chamber)—that is to say, of those forms in which the animal consists of a single segment, and the shell of a single chamber. All the *Foraminifera*, without exception, commence life as "simple" or "monothalamous" forms, like *Lagena*, but it is comparatively seldom that they retain this simplicity throughout life. In the great majority of cases the primitive mass of sarcode undergoes constriction or segmentation, according to a determinate law, the segments thus produced remaining in organic connection. In this way we get ultimately a compound organism, composed of a number of little masses of sarcode, all permanently united to one another, and all enclosed in a common shell. In this way are produced forms like *Nodosaria* (fig. 9, *d*, *e*), which may be regarded as a good example of these so-called "compound" or "polythalamous" *Foraminifera* (Gr. *polus*, many; *thalamos*, a chamber). The exact form of shell which is produced by this process will depend upon the direction in which the segments are given off by the primordial segment. If the segments are developed in a line, we get such a form as *Nodosaria*. If they are given off in a spiral direction, each succeeding segment being a little larger than the one before it, and the coils of the spiral all lying in one plane, then we get such a shell as *Discorbina* (fig. 9, *c*). This is one of the commonest forms of

shell amongst the *Foraminifera*, and it is often called the “nautiloid” shell, from the close resemblance which it bears in shape to the well-known shell of the Pearly Nautilus. It was, in fact, this external similarity which induced the older naturalists to place the *Foraminifera* amongst the *Mollusca* in the neighbourhood of the Cuttle-fishes. There are numerous other types of shell, all of which can be referred to the manner in which the primordial segment becomes constricted or segmented; but the two forms above mentioned may be taken as sufficient examples. It may be mentioned, however, that there are forms in which the new segments are added in a very irregular manner, and the resulting shell has no very definite shape.

The great majority of the *Foraminifera* are inhabitants of the sea, and they are mostly very minute. A few living forms may

Fig. 10.—Organisms in the Atlantic Ooze, chiefly *Foraminifera* (*Globigerina* and *Textularia*), with *Polycystina* and sponge-spicules; highly magnified.

Fig. 11.—Section of Gravesend Chalk, examined by transmitted light and highly magnified. Besides the entire shells of *Globigerina*, *Rotalia*, and *Textularia*, numerous detached chambers of *Globigerina* are seen.

reach a quarter of an inch, half an inch, or even more than an inch in diameter. The commoner forms may usually be found by examining with a lens the sand of the sea-shore in places where there is a large intermixture of broken shells and fragments of other marine animals. Many forms live in the open ocean floating near the surface of the water. Others live on the bottom of the sea up to the greatest depths which have yet been examined by the dredge. At great depths in the sea—depths, it may be, of over two or three thousand fathoms—the bottom is often found to be covered with a whitish chalky mud, which is seen under the microscope to be almost entirely made up of the shells of various *Foraminifera*, and

especially of the shells of *Globigerina* (fig. 10). The name of "Globigerina mud" is often given to this deep-sea ooze, and it is remarkable as having a close resemblance to the well-known White Chalk. Thus, if we examine chalk under the microscope, we find that it is also composed to a large extent of the shells of *Foraminifera*, and especially of the shells of *Globigerina* (fig. 11). We may therefore regard the "*Globigerina* ooze" of the deep Atlantic and Pacific as a modern representative of the great geological formation known as the White Chalk—a formation which may be many hundreds of feet in thickness, but is nevertheless principally made up of the accumulated shells of these minute organisms. Many of the massive limestones of the earth's crust are, in like manner, largely made up of the shells of *Foraminifera*. A striking example of this is found in the so-called "Nummulitic Limestone," which owes its name to the fact that it is largely made up of the coin-shaped shells of a large Foraminifer, termed the Nummulate. Nummulites (fig. 12) vary in size from the size of a split pea up to an inch in diameter, and they are now almost wholly extinct.

Fig. 12.—*Nummulites laevigatus*.

The Nummulitic limestone stretches from France on the west to the frontiers of China on the east, and is almost everywhere readily recognisable as a distinct formation. It attains in places a thickness of several thousand feet, and is especially largely developed in the Alps. It has an historic interest from the fact that the Pyramids are built of it, and that the Nummulites in it were noticed by Herodotus, "the father of history."

ORDER IV. RADIOLARIA.

The third order of the *Rhizopoda* is that of the *Radiolaria*, essentially distinguished by the fact that the sarcode-body has generally the power of secreting a "siliceous" or flinty skeleton, either in the form of a shell, or of detached spicules or needles; whilst the pseudopodia are long and thread-like, and stand out from the body like rays. In this last character the *Radiolaria* approach very

closely to the *Foraminifera* ; and the resemblance between the two groups is still further increased by the fact that the pseudopodia often run into one another so as to form a network, and sometimes show a circulation of granules along their edges. There is generally a central capsule surrounded by a layer of sarcode exteriorly, and the latter usually contains coloured cells. A contractile vesicle is usually wanting. Four principal groups of organisms have been described as belonging to the *Radiolaria*, and we may briefly notice an example of each of these.

In the first family we have organisms like *Acanthometra* (fig. 13, *a*), in which the body is composed of sarcode, supported by a framework of siliceous or flinty rods, which all meet in a common centre. The spines or rods are all perforated by canals, and each conveys a pseudopodium, which is protruded from an aperture at its

Fig. 13 — *a* *Acanthometra lanceolata* ; *b* *Haliomma hexacanthum*, one of the *Polycystina* (after Muller).

apex. Many pseudopodia, however, are given off from the surface of the body directly, and are not enclosed in the spines. The *Acanthometrae* are all minute, and are found floating near the surface in the open ocean, sometimes in great numbers.

In the second family (*Polycystina*, fig. 13, *b*) we have a number of beautiful little organisms allied to the *Foraminifera*, but differing in the fact that the body is enclosed in a glassy shell composed of flint. The shell is perforated by numerous holes through which the pseudopodia are emitted, and it is usually of extreme beauty, being sculptured in various ways, and often adorned with spines. The sarcode of the body is usually olive brown in colour, and often does not quite fill the shell.

The pseudopodia are filamentous, and exhibit a slow circulation of granules along their borders, but they do not run into one another.

All the *Polycystina* are microscopic, and they are all inhabitants of the sea. They are best known to students of the microscope as the "Fossil Infusoria of Barbadoes" (fig. 14), as they occur in incalculable numbers in a sandstone in that island.

They are, however, in no way related to the "Infusoria" properly so called, having much stronger affinities with the *Foraminifera*. We know, also, now, that deposits of the flinty shells of these beautiful microscopic organisms are in process of formation in our oceans at great depths.

In the third family (*Collozoa*) are included a number of singular gelatinous organisms which may be as large as an ordinary marble, but are often hardly visible to the unassisted eye. They are found floating passively at the surface of most seas; and they may either have no skeleton, or may secrete a flinty framework, which may give rise to a fenestrated

Fig. 14.—Shells of *Polycystina* from the "Barbadoes Earth," greatly magnified. (Original.)

Fig. 15.—a Siliceous shell of *Collosphæra*; b *Sphærozoum*, showing the radiating pseudopodia and groups of siliceous spicula (after Muller).

shell, as in *Collosphæra* (fig. 15, a), or may remain in the form of scattered spicules, as in *Sphærozoum* (fig. 15, b). In *Thalassicolla* the skeleton is wanting.

A fourth family has been constituted under the name of *Heliozoa*, for a number of singular and beautiful microscopic organisms, which mostly occur in fresh water, and which cannot be regarded as typical Radiolarians, though more closely allied to this group of the *Pro-*

tozoa than to any other. In these forms (fig. 16) the body is provided with long filamentous pseudopodia, which stand out like rays, and which may anastomose with one another. The body may be quite soft, as in the common "Sun-animalcule" (*Actinophrys*), but

Fig. 16.—*Heterophrys spinifera*, one of the *Heliozoa*, greatly enlarged (after Heitwig and Lesser). c c Contractile vesicles

there may be, and often are, delicate spines of flint radiating from the central sarcodic mass, and there is sometimes a regular siliceous skeleton. The *Heliozoa* are further furnished with the structures which are known as the "contractile vesicle" and "nucleus."

CHAPTER III.

INFUSORIA.

THE Infusorian Animalcules are minute *Protozoa* of almost universal distribution, abounding in almost all collections of fresh or salt water in which organic matter may be present. They commonly have the power of becoming "encysted," and of remaining dormant, when deprived of water or of other conditions necessary to their active existence, the external layer of the body forming a kind of case within which the soft central protoplasm is enclosed. Their desiccated bodies, or their similarly desiccated germs, may thus be carried through the atmosphere from place to place, and may at any moment pass into a condition of active life, if they should meet with favourable conditions. Hence, whenever water containing organic matter in solution is freely exposed to the air, it will almost certainly be found to be charged with a larger or smaller number of these minute organisms. It is for this reason that the name of *Infusoria* was originally applied to this group of the *Protozoa*; it having been observed that "organic infusions"—i.e., water in which an animal or vegetable substance had been boiled—very commonly came to contain Infusorian Animalcules after exposure to the air for a limited period.

Morphologically, the Infusorian Animalcules are unicellular animals, consisting of a primitive mass of soft protoplasm, provided with an outer membranous wall, and furnished with one or more nuclei. Very usually the outer wall of the body is pierced by a definite oral opening; and they are sometimes for this reason collectively spoken of as the "stomatode," or mouth-bearing, *Protozoa*. There are, however, certain groups of the *Infusoria* in which there cannot be said to be any proper mouth.

There are two principal groups of the *Infusoria*, known as the Ciliated Infusorians and the Flagellated Infusorians; the former (fig. 17, A, B, C) having the external surface covered with vibrating cilia, in part or wholly; whilst the latter (fig. 17, D and E) have one or more long lash-like filaments or "flagella," and are usually destitute

of cilia. There is a third smaller group— the *Suctoria*—in which the body is furnished with contractile tentacle-like filaments, which end in little discs, and are used as sucking-tubes. It will not be necessary to do more than mention the Suctorial Infusoria here ; but the two groups of the *Ciliata* and *Flagellata* require more detailed attention.

Fig. 17.—Ciliated and Flagellate Infusoria. A, *Bursaria truncatella*, enlarged 50 times. B, *Nyctotherus cordiformis*, enlarged 150 times. C, *Amphileptus anser*, enlarged 120 times. D, *Ceratium tripos*, enlarged 250 times, with its carapace and single flagellum. E, *Monosiga angustata*, enlarged 2500 times: *n* Nucleus; *c* Contractile vesicle; *f* Flagellum; *m* Membranous collar surrounding the base of the flagellum. (After, or copied from, Saville Kent.)

The *Ciliated Infusoria* may be defined as *Protozoa* which are provided with a mouth, and usually a short gullet and a distinct anus. Their bodies consist of soft semi-fluid protoplasm ("endoplasm") enclosed by a more or less complex external layer ("exoplasm"); and the external surface is partly or wholly covered with vibrating cilia. They are mostly simple free-swimming organisms ; but they sometimes form colonies by budding, and are fixed to some solid object in their adult condition. As types of these two sections of the *Infusoria*, we may take respectively *Paramæcium* and *Vorticella*.

Paramœcium (fig. 18) is a beautiful slipper-shaped little creature, which may be found commonly in stagnant waters or in artificially prepared infusions. The body is nearly quite transparent, and consists of three layers—1, a structureless, transparent, external film or pellicle, called the “cuticle”; 2, a central mass of soft semi-fluid sarcode which receives the particles of food; and 3, an intermediate layer of firm and consistent sarcode, which is called the “cortical layer” (Lat. *cortex*, bark). The external membrane or cuticle is richly covered with minute vibrating hairs or cilia, which in this particular type are of approximately equal length, and are arranged in close-set longitudinal rows. In many of the *Infusoria*, however, the cilia in the neighbourhood of the mouth are much longer than those covering the general surface. The cuticle is also perforated by the aperture of the mouth, which is continued into a short funnel-shaped gullet (fig. 18, *m g*). The gullet, however, is not continued into any distinct stomach, but opens directly into the soft semi-fluid sarcode (endoplasm) which constitutes the central mass of the body. The particles of food on passing through the gullet are directly received into the central mass of diffuent sarcode, where they undergo a kind of slow circulation or rotation. As in the case of the *Amœba*, each particle of food generally carries with it a little water, so that the appearance is produced of a number of little clear

Fig. 18.—*Paramœcium*, viewed dorsally, and greatly magnified. *m* Mouth; *m g* Gullet; *a* Anus; *cv* and *cv* The contractile vesicles; I, II, III, Canals proceeding from the anterior contractile vesicle; *n* Nucleus; *v* Large cilia bounding the depression (“vestibule”) leading to the mouth. The arrows indicate the course in which the particles of food circulate in the semi-fluid protoplasm of the interior of the body. (After James-Clark.)

spaces in the central sarcode. These are now called vacuoles, or food-vacuoles; but they were originally described by Ehrenberg, the

famous Prussian microscopist, as so many distinct stomachs, in consequence of which he named the *Infusoria* the *Polygastrica* (Gr. *polus*, many; and *gaster*, stomach). The vibrating cilia which clothe the surface of *Paramæcium* serve partly to drive the animal rapidly through the water, and partly to set up currents by means of which food is conveyed to the mouth. All the nutrient particles obtained in this way undergo the circulation in the central sarcodæ above spoken of, where they are partially or completely digested. The indigestible portions of the food are got rid of by a second aperture (*anus*) placed near the mouth (fig. 18, *a*). The only other organs possessed by *Paramæcium* are the so-called nucleus and nucleolus, and the contractile vesicle (or vesicles), all of which appear to be situated in the cortical layer of the body. The nucleus is a little solid body, composed of an external membrane, with granular contents, and having the nucleolus (or paranucleus) firmly attached to its exterior

Fig. 19.—Ciliated Infusoria. A, *Paramæcium*, showing the nucleus (*n*) and two contractile vesicles (*v*). B, *Paramæcium bursaria* (after Stein), dividing transversely: *n* Nucleus; *n'* Nucleolus; *v* Contractile vesicle. C, *Paramæcium aurelia* (after Ehrenberg), undergoing “conjugation,” two individuals being partially united by their ventral faces.

in the form of a little spherical particle. The nucleus and nucleolus used to be regarded as corresponding with the reproductive organs of the higher animals; but this view is now known to be without foundation. The contractile vesicle has essentially the same structure as in the *Amœba*. It is a little wall-less space in the protoplasm, which is filled with a transparent fluid, and contracts and dilates at intervals. Sometimes it assumes a stellate form (fig. 19, A), or irregular radiating canals can be traced proceeding from it; while a communication with the exterior has been stated to exist in some cases. Not uncommonly two vesicles are present. It is not

improbable that the contractile vesicles should be looked upon as corresponding with the water-vessels of the lower groups of Worms, and as having the function of excretory, rather than of circulatory organs.

Reproduction in *Paramecium* may be effected simply by transverse cleavage or fission of the body into two portions (fig. 19, B). In other cases "conjugation" of two *Paramecia* takes place. In this process two individuals come together, and adhere closely to one another by their ventral surfaces, in such a way that they present the appearance of a single individual undergoing longitudinal fission (fig. 19, C). Partial fusion of the conjugating individuals takes place, and the nucleus and nucleolus pass through certain curious changes. Ultimately, the conjugating individuals separate again, and each probably then undergoes repeated fission, and thus gives rise to fresh *Paramecia*.

As a common and beautiful example of the Stalked *Infusoria*, we may take the so-called Bell-animalcule (*Vorticella*, fig. 20, C), which

Fig. 20.—A, *Stentor Müllerii*. B, *Vaginicola crystallina*. C, Group of *Vorticellæ*. D, Detached bud of *Vorticella*, showing the posterior circle of cilia.

may be found in any stagnant pool attached to the stems of aquatic plants. The body in *Vorticella* forms a kind of cup or "calyx" supported upon a long stalk, which is in turn fixed to some solid object. The stem contains a contractile fibre in its interior, and the animal can by this means push itself out or coil itself up with the utmost rapidity. The vibrating filaments or cilia are not scattered over the whole surface of the bell-shaped body, but are collected to form a

kind of fringe or circle round the mouth of the calyx. Nearly in the centre of this ring, or on one side, is placed the aperture of the mouth, which leads by a short gullet straight into the central soft sarcode of the interior of the body. A nucleus and contractile vesicle are also present, so that in the essential points of its anatomy *Vorticella* does not differ from a free-swimming Infusorian such as *Paramecium*. Indeed, a transition between the two forms is found in the so-called Trumpet-animalcule or *Stentor* (fig. 20, A), which can detach itself and swim about at will, at the same time that it is ordinarily fixed by its thinner extremity to some solid object. In *Vaginicola* (fig. 20, B), again, we have an animalcule closely related to *Stentor*, but having the body protected by a horny or membranous sheath.

The group of the *Flagellated Infusoria* is distinguished from that of the *Ciliata*, by the fact that the body is furnished with one or more long lash-like filaments or flagella, usually without any cilia. A nucleus and contractile vesicle are present. The flagella of these singular Infusorians are the main locomotive organs, serving by their lash-like movements to drive the animal through the water, as also to set up currents by means of which food is brought to the organism. In many instances, the latter is their principal function, as the animal is fixed by a stalk in its adult condition. A few forms have a mouth (e.g., *Euglena*); but most have no distinct oral aperture, the inception of food being limited to a definite discoidal area surrounding the base of the flagellum. This area is enclosed by a delicate membrane, which is prolonged upwards round the lower part of the flagellum as a kind of cup or "collar" (fig. 17, E). The movements of the flagellum produce a kind of miniature whirlpool inside the collar, and the animal is thus supplied with food. These "collar-bearing" Infusorians possess, as will be subsequently seen, a striking resemblance to certain of the cells which form the body of a sponge. A number of the Flagellated Infusorians possess a limited number of cilia, in addition to the flagellum. This is the case, for example, in the curious forms known as *Peridinium* and *Ceratium* (fig. 17, D), in which the body is enclosed in a kind of horny shell with long projecting processes.

In their internal structure, the Flagellated Infusorians do not differ essentially from the Ciliated forms. They occur both in fresh and in salt water, and often form colonies. They are mostly of very minute size; and it is difficult to separate certain forms from certain groups of plants (*Algae*).

CHAPTER IV.

PORIFERA (SPONGES).

ORIGINALLY regarded as being of a vegetable nature, the Sponges are now universally admitted to be animals; and are by many naturalists associated with the Sea-anemones and Corals (*Cœlenterata*). They have, however, many remarkable points of relationship to the typical *Protozoa*, and particularly to the Flagellated *Infusoria*. Upon the whole, therefore, it may be as well to treat them here as a special group, intermediate between the *Protozoa* and *Cœlenterata*, under the name of *Porifera*.

The Sponges may be defined as *multicellular protoplasmic masses, supported in most cases by a framework of horny fibres or of calcareous or flinty needles, and traversed by canals which open on the surface, and are dilated at intervals into chambers lined by flagellate cells.*

In the first place, then, a Sponge differs from the typical *Protozoa*, and agrees with all the higher animals (*Metazoa*), in the fact that the body is multicellular, being composed of a vast number of separate protoplasmic units, which may be termed "sponge-particles" or "sarcoids," and each of which may be regarded as being a single cell. In the second place, this protoplasmic aggregate is almost always, though not invariably, strengthened and endowed with a definite form, by the presence in it of a "skeleton," consisting of horny fibres, or of "spicules" of lime or silica. In the third place, the entire organism is traversed by a complicated "canal-system," which opens on the surface by two sets of apertures ("pores" and "oscula"), and the branches of which are dilated at intervals into "ciliated chambers." There is no distinct mouth, no digestive system, no circulatory or definite nervous organs, and no body-cavity; but we must consider in greater detail the characters and structure of the "sponge-flesh," the "skeleton," and the "canal-system."

If we take the ordinary horny sponges of commerce, what we call the "sponge" is, of course, nothing but the *skeleton* of the

sponge-colony, comprised of innumerable horny fibres interlaced into a continuous network, in such a way as to leave innumerable holes and canals between its bundles. In the living condition, the

Fig. 21. Structure of *Spongia*. A, Vertical section of the outer layer of *Halysarca lobularis*, a Sponge in which the skeleton is wanting, enlarged 75 times (after F. E. Schultze): *pp* "Pores," or openings of inhalant canals by which water is conducted to the ciliated chambers (*aa*); *e* Commencement of a larger exhalant canal, conducting from the ciliated chambers to the deeper canals, by which the water is finally carried off to be expelled from the "oscula"; *gg* Young stages of the reproductive bodies or spores. B, Part of a single ciliated chamber of the same sponge, transversely divided, and enlarged 800 diameters (after Saville Kent), showing the flagellate cells; or "sponge-particles," with their inwardly directed flagella. whole of this skeleton is covered externally and internally with a soft protoplasmic material, which has been often termed the "sponge-flesh," as it represents the soft parts of the sponge. Examined microscopically, the "sponge-flesh" is found to be composed of an enormous number of minute protoplasmic bodies or

cells—the “sponge-particles” or “sarcoids”—which differ in their characters in different parts of the sponge. Some of the sponge-particles are very like *Amœbæ*, since they consist of little masses of granular protoplasm, furnished with a nucleus, and capable of throwing out pseudopodia (fig. 22, C), by means of which they feed. In the outer layer of the sponge, these sponge-particles may be arranged so as to form a kind of membrane; and at other times they become more or less coalescent, giving rise to a common gelatinous matrix, and losing their separate distinctness. Other sponge-particles, again, instead of being like *Amœbæ*, are closely similar to those Flagellate *Infusoria* which possess a collar round the flagellum. These flagellate sponge-particles (fig. 21, C, and fig. 22, B) possess a nucleus and one or more contractile vesicles, and they are arranged within the so-called “ciliated chambers” (fig. 21, *α α*) of the canal-system.

The entire aggregate of sponge-particles is so arranged as to be traversed by a series of canals, which convey water in and out of the organism, and are connected with respiration and the procuring

Fig. 22.—A, Portion of *Grantia*, highly magnified, showing the spicules and the sponge-particles. B, A single sponge-particle of *Grantia compressa*, greatly enlarged, showing the membranous collar (*a*), the flagellum (*f*), the contractile vesicles (*c c*), and the nucleus (*n*). of food. Looking at the skeleton of the dried sponge, the most obvious sign of the existence of this “aquiferous system” that we see is the presence of one or more large openings (fig. 23, A), together with a vast number of much smaller apertures. These latter

are termed the "pores"; and though permanently present in the skeleton, they are only temporarily present in the sponge-flesh, being produced afresh, when required, as openings between the sponge-particles which form the outer layer of the sponge. The "pores" are the external openings of a series of canals which ramify in every direction through the sponge, and which are usually called "inhalant canals," as it is through these that the outer water is conveyed into the interior of the sponge. The "inhalant canals" ultimately open into a second series of canals, which converge to form one or more large tubes which open on the surface by a corresponding number of large apertures. These large tubes carry the water out of the organism again, and they are hence called "exhalant canals" (fig. 21), while their surface-openings are the "oscula."

Fig. 23. — A, *Arinella polypoides*, a fibrous sponge showing oscula and pores. B, *Sycaandra ciliata*, a calcareous sponge, enlarged, showing the single terminal osculum. (After Schmidt.)

The "oscula" are permanent (fig. 23, A), and are often placed on chimney-like elevations. If there is only one osculum, it is placed at the apex of the sponge (fig. 23, B). What we usually call a sponge may consist of only a single excretory opening or "osculum,"

together with the pores belonging to this (fig. 23, B); or it may consist of a larger or smaller number of such "oscula," each with its proper complement of "pores" (fig. 23, A). In the latter case, there is produced what is commonly called a "sponge-stock."

In a living sponge, in its active condition, a circulation of water is kept up throughout the organism by means of this canal-system. The water is admitted by means of the "pores" (fig. 21, A, *pp*), is driven into the interior of the sponge, and is finally expelled in steady streams from the osculum or oscula. The mechanism by which this circulation of water is effected was long unknown. It is now known, however, that the circulation of water is maintained by the vibrations of the flagella, with which we have seen certain of the sponge-particles to be provided. In some cases, the entire system of water-canals seems to be lined with these flagellate sponge-particles. More commonly, the "inhalant canals" are dilated at intervals into globular chambers (fig. 21, A, *aa*), which are lined with flagellate sponge-cells. These sponge-particles are so arranged that all their flagella point inwards into the centre of the chamber (fig. 21, B), and in their structure they precisely resemble Flagellate *Infusoria*. The flagella within these so-called "ciliated chambers" all work towards the interior of the sponge, and thus supply the motive power needed for the keeping up of the water-currents. By means of these water-currents the organism obtains oxygen, and gets rid of waste matter;

Fig. 24.—A, Fragment of the skeleton of a horny sponge (after Bowerbank), showing interlacing horny fibres with spicula. B, Different forms of the spicules of sponges, much magnified.

while the individual sponge-particles appropriate the minute particles of nutrient matter which may be carried in suspension in the water.

Such, then, are the general phenomena exhibited by any sponge, and the principal point which still remains for consideration is the nature of the hard structures which form the "skeleton" of the Sponges. Some sponges (such as *Halysarca*) have no skeleton; and when a skeleton is present, it varies much in its constitution. In the sponges of commerce (*Euspongia*) the skeleton consists solely of hollow horny fibres, which are interlaced with one another so as to form a close reticulation. In many other common sponges, a horny skeleton is also present, but it is associated with, and sometimes largely replaced by, microscopic needles or "spicules" of flint. These spicules (fig. 24, B) are of very various shapes in different sponges, and they may be either scattered through the sponge-flesh, or contained in the interior of the horny skeleton-fibre, which they often extensively replace. In the so-called "Siliceous" Sponges, or "Glass Sponges," no horny fibre is developed, but the whole skeleton is composed of spicules of flint, which are often soldered together so as to form a continuous framework, which looks like a lattice of spun glass. The beautiful Venus's Flower-basket (*Euplectella*) and the Bird's-nest Sponges (*Holtenia*) are examples of such sponges. Lastly, in the so-called "Calcareous Sponges," such as *Grantia* (fig. 22, A), the skeleton is composed of aggregated, but disunited, spicules of lime, instead of flint. These spicules mostly have a characteristic three-rayed form.

Fig. 25.—a Gemmule of *Spongilla*; h Hilum; b Diagrammatic section of the gemmule, showing the outer layer of amphidiscs and the inner mass of cells; c One of the amphidiscs seen in profile.

As regards the reproductive process in the Sponges, it will be sufficient to state very briefly the leading phenomena which have been observed in the Fresh-water Sponge (*Spongilla fluviatilis*). If a specimen of *Spongilla* be observed towards the approach of winter, its deeper portions will be found to be filled with numerous small rounded bodies like seeds, which have been called "gemmules." Each gemmule (fig 25, a b) exhibits at one point a small aperture or "hilum"; and is found to be composed of a leathery membrane, surrounded by a layer of sarcode, in which are embedded a number of spicula. These spicula are called "amphidiscs," and consist each of a central rod or axle carrying a toothed wheel or disc at each end (fig. 25, c). In the interior of

the capsule thus formed is a mass of cells, of which the central ones contain numerous reproductive germs. When the spring comes, these masses are discharged into the water through the aperture or hilum of the gemmule, and become developed into fresh *Spongilla*. The above is a non-sexual method of reproduction; but it is believed that most of the marine Sponges exhibit sexual

reproduction also, and are capable of producing at certain seasons eggs or ova, and sperm-cells. The impregnated ova develop themselves into embryos, which are provided with numerous cilia by means of which they swim about freely. Finally, upon finding a suitable locality, they fix themselves to some solid object, lose their cilia, and grow up into the fixed adult. Indeed, as a general if not universal rule, the embryos of the sponges are provided with cilia, and are thus capable of active locomotion. In this way is secured the extension over a wide area of these otherwise fixed and plant-like organisms.

As to the distribution of the Sponges in space, the common *Spongyllæ* and certain allied types are known as "fresh-water sponges," as they occur in lakes and rivers; but most sponges are inhabitants of the sea. The common Horny Sponges are mostly found attached to stones or other foreign objects between tide-marks, or in comparatively shallow water. Certain singular types (*Cliona*) burrow into shells, in which they form winding and branched tunnels, but the mechanism by which this is effected is not clearly known. The Glass Sponges are all marine, and are mostly found at comparatively great depths in the sea, being often anchored to the mud or sand at the bottom by longer or shorter root-fibres of flint. Lastly, the Calcareous Sponges are all marine, and are mostly confined to shallow water, or live between tide-marks. They are all small in point of size, and delicate in texture.

SUB-KINGDOM II. CŒLEENTERATA.

CHAPTER V.

1. CHARACTERS OF THE SUB-KINGDOM. 2. DIVISIONS.

3. GENERAL CHARACTERS OF THE HYDROZOA.

4. EXPLANATION OF TECHNICAL TERMS.

THE second great primary division or sub-kingdom of animals is that of the *Cœlenterata* or "hollow-entrailed" animals (Gr. *kôilos*, hollow; *enteron*, intestine). This sub-kingdom embraces the Sea-anemones, Corals, Sea-jellies, Sea-firs, Sea-pens, and other allied animals, all of which are characterised, amongst other things, by having their bodies built up of parts which are arranged in a more or less star-like or "*radiate*" manner. Hence these creatures were long known as "Radiate Animals." So many other animals of different kinds were, however, included in the old sub-kingdom *Radiata*, that naturalists have generally abandoned this term. Most of the Cœlenterate animals would come under the popular term of "Zoophytes" or plant-animals (Gr. *zôön*, animal; *phuton*, plant), from the external resemblance which many of them bear to plants.

The *Cœlenterata* may be defined as *radially symmetrical animals, in which the mouth opens into a simple or variously divided space, which represents the alimentary cavity of the higher animals. This internal space may or may not be divided into two portions—one specially connected with digestion, and the other corresponding with the body-cavity of the higher animals. The body-wall is composed of two fundamental layers (the "ectoderm" and "endoderm"). The nervous system is represented by diffused ganglion-cells, or sometimes by a simple nerve-ring; but there are no circulatory organs. Distinct reproductive organs are present at some period or another of life; but non-sexual reproduction is very general.*

The leading feature which distinguishes the *Cœlenterata*, and the one from which the name of the sub-kingdom is derived, is the peculiar arrangement of the digestive system. In the *Protozoa*, as

we have seen, a mouth is only present in some groups, and in no case is there any definite internal cavity bounded by the walls of the body, to which the name of "body-cavity" or "somatic cavity" could be properly applied. In most of the higher animals, on the other hand, not only is a permanent mouth present, but the walls of the body enclose a distinct and permanent chamber or body-cavity. Further, in most cases the mouth opens into an alimentary or diges-

Fig. 26.—Diagrammatic vertical section of a Sea-anemone. *a* Mouth; *s* Stomach; *b* Body-cavity; *c c* Convoluted cords ("craspeda") containing thread-cells, and forming the free edges of the mesentery (*m*); *t t* Tentacles; *o* Reproductive organ contained within the mesentery. The ectoderm (*e*) is indicated by the broad external line; the endoderm (*e'*) by the thin line and the space between that and the ectoderm.

tive tube, which is always distinct from the body-cavity, and never opens into it, usually passing through it to open on the surface by another distinct aperture (the anus). In most cases, therefore, the alimentary canal is a tube which communicates with the outer world by two apertures—a mouth and an anus—but which simply passes through the body-cavity without in any way communicating with it. In the *Cœlenterata* the condition of parts is intermediate in its arrangement. There is a distinct and permanent mouth, and there is a distinct and permanent cavity enclosed within the body-walls, but the mouth opens into, and thus communicates freely with, the latter. In some cases the mouth opens straight into the general body-cavity, which then serves as a digestive cavity as well (fig. 28). In other cases there intervenes between the mouth and the body-cavity a short alimentary tube, which communicates externally with the outer world through the mouth, and opens below by a wide aperture into the general cavity of the body (fig. 26). In no case is

there a distinct intestinal tube which runs through the body-cavity and opens on the surface by a mouth at one end and an excretory aperture or anus at the other. It may be added in this connection that, though it is convenient to apply the term of "body-cavity" to the general space included within the body-walls of a Cœlenterate animal, the space does not correspond in its mode of development with what is known as the body-cavity of the higher animals.

Another leading character of the *Cœlenterata* is the composition of the body out of two fundamental membranes (fig. 26), which are usually of a very simple structure in the embryo, but which in the adult become more or less complicated by the development of muscular fibres and other tissues. The outer of these layers or membranes is known as the "ectoderm," and it forms the whole of the

Fig. 27.—Thread-cells of Cœlenterate animals, greatly magnified. A and B, Thread-cell of a coral (*Caryophyllia*), with the thread everted. C and D, Thread-cell of a Sea-anemone (*Corallimorphus*), in its quiescent and active condition. E, Thread-cell of *Hydra*, with the thread everted.

outer surface of the body, terminating at the margins of the mouth. The inner layer is known as the "endoderm," and it lines the whole of the interior of the body, being prolonged into the tubular tentacles round the mouth. Both of these membranes, but especially the endoderm, are usually more or less richly furnished with vibrating cilia. The muscular and other tissues which are developed between the ectoderm and endoderm, constitute what is called the "mesoderm." The peculiar microscopic organs called "thread-cells," "nettle-cells," or "cnidæ," which communicate to many of the *Cœlenterata* (such as the sea-jellies) their peculiar power of stinging, are

structures found in the integument of almost all the members of this sub-kingdom, and sometimes in internal parts as well. They are very beautiful objects of microscopical examination, and differ very considerably in the details of their structure. Each thread-cell (fig. 27) is essentially a double-walled sac or capsule filled with fluid, and containing internally a longer or shorter spirally-coiled thread or filament. The thread is pointed at its free extremity, and often barbed at its base or serrated along the edges. When the external capsule is touched it ruptures; and the coiled-up thread is thrown out, like a lasso, to a distance often equal to many times the length of the enclosing capsule. The pointed end of the thread pierces the object which it strikes—supposing the latter to be of a sufficiently soft nature—and apparently envenoms the puncture thus produced with the fluid contained in the sac, this seeming to have some poisonous or irritating character.

In accordance with the above-mentioned differences in the arrangement of the digestive system, the *Cœlenterata* are divided into two great classes, termed respectively the *Hydrozoa* and the *Actinozoa*. In the *Hydrozoa*, there is no body-cavity distinct from the digestive cavity—or, in other words, the body-cavity *is* the digestive cavity, the mouth opening directly into the body-cavity (fig. 28). In the *Actinozoa*, on the other hand, there is a distinct digestive cavity, but this opens directly into the general body-cavity, so that the two form distinct but freely communicating divisions of the same chamber.

Fig. 28.—Diagrammatic section of *Hydra*; the dark line is the ectoderm, the fine line and clear space adjacent indicate the endoderm.

CLASS I. HYDROZOA.

The *Hydrozoa* are defined as *Cœlenterata* in which there is no digestive sac separate from the general cavity of the body. The reproductive organs are external, in the form of outward processes of the body-wall (fig. 30).

The *Hydrozoa* are all aquatic in their habits, and, with few exceptions, all are inhabitants of salt water. The class includes both simple and composite organisms, of which the most familiar are the Sea-firs and their allies (Hydroid Zoophytes), the Fresh-water Polype or *Hydra*, the Sea-jellies (*Medusæ*), and the Portuguese Man-of-war (*Physalia*). Owing to the extremely complicated nature of many of the *Hydrozoa*, it appears advisable to preface their description by an explanation of some of the more important terms which are employed in connection with various members of the class.

GENERAL TERMINOLOGY OF THE HYDROZOA.

Individual.—In order to understand fully the meaning which is attached to the term “individual” in zoological language, it is necessary to glance briefly at the general features of reproduction as displayed in different sections of the animal kingdom. Reproduction is the process by means of which new individuals are produced and the perpetuation of the species ensured. This end may be attained in various ways, but these all come under the two heads of “sexual” and “non-sexual” reproduction. In *sexual* reproduction, by which alone can fresh beings be produced amongst the higher animals, the essential element of the process consists in the formation of two distinct structures, a germ-cell or ovum, and a sperm-cell or spermatozoid. By the union of these distinct reproductive elements, fresh beings can be produced. As a general rule, the germ-cell is produced by one individual (female), and the sperm-cell by another (male); but amongst the lower animals it is not uncommon for the same individual to produce both of these elements, in which case the individual is said to be “hermaphrodite.” Amongst the lower animals, however, fresh beings may be produced without the contact of a sperm-cell and an ovum—that is to say, without any genuine act of reproduction. The processes by which this can be effected in different animals vary considerably, but they are all spoken of as forms of “non-sexual” reproduction. The only varieties, however, of the process which require consideration, are those in which fresh beings are produced by what is called “gemmation” or “fission.”

Gemmation (Lat. *gemma*, a bud) consists in the production of a bud or buds, usually from the outside, but sometimes from the inside of an animal; which buds become developed into more or less completely independent beings. The fresh beings thus produced by budding are all known as *zooids*, and are not spoken of as distinct animals, for reasons which will be immediately evident. When the zooids produced by budding remain permanently attached to one another and to the parent organism which produced them, the case is said to be one of “continuous” gemmation, and the ultimate result of this is to produce a colony or composite structure, composed of a number of similar and partially independent beings, all produced by budding, but all remaining in organic connection. This is seen very well in a great number of the *Hydrozoa* (fig. 29). When, on the other hand, the zooids produced by budding become finally detached from the parent organism, we have a case of what is called “discontinuous” gemmation. In this case, the detached zooids become completely independent beings; and they are often wholly

unlike the original zoöid in structure and in habits, so much so that they have in various cases been described as altogether distinct animals. Discontinuous gemmation is very well seen in many of the *Hydrozoa*, and in them the case is still further complicated by the coexistence of discontinuous gemmation with the continuous form of the process. Thus it is not an uncommon thing amongst the *Hydrozoa* to find a composite organism or colony produced from a primordial zoöid by continuous gemmation, and having at the same time the power of giving rise to detached and completely independent beings by a process of discontinuous gemmation.

In what is called "fission" (Lat. *findo*, I cleave), exactly the same results are attained as in gemmation, but in a slightly different manner. In gemmation the new beings are produced by means of buds thrown out by a primitive zoöid. In fission the new beings are produced by a cleavage or division of a primitive zoöid into two or more parts, each of which becomes finally developed into a new and more or less completely independent being. In fission, as in gemmation, the new beings or zoöids may remain permanently in connection with one another, when the process is a continuous one, and a composite organism is produced, as in many Corals. Or, in other cases, the new zoöids produced by fission are detached to lead an independent existence, as in some of the *Hydrozoa*, the process thus becoming a discontinuous one.

We are now able to understand what is meant, in strict zoological language, by the term "individual," as applied to animals. Zoologically speaking, an *individual* is defined as "*equal to the total result of the development of a single ovum.*" In the higher animals there is no sort of difficulty about this, for each ovum gives rise to no more than one single animal, which cannot produce fresh beings in any other way than by producing another ovum. In this case, therefore, each animal is an individual. In the lower animals, however, the being produced by an ovum has often the power of giving rise to fresh beings by a process of gemmation or fission, and these beings may either remain attached to one another so as to form a colony, or may become detached to lead independent lives. In either case, the term "individual" can only be properly applied to the whole assemblage of beings produced in this way, however much they may differ from one another in appearance, structure, or mode of life. In these cases, therefore, the individual may be, *firstly*, a single independent being—as, for instance, an *Amæba*, or an Infusorian such as *Paramæcium*; *secondly*, a colony or composite organism composed of a number of more or less nearly similar beings or zoöids, produced by budding from a primitive zoöid—as, for instance, is seen in many of the *Infusoria* (e.g., *Epistylis*); and

thirdly, an assemblage of zoöids produced by budding or fission from a primitive being, but not necessarily remaining connected with one

Fig. 29. — A, Part of the colony of *Bougainvillea muscus*, one of the compound *Hydrozoa*, of the natural size. B, Part of the same enlarged: *p* A polypite fully expanded; *m* An incompletely developed reproductive bud; *m'* A more completely developed reproductive bud; *f* Caenosarc with its investing periderm and central canal. C, A free reproductive bud or medusiform gonophore of the same: *n* Gonocalyx; *p* Manubrium; *c* One of the radiating gastro vascular canals; *o* Ocellus; *v* Velum; *t* Tentacle. (After Allman.)

another or exhibiting any common features of likeness, as we shall see is the case in many of the *Hydrozoa*. Lastly, cases may occur in which the individual consists partly of similar zoöids which

remain permanently connected with one another, and partly of dissimilar zoöids which are detached to lead an independent life, all alike being the result of the development of a single ovum.

Zoöid.—The term “zoöid” is indifferently applied to all the more or less completely independent beings which are produced by budding, or by cleavage from a primitive organism. It does not matter, therefore, for the purposes of this definition, whether these beings remain permanently attached to the original organism, or whether they are finally separated to enjoy an independent existence.

Hydrosoma.—The term “hydrosoma” is one which is very conveniently applied to the entire organism in any *Hydrozoön*, whether this be simple, or whether it be composite and made up of a number of connected zoöids.

Polypite.—That portion of any *Hydrozoön* which is concerned with the process of digestion, or, in other words, the “alimentary region,” is termed the “polypite”—the more generally current term of “polype” being now restricted in meaning to the same region in the higher *Cœlenterata* (*Actinozoa*). In such of the *Hydrozoa* as the Fresh-water Polype or *Hydra*, in which the hydrosoma is simple, the whole organism is termed a polypite; but the term is more generally employed to indicate the nutritive zoöids of any compound *Hydrozoön*.

Cœnosarc.—The term “cœnosarc” (Gr. *koinos*, common; *sarx*, flesh) is employed to designate the common trunk or flesh by which the separate polypites of any compound *Hydrozoön* are united into a single organic whole.

Distal and proximal.—These are terms applied to different extremities of the hydrosoma. It is found that one extremity grows more quickly than the other, and to this free-growing end—at which the mouth is usually situated—the term “distal” is applied. To the more slowly-growing end of the hydrosoma the term “proximal” is applied. When the *Hydrozoön* is fixed to any solid object, it is by the proximal end that attachment is effected; but in such forms as are permanently free this mode of distinction is inapplicable. The terms may be used either in reference to a single polypite in the compound *Hydrozoa*, or as regards the entire hydrosoma, whether this be simple or compound.

Polypary.—The term “polypary” or “polypidom” is applied to the horny or chitinous outer covering or envelope with which many of the *Hydrozoa* are furnished. These terms have also been not uncommonly employed to designate the very similar structures produced by the much more highly organised Sea-mats and their allies (*Polyzoa*), but it is better to restrict their use entirely to the *Hydrozoa*.

CHAPTER VI.

DIVISIONS OF THE HYDROZOA.

THE *Hydrozoa* are divided into five great divisions, each of which requires some notice, as presenting points of special interest. These divisions or sub-classes are known by the names of *Hydroida*, *Siphonophora*, *Lucernarida*, *Graptolitidae*, and *Hydrocorallinæ*.

SUB-CLASS HYDROIDA.

This sub-class comprises all the Sea-firs and their allies, commonly known to naturalists as the "Hydroid Zoophytes," from their resemblance to the Fresh-water Polype (*Hydra*), which is also a member of this division. The *Hydroida* are defined by the fact that *they consist of an alimentary region or "polypite," which is furnished with a mouth and prehensile tentacles at its distal end, and with an adherent disc at its proximal extremity.* In some few cases the hydrosoma consists of but one such polypite (as in the *Hydrida* and some of the *Corynida*); but generally the hydrosoma is composed of a greater or less number of similar polypites all united by a cœnosarc or common trunk (as in the majority of the *Corynida*, and in the *Sertularida* and *Campanularida*). In the great majority of cases, also, the hydrosoma is not unattached, but is fixed to some solid object by its proximal extremity or "hydrorhiza." The Hydroid Zoophytes exhibit four principal types of structure, which constitute so many orders.

ORDER I. HYDRIDA.

In the first order we have only the well-known Fresh-water Polypes or *Hydræ*, of which we may take the common green *Hydra* (*H. viridis*) as the type. When uncontracted, the body of the *Hydra* is in the form of a cylindrical tube (fig. 30), composed of the two fundamental layers, the ectoderm and endoderm, of which the former contains many thread-cells. The integument

also contains numerous green granules, apparently identical with "chlorophyll," or the green colouring-matter of plants. At the base or proximal extremity of the cylindrical body is a kind of disc-shaped sucker or hydrorhiza, by means of which the animal can attach itself at will to any foreign body. Its favourite position appears to be that of hanging head-downwards, suspended from the stem of some water-plant. It is not, however, permanently fixed, but it can detach itself and change its place at will.

At the opposite or distal extremity of the body is placed the aperture of the mouth, surrounded by a circle of from five to fifteen small tubular filaments, which are termed the "tentacles" (fig. 30, *a*). Each tentacle consists of a tubular prolongation of both ectoderm and endoderm, and encloses a canal which opens at its base into the general cavity of the body. The ectoderm is richly furnished with thread-cells, which are especially abundant in the tentacles. On the inside of the ectoderm, between it and the endoderm, exists also a peculiar fibrous layer, which has been generally regarded as partly of a nervous and partly of a muscular character. The tentacles exhibit the most extraordinary contractility, being capable of retraction till they appear as nothing more than so many little warts or tubercles, and of being extended to a length which is in some species many times longer than the body itself. They are the organs by means of which the *Hydra* obtains its food, consisting chiefly of minute aquatic organisms, such as small worms, insects, *Crustacea* and *Rotifera*. These are seized by the tentacles and gradually drawn into the mouth; but in

Fig. 30.—The Green Fresh-water Polype (*Hydra viridis*), suspended head-downwards from a piece of a stem of an aquatic plant, enlarged. *a* One of the tentacles; *b* Testis or spermatarium, with spermatozoa in its interior; *c* A single large ovum, protruding from the side of the body; *d* Disc of attachment ("hydrorhiza").

The tentacles exhibit the most extraordinary contractility, being capable of retraction till they appear as nothing more than so many little warts or tubercles, and of being extended to a length which is in some species many times longer than the body itself. They are the organs by means of which the *Hydra* obtains its food, consisting chiefly of minute aquatic organisms, such as small worms, insects, *Crustacea* and *Rotifera*. These are seized by the tentacles and gradually drawn into the mouth; but in

addition to this merely mechanical action, the tentacles appear to exercise a benumbing or even fatal influence upon the animals grasped by them—this being apparently due to the thread-cells with which they are furnished. The mouth in the *Hydra* opens directly into a capacious cylindrical cavity, which is excavated along the whole length of the body, and which is both the body-cavity and the stomach in one. This cavity (fig. 28) is filled with water derived from the exterior, and also with the nutritive particles derived from the food. Indigestible fragments are rejected by the mouth, a separate anal opening being wanting. A striking proof of the essentially low position of the *Hydra* in the animal scale is to be found in its extraordinary capacity of resisting mutilation, or, in fact, mechanical injury of any kind short of absolute annihilation. The briefest illustration of this fact is all that can here be given, but with that the name of Trembley of Geneva must be associated. This well-known observer, in a long series of experiments, most of which have been successfully repeated by subsequent naturalists, discovered that the *Hydra* could be mechanically divided with a knife into any number of fragments, with the sole result that each and all of these possessed the power of developing themselves into fresh and independent polypites. Further, the animal could even be turned inside out, with a necessary transposition of the ectoderm and endoderm, without any apparent inconvenience or interference with its health.

Reproduction in the *Hydra* is effected non-sexually by gemmation, and sexually by the production of ova and sperm-cells; the former process being followed in summer and the latter in autumn, few individuals appearing to survive the winter. In the first or non-sexual method, the *Hydra* throws out one or more buds, usually from near the fixed or proximal extremity. These buds at first consist simply of a tubular prolongation of the ectoderm and endoderm, enclosing a cavity which communicates with the general cavity of the body. A new mouth and tentacles are soon developed at the distal end of this bud, and after a longer or shorter period the new *Hydra*, thus produced, is detached to lead an independent life. Each *Hydra* can produce many such buds during the summer season, and the liberated buds can also repeat the same process, so that in this way reproduction is rapidly carried on. In the second or sexual method of reproduction, ova and sperm-cells are produced towards the winter in external processes of the body-wall. The spermatozoa are developed in little conical elevations (fig. 30, *b*), which are produced near the bases of the tentacles; and the ova are formed in much larger elevations, of which there is ordinarily but one, placed nearer to the fixed or proximal extremity of the animal (fig. 30, *c*). When mature, the ovum is fertilised by the sperm-cells, both being set free into the water by the rupture of the body-wall. The embryo *Hydra* is at first covered with vibrating cilia, and swims freely about, until it meets with a suitable locality. It then fixes itself by one extremity, the cilia drop off, and a mouth and tentacles are developed at the distal end of the body.

ORDER II. CORYNIDA.

In the second order of the Hydroid Zoophytes, known as the *Corynida* or *Tubularida*, we have a number of organisms which in their essential structure are closely related to the *Hydra*, but which differ considerably in the nature of the reproductive process. All of them are marine, with the single exception of the genus *Cordylophora*, which inhabits fresh water. Some of the members of the order are simple, consisting of no more than a single polypite. In these cases there is an exceedingly close approach to the structure of the common *Hydra*, but the polypite is permanently fixed without the power of voluntarily changing its place, whilst the reproductive process is considerably different. In the majority of the *Corynida*, however, the hydrosoma is compound, consisting of a greater or less number of separate polypites or zooids, all connected with one another by a common flesh or cœnosarc, and all forming parts of a plant-like rooted colony. In some of the *Corynida* the polypites are naked, but in most cases the cœnosarc is protected by a horny-looking chitinous¹ envelope or "polypary," as in *Tubularia indivisa* (fig. 31). In no case, however, is this horny covering so prolonged as to form little cups in which each polypite is contained. It always stops short at the bases of the polypites, and in this way the *Corynida* can always be distinguished from their near allies, the Sea-firs (*Sertularida*).

Good examples of the *Corynida* are the common Pipe-corallines (*Tubularia*), in which the cœnosarc is enclosed in a horny tubular polypary (fig. 31), each tube containing a single polypite. Other

Fig. 31.—Fragment of *Tubularia indivisa*, natural size.

¹ *Chitine* is a substance which is nearly allied to horn, but is distinguished from it by the fact that it is not soluble in caustic potash.

common examples are the singular *Hydractinice*, which form brown prickly crusts upon the empty shells of univalve Molluscs, invariably selecting those shells which are inhabited by Hermit-crabs. Other common types belong to *Eudendrium*. The genus *Cordylophora* is found in fresh water; and in *Coryomorpha* we have a type in which the hydrosoma consists of no more than a single polypite.

As regards the generative process in the *Corynida*, it may be as well to consider the general phenomena of reproduction as carried on by all the Hydroid Zoophytes, the general characters of the process being of a most remarkable nature. As has been already explained, the "individual" in the case of the compound *Hydrozoa* consists of an aggregation or colony of partially independent beings or zooids, produced by gemmation or fission from a primordial organism. This is the case in all composite animals, such as Sponges, Sea-mats, Corals, and many others. In many of the compound *Hydrozoa*, however, the case becomes still further complicated. In many of these organisms, namely, the zooids differ very much from one another both in structure and in function. One set of zooids is entirely devoted to the duty of providing food for the colony, and in these no reproductive organs are ever developed. These nutritive zooids are all like each other in form, and the whole assemblage of them has been appropriately termed the "trophosome" (Allman), from the Greek *trephe*, I nourish; and *soma*, body. The colony or trophosome thus formed by the nutritive zooids can go on increasing by the production of fresh zooids for an almost indefinite period; but in all cases there ultimately comes a time when it becomes necessary to produce the essential elements of reproduction in order to secure the perpetuation of the species. The nutritive zooids, as just stated, cannot produce the ova and sperm-cells, being destitute of reproductive organs, and the colony is therefore compelled to produce a second set of buds, which have the power of producing the essential elements of reproduction. These buds are collectively called the "gonosome" (Gr. *gonos*, offspring; and *soma*, body). The generative buds have the further peculiarity that not only can they produce the generative elements, but they are altogether unlike the nutritive zooids in appearance. This difference in external appearance and in structure is sometimes so great as to lead to a most remarkable series of phenomena. In the simplest form in which these generative buds or "gonophores" appear, they have the form of mere protuberances of the ectoderm and endoderm (fig. 32), enclosing a cavity derived from the body-cavity. In these buds the generative elements—ova and spermatozoa—are developed. In other instances, the generative buds have a more complicated structure. They consist now (fig. 29 m') of a

bell-shaped disc, which is attached by its base to the parent organism, and has its cavity turned outwards. From the roof of this disc there is suspended a kind of handle, which corresponds to the clapper of the bell, and is termed the "manubrium" (Lat. for handle). From the fixed or proximal extremity of the central process or manubrium proceed four or eight canals, which extend to the margin of the bell, where they all open into a circular canal

Fig. 32.—Group of zooids of *Hydraetia echinata*. Enlarged (after Hincks). *a a* Nutritive zooids; *b b* Generative zooids, carrying sacs filled with ova ("sporosacs").

surrounding the mouth of the bell. This bell-shaped reproductive bud may attain no higher development than this, and may remain permanently attached to the parent organism from which it is produced. In other cases, however, a higher state of development is reached. The generative bud or gonophore (fig. 29, C) becomes detached from its parent colony; the manubrium or central process develops a mouth at its free or distal extremity; the mouth of the

bell becomes partially closed by an inward prolongation or shelf, called the "veil"; and a series of tentacles are developed from its margin. The generative bud, thus liberated, leads a wholly independent existence. The manubrium, having developed a mouth, assumes the functions of a true polypite, and its cavity acts as a digestive sac. The whole organism swims about freely, and has the power of assimilating food, and thus of attaining to a comparatively gigantic size. This independent existence, however, only goes on till such time as the elements of reproduction can be produced. The ova and sperm-cells are developed in specialised portions of this generative bud, and then it ceases to exist. The ova, however, when fertilised, do not develop themselves into the free-swimming bell-shaped organisms in which they were actually produced, but

Fig. 33.—Free-swimming medusiform gonophore of *Bougainvillea superciliaris*, a fixed Hydroid. Enlarged (after A. Agassiz).

into the plant-like, rooted, and compound zoophyte, from which the generative buds were originally given forth. These free-swimming bell-shaped reproductive buds or gonophores (fig. 33), as we shall see, are structurally identical with the smaller forms of the so-called Sea-jellies or *Medusæ*; and it is now known that most of these *Medusæ*, though originally described as distinct beings, are really nothing more than the free generative buds of the fixed *Hydrozoa*. Hence, these free reproductive buds are usually spoken of as "medusiform gonophores." We have here, then, an instance of what has been, not quite appropriately, called "alternation of generations."

We have a compound fixed animal, in many respects comparable to a plant, producing a special series of buds which are devoted to the process of reproduction. These buds are cast off as independent beings to lead an independent life, and they are furnished with the necessary organs to preserve their existence till they are able to mature the reproductive elements. When once able to consummate this, they die; but the young to which they give origin are wholly unlike themselves. The young, namely, instead of being free-swimming "medusiform" beings, become developed into the fixed plant-like colony from which the generative buds were originally produced. The term "alternation of generations" is not an altogether good one, and does not quite express the facts of the case. There is not any alternation of generations, but there is an alternation of generation with gemmation or budding. The only true generative act takes place in the reproductive zoöid or gonophore, in which the ova and sperm-cells are developed. The production of this gonophore from the parent organism (trophosome) is a process, not of generation, but of gemmation or budding. The whole process, therefore, is, properly speaking, not an "alternation of generations," but an alternation of generation with gemmation.

To recapitulate, then,—the process of reproduction in the Hydroid Zoophytes is carried on by means of reproductive buds or gonophores, which are produced at special seasons, and in which the reproductive elements are developed. These generative buds differ a good deal in their character, but three chief kinds may be distinguished: 1. Simple closed sacs or protuberances ("sporosacs") formed out of both ectoderm and endoderm, and having the special elements of generation developed in their interior. 2. Bell-shaped buds attached to the parent colony by their bases, and having a central process or manubrium, which is furnished with a mouth and central cavity, from which there is given off a system of canals to ramify in the substance of the disc. The reproductive elements are developed either in the walls of these canals or between the ectoderm and endoderm of the manubrium. From the resemblance of these buds in anatomical structure to the so-called Sea-jellies or *Medusæ*, they are usually spoken of as "medusiform gonophores," or simply as "medusoids." In this form, however, though highly organised, the buds never become detached from the parent colony. 3. Buds which become developed into bell-shaped medusiform bodies exactly similar in structure to the last, but detached to lead an independent existence. These free-swimming medusiform gonophores are anatomically indistinguishable from ordinary *Medusæ*; and it is now known that most of the so-called "naked-eyed" *Medusæ*, are really the detached generative buds of other orders of

Hydrozoa. The special elements of reproduction are developed in these detached buds, but the resulting embryos are not developed into *Medusæ*, such as produce the ova and sperm-cells, but straight-way grow up into the plant-like sexless colony, from which the medusiform gonophores were originally budded forth. In these cases, therefore, the *individual* Hydroid consists of a fixed, rooted colony (or trophosome), producing fresh zooids by a process of budding, but incapable of producing the essential elements of reproduction, together with a free and independent series of generative buds (or gonosome), in which the elements of reproduction are developed.

ORDER III. SERTULARIDA.

In this order of the *Hydroida* we have the most familiar and best known of all our zoophytes—namely, the Sea-firs and their allies. The horny plant-like polyparies of the *Sertularida* are

Fig 34.—*a* *Sertularia* (*Euphasia*) *pinnata*, natural size; *a'* Fragment of the same enlarged, carrying a male capsule (*o*), and showing the hydrothecæ (*h*); *b* Fragment of *Campanularia neglecta* (after Hincks), showing the polypites contained in their hydrothecæ (*h*), and also the point at which the coenosarc communicates with the stomach of the polypite (*c*).

familiar to every visitor at the sea-side, and by those unacquainted with their true nature they are almost universally set down as seaweeds. The *Sertularida* are very closely allied to the compound forms of the *Corynida*, resembling them in being rooted, plant-like colonies, composed of a number of similar polypites or zooids, produced by budding from a primitive zooid. As in the Tubularians

amongst the *Corynida*, the whole cœnosarc is enveloped in a horny or chitinous envelope or polypary (fig. 34, *a*), and this is the structure which is most familiarly known to sea-side observers. The *Sertularida*, however, are distinguished from the *Corynida* by two points. Firstly, none of the *Sertularida* are simple, but all are compound, consisting of more or less numerous polypites, united by a branched cœnosarc. Secondly, the polypary of the *Sertularida* differs from that of the *Corynida* in not simply reaching to the bases of the polypites, but in being prolonged to form a number of little cups or "hydrothecæ" (fig. 34, *a, b*) within which the polypites are lodged. Each polypite has a hydrotheca of its own, within which it can entirely withdraw, and from which it can protrude its distal extremity.

The polypites of the *Sertularida* have essentially the same structure as in the *Corynida*, and each may be compared to a little *Hydra*. Each, namely, consists of a soft contractile and extensile body, which is furnished at its distal extremity with a mouth and a circlet of prehensile tentacles, richly furnished with thread-cells. The mouth opens into a chamber which occupies the whole length of the polypite, and which is to be regarded as the combined body-cavity and digestive sac. At its lower end this chamber opens by a constricted aperture into a tubular cavity, which is everywhere excavated in the substance of the cœnosarc (fig. 34, *b*). The nutrient particles obtained by each polypite thus serve for the support of the entire colony, and are distributed throughout the entire organism. The nutritive fluid prepared in the interior of each polypite gains access through the above-mentioned aperture to the cavity of the cœnosarc, which, by the combined exertions of the whole assemblage of polypites, thus become filled with a granular nutritive liquid. This cœnosarcial fluid is in constant movement, circulating through all parts of the colony, and thus maintaining its vitality—the cause of the movement being probably due, in part, at any rate, to the existence of vibrating cilia.

The process of reproduction varies somewhat in different members of the order. In all alike, however, the ordinary polypites are incapable of producing the essential elements of reproduction, and for this purpose special generative buds have to be developed. In the typical Sertularians the reproductive buds are developed at certain seasons in great numbers, and they constitute what used to be called the "ovarian vesicles" or "capsules" (fig. 35). These reproductive buds are enclosed in horny cups or receptacles, often of a very beautiful shape, and much larger in size

Fig. 35.—Ovarian capsule of *Diphasia* (*Sertularia*) *operculata*, Linn. (after Hincks). Greatly enlarged.

than the ordinary hydrothecæ. As a general rule, each capsule in the *Sertularida* contains a number of the reproductive buds, which are all borne upon a central axis which runs up the middle of the capsule, and is derived from the cœnosarc.

In one division of this group—often described as a separate order, under the name of *Campanularida*—some points of difference are observable. In the typical Sertularians the little cups or hydrothecæ for the polypites are placed on the sides of the branches, and they are not stalked (fig. 34, *a'*), whilst the reproductive elements are produced in fixed buds. In the *Campanularida*, on the other hand (fig. 34, *b*), the hydrothecæ are supported upon stalks, and are placed at the ends of the branches, whilst the generative buds are usually detached to lead an independent existence. In these forms the reproductive zooids or gonophores start as simple buds; but they become gradually developed into free-swimming medusoids, such as have been before alluded to. Each medusoid consists of a little

Fig. 35.—Gonophore of one of the *Campanularida*.

transparent glassy bell, from the under surface of which there is suspended a modified polypite, in the form of a manubrium (fig. 36, *a*). The whole organism swims gaily through the water, propelled by the contractions of the bell or disc; and no one would suspect now that it was in any way related to the fixed plant-like zoophyte from which it was originally budded off. The central polypite is furnished with a mouth at its distal end, and the mouth opens into a digestive sac. From the proximal end of this stomach proceed four radiating canals which extend to the margins of the bell, where they all open into a circular vessel which runs round the mouth of the bell. From the circumference of the bell hang also a number of delicate extensile filaments or tentacles; and the margin is further adorned with a series of brightly coloured spots, which are probably rudimentary organs of vision and hearing. The mouth of

the bell is partially closed by a delicate transparent membrane or shelf, the so-called "veil." Thus constituted, these beautiful little beings lead an independent and locomotive existence for a longer or shorter period. Ultimately, ova and sperm-cells are produced in

special organs, which are developed in the course of the radiating canals of the disc. The resulting embryos are minute free-swimming bodies, covered with cilia, which finally fix themselves, and develop into the plant-like colonies from which the medusoids were derived.

ORDER IV. MEDUSIDÆ.

Among the most familiar and beautiful of all marine organisms are the delicate, transparent, bell-shaped creatures generally known as Jelly-fishes. All the organisms, which are generally spoken of as Jelly-fishes, belong to the *Hydrozoa*, but they differ greatly as to their precise nature. The great gelatinous discs which are so frequently cast up on the sea-shore, and which are more especially spoken of in common language as "Jelly-fishes," are mostly the reproductive zooids of a particular group of *Hydrozoa* (the *Lucernarida*), and will be subsequently noticed. Less familiar than these, but equally abundant, are certain, usually much smaller, Jelly-fishes which are found floating in the sea near the surface, often in vast numbers, at particular seasons of the year. Many of

Fig. 37.—*a* A medusiform gonophore (*Thaumantias*) seen in profile, showing the central polypite, the radiating and circular canals of the disc, the reproductive organs borne in the course of the former, the marginal bodies and tentacles; *b* The same, viewed from below. The dotted line indicates the margin of the "veil."

these comparatively minute Jelly-fishes are in reality, as previously noted, neither more nor less than the free-swimming reproductive buds of the Hydroid Zoophytes, or of other groups of *Hydrozoa*. That this is their true nature is shown by the fact that the eggs which they produce develop themselves not into fresh *Meduse*, but into various other forms of *Hydrozoa*, which may be either fixed or oceanic. On the other hand, there are certain Jelly-fishes (*Trachynemidæ*, *Æginidæ*, &c.) the eggs of which really give origin to fresh Jelly-fishes. These, therefore, must be considered as a special group of the *Hydrozoa*, to which the name of *Medusidæ* may be applied.

As regards the *structure* of such *Medusæ*, there is nothing to enable the observer to know for certain whether a given Jelly-fish is merely the free generative bud of some fixed Hydroid, or whether it is an independent organism. In either case, the anatomical structure is essentially the same, and may be briefly stated as follows: The hydrosoma is free and oceanic, the organism living near the surface of the sea. The body is composed of a thick, transparent, gelatinous disc or swimming-bell (the nectocalyx) by the pulsations of which the animal is driven through the water. From the under surface or roof of this bell-shaped disc is suspended

Fig. 38.—*Trachynema digitale*, a naked-eyed Medusa, female, enlarged. (After A. Agassiz.) *p* Manubrium or central polypite; *t* One of the tentacles; *c* One of the gastro-vascular canals; *o* One of the ovaries.

a single polypite (the manubrium), which bears to the disc the same relative position as the clapper does to an ordinary hand-bell. The distal end of the central polypite (fig. 38) is furnished with a mouth, the lips of which are often prolonged into four longer or shorter lobes or processes. The mouth opens into a digestive sac, occupying the axis of the polypite; and from the upper end of this proceed four radiating canals, which run in the substance of the disc to its margin, where they are united by a single circular vessel,

the whole system constituting the so-called "gastro-vascular" or "nectocalycine" canals. The margin of the bell is narrowed by a kind of shelf, which runs round the whole circumference, leaving a central aperture, and which is known as the "veil." From the margin of the disc hang more or less numerous tentacles, which in these forms are mostly solid, instead of being hollow. Also round the circumference of the swimming-bell are disposed certain "marginal bodies," which are doubtless organs of sense. Some of these marginal bodies consist of little rounded sacs or "vesicles," filled with a transparent fluid, and containing mineral particles, apparently of carbonate of lime. These are probably rudimentary organs of hearing. Others of the marginal bodies are in the form of little masses of colouring-matter or pigment, often of a strikingly bright colour, enclosed in distinct cavities. These are known as the "pigment-spots" or "eye-specks," and they are of the nature of rudimentary organs of vision. They are placed in a conspicuous and unprotected position on the margin of the disc, and hence these organisms were termed "naked-eyed" *Medusæ* by Edward Forbes. Round the margin of the swimming-disc there is also placed a distinct nerve-ring. The reproductive organs (fig. 38) are usually developed in the course of the radiating gastro-vascular canals, but are sometimes situated in the walls of the central polypite.

The naked-eyed *Medusæ*, including under this name both the true *Medusæ* and the free medusoid buds of other *Hydrozoa*, are all exceedingly elegant and attractive, when examined in a living condition, resembling little bells of the most transparent glass, adorned here and there with the most brilliant colours. They occur, in their proper localities and at proper seasons, in enormous numbers. They are mostly phosphorescent, or capable of giving out light at night, and they appear to be one of the principal sources of the luminosity of the sea. It does not seem, however, that they phosphoresce unless disturbed or irritated in some way.

Most *Medusæ* and medusoid gonophores are of comparatively small size, but some types of the latter may grow to a diameter of eight or ten inches or more (*e.g.*, *Æquorea*). A single Medusoid (*Limnocodium*) has been found inhabiting fresh water; but this is known to be the generative bud of a fixed Hydroid.

CHAPTER VII.

SUB-CLASS SIPHONOPHORA.

THE animals included under the name of *Siphonophora* are often known as the "Oceanic Hydrozoa," as they are not fixed like the Hydroid Zoophytes, but are found swimming at the surface of the open ocean, far from land. They are all singularly delicate and beautiful organisms, but they require little notice here. They are distinguished from the Hydroid Zoophytes, which we have been just considering, by the fact that the hydrosoma consists of numerous polypites, united by a common trunk or *cœnosarc*, which is very rarely branched, and is never furnished with any hard outer covering or polypary, so that it remains permanently soft and flexible throughout life. The proximal end of the *cœnosarc*, as already remarked, is not fixed, or capable of being fixed, to any solid object, but is variously modified to suit the requirements of the floating colony. As in the *Hydroida*, the reproductive organs are in the form of special buds, which have the power of developing the essential elements of generation, and which are often detached as free-swimming medusoids.

The entire sub-class is divided into two great groups or orders, and it will be sufficient to consider shortly a typical form of each. In the first order—that of the *Calycephoride*—the *cœnosarc* is thread-like, cylindrical, unbranched, and highly contractile. The cavity of the *cœnosarc* dilates proximally into a peculiar ciliated chamber, which is the distinguishing character of the order. The name of *Calycephoride* (Gr. *kalyx*, a cup; and *phero*, I bear), is, however, derived from another circumstance—namely, that the proximal end of the *cœnosarc* is always furnished with a series of bell-shaped discs, which are known as "swimming-bells" or "nectocalyces." Each nectocalyx consists of a bell-shaped cup (fig. 39, *n*), attached by its base to the *cœnosarc*, and having its cavity turned outwards. In the substance of the disc run at least four canals, which communicate with the cavity of the *cœnosarc*, and proceed to the margin of the bell, where they all open into a circular vessel. The mouth of

the bell is also furnished with a delicate ledge, which runs round its circumference, and is known as the "veil." The structure, therefore, of the nectocalyces, is very similar to that of an ordinary medusiform gonophore, the chief difference being the absence in the former of the central polypite or manubrium. The nectocalyces are highly muscular, and have the power of alternately contracting and dilating, thus driving the whole organism through the water. In *Praya* (fig. 39), which may be taken as a good example of the group, the

Fig. 39.—*Siphonophoridae*. A, Upper portion of the colony of *Praya maxima*, of the natural size: *n* The proximal nectocalyces; *n'n'* Mouths of the same; *c* Cœnosarc, carrying polypites (*p p*) at intervals, along with their swimming-bells (*s s*) the openings of these being indicated by the letters *m m*; *t* Tentacles. B, A single polypite of the same (*p*), separated from the cœnosarc, and enlarged, with its swimming-bell (*s*), the opening of the bell (*m*), and the tentacles (*t*). (After Gegenbaur.)

nectocalyces (*n*) are succeeded by a series of polypites. Each polypite (*p*) is furnished with a mouth, opening into a digestive sac, which in turn communicates with the cavity of the cœnosarc. In this form each polypite has a little swimming-bell of its own; but in many forms each is protected by an over-arching plate, termed a "bract." Each polypite has in general a single tentacle, rising from near its base, usually of great length, and provided with lateral branches armed with numerous thread-cells. The reproductive organs

of the *Calycophoridae* are in the form of medusiform gonophores, which are budded from the stalks of the polypites, and which are mostly detached to lead an independent existence.

The second order of the Oceanic Hydrozoa is that of the *Physophoridae* (Gr. *physa*, a bladder; and *phero*, I carry), of which the most familiar, though not the most typical, example is the Portuguese Man-of-war, *Physalia* (fig. 40, *a*). The *Physophoridae* are distinguished from the organisms which we have been just considering by the fact that the proximal extremity of the coenosarc is devel-

Fig. 40.—*a* Portuguese Man-of-war (*Physalia*).
b *Veella vulgaris*.

oped into a structure which is known as the “float” or “pneumatophore.” The float contains a larger or smaller sac, composed of some elastic horny substance, probably chitine, often communicating with the exterior by one or more apertures, and always more or less completely filled with air. The function of the float is no doubt that of enabling the organism to maintain its position at the surface of the sea. As in the *Calycophoridae*, the coenosarc is always perfectly flexible, contractile, and soft, and is never furnished with any

chitinous covering or polypary. There may or may not be swimming-bells or nectocalyces, and the tentacles are very complicated in structure, and often attain a great length. The polypites present no special points of interest, but are often furnished with the protective plates which have been already spoken of as "bracts."

As a good example of the *Physophoridae*, the Portuguese Man-of-war may be taken (fig. 40, *a*). It is composed of a large spindle-shaped float, often of several inches in length, upon the under surface of which are arranged a number of polypites, together with highly contractile tentacles of great length, and reproductive organs. The tentacles are richly furnished with thread-cells; and it has the power of stinging very severely. *Physalia* is commonly found floating at the surface of tropical and sub-tropical seas.

Another very beautiful member of the *Physophoridae* is the *Velella vulgaris*, which occurs abundantly in many seas. It is about two inches in length by one and a half in height. The proximal end of the coenosarc is greatly expanded and flattened out into an oval disc, which carries a vertical triangular crest, running obliquely across its upper surface (fig. 40, *b*). The whole organism is semi-transparent and of a beautiful bluish colour, and it floats at the surface of the sea with the vertical crest exposed to the influence of the wind, and thus officiating as a sail. From the under surface of the disc are suspended the various appendages of the organism, consisting of a single large central polypite; a number of processes, like polypites in shape, and carrying medusiform gonophores; and lastly, a single series of tentacles which arise from the coenosarc quite independently of the polypites.

CHAPTER VIII.

SUB-CLASSES LUCERNARIDA, GRAPTOLITIDÆ,
AND HYDROCORALLINÆ.

SUB-CLASS LUCERNARIDA.

THE next group of the living *Hydrozoa* is that of the *Lucernarida*, under which name are included a considerable number of forms, differing from one another to a great extent in external appearance. It will be sufficient here to describe one or two typical forms.

Fig. 41. — Two specimens of *Lucernaria auricula* attached to a piece of sea weed (after Johnston).

One group of the *Lucernarida* is represented by *Lucernaria* itself (fig. 41), in which there is a cup-shaped body of a more or less gelatinous consistence, usually attached by its smaller extremity to sea-weeds, this end of the body being developed into a small sucker. Like the *Hydra*, however, *Lucernaria* is not fixed, but can detach itself at will, and can even swim freely by means of the alternate contraction and expansion of the cup-shaped body (or "umbrella," as it is termed). Round the margin of the cup are tufts of short tentacular processes, and in its centre is fixed a single polypite, furnished with a four-lobed mouth. The essential elements of reproduction are developed within the body of *Lucernaria* itself, and it does not give off any generative buds, as so commonly occurs in other forms.

Another type of the *Lucernarida* is represented by the organisms formerly termed "hidden-eyed" *Medusæ*, and familiarly known as

Sea-nettles or Sea-blubbers. Every sea-side visitor is familiar with the great circular discs of jelly which are left upon the sands by the retreating tide during the summer months; and many must have noticed on a calm day the large transparent discs of these same creatures slowly flapping their way through the water. Not a few, too, must have learnt by painful experience that some of these singular organisms have the power of stinging most severely, if incautiously handled. The forms included under the old name of "covered-eyed" *Medusæ* differ considerably from one another in their nature, and even in their structure, though they all present, in spite of their usually greater size, a decided resemblance to the naked-

Fig. 42.—Development of *Aurelia*, one of the *Lucernarida*. *a* Ciliated free-swimming embryo, or "planula"; *b* Hydra-tuba; *c* Hydra-tuba in which fission has considerably advanced; *d* Hydra-tuba in which the fission has proceeded still further, and a large number of the segments have been already detached to lead an independent existence.

eyed *Medusæ* already described. Some of the covered-eyed *Medusæ* produce eggs which are developed into organisms resembling themselves; but most of them are now known to be nothing more than the free-swimming reproductive buds of minute rooted *Hydrozoa*. It will be sufficient here to describe shortly the life-history of one of the more remarkable forms of this section.

If we commence with the young form of one of these singular animals, we find that the egg gives origin to a little microscopic ciliated body, which swims about freely by means of the cilia with which its surface is covered (fig. 42, *a*). This little body, on finding a suitable locality, fixes itself by one end, and develops a mouth and tentacles at the other, when it is known as a "Hydra-tuba" (fig. 42,

b), from its resemblance in shape to the Fresh-water Polype or *Hydra*. The Hydra-tuba is only about half an inch in height, and it possesses the power of forming large colonies by gemmation, whilst it is incapable of developing the essential elements of reproduction. Under certain circumstances, however, reproductive zooids are produced by the following singular process: The Hydra-tuba becomes elongated and exhibits a number of transverse grooves. These grooves go on getting deeper and deeper, and become lobed at their margins, till the whole organism assumes the aspect of a pile of saucers placed one above the other (fig. 42, c). The tentacles now disappear, and a fresh circle is formed close to the base of the Hydra-tuba. Finally, all the saucer-like segments above the new circle of tentacles (fig. 42, d) drop off, one by one, and present themselves in the form of independent free-swimming *Medusæ*. These reproductive zooids or *Medusæ* eat voraciously, and increase rapidly in size, becoming not only comparatively, but often actually, gigantic. Thus, in one case the reproductive zooid has been known to attain a size of seven feet across, with tentacles one hundred feet or more in length, though the fixed organism from which it was produced was no more than half an inch in height. These gigantic reproductive bodies live an independent life until they are able to produce ova and sperm-cells, when they die. The fertilised egg, however, develops itself, not into the monstrous organism by which it was produced, but into the little fixed sexless Hydra-tuba, from which the generative bud was detached. We have, then, here another instance of the so-called "alternation of generations."

It is now known, then, that most of the great Sea-blubbers which abound around most coasts in summer are really the detached reproductive buds of minute fixed *Hydrozoa*; and it may be as well to mention the leading features in their structure, and the points by which they may be distinguished from the smaller or naked-eyed *Medusæ*, to which they have a decided superficial likeness. In the commonest forms of these zooids (such as the common Sea-blubbers *Aurelia* and *Gyanea*), the body consists of a great bell-shaped gelatinous disc or "umbrella" (fig. 43), from the roof of which is suspended a single polypite, the lips of which are extended into lobed processes,* often extending far below the margin of the disc. The digestive cavity of the polypite gives out from its upper extremity a series of radiating gastro-vascular canals, which proceed towards the margin of the umbrella. These radiating canals are never less than eight in number, and on their way to the margin of the disc they break up into a great number of smaller vessels, which unite with one another to form a complicated network. At the margin of the bell they all open into a circular vessel, which in turn sends processes into a

series of marginal tentacles, which are often of extraordinary length. Besides the tentacles, the margin of the umbrella is provided with a number of marginal bodies, each of which consists of a little collection of pigment, or "eye-speck," and a little sac filled with fluid and containing mineral particles. Each of these marginal bodies is covered and concealed from view by a kind of hood derived from the ectoderm. Hence the name of "hidden-eyed" *Medusæ*, applied

Fig. 43. — Generative zoöid of one of the *Lucernarida* (*Chrysaora hyrcella*).
(After Gosse.)

to these forms, in contradistinction to the "naked-eyed" *Medusæ*, in which the eye-specks are exposed to view. There is also a well-developed nerve-ring running round the mouth of the umbrella. The reproductive organs are usually of some bright colour, and "form a conspicuous cross shining through the thickness of the disc."

From the above description it will be evident that there is a considerable resemblance between the so-called "hidden-eyed" *Medusæ*, or the reproductive zoöids of many of the *Lucernarida*, and the medusiform gonophores of so many of the *Hydrozoa*, as well as the true *Medusidæ* or naked-eyed *Medusæ*. The differences, however, between them are these: The swimming-disc of the naked-eyed *Medusæ* and of any medusiform gonophore is furnished at its mouth with an internal shelf or veil; the radiating gastro-vascular canals are very rarely more than four in number, and should they subdivide (as in rare cases

they do), they do not form an intricate network; lastly, the marginal bodies are simply placed in an uncovered situation on the margin of the disc. In the reproductive zooids of the *Lucernarida* or hidden-eyed *Meduse*, on the other hand, the swimming-disc or umbrella is destitute of any marginal shelf or veil; the radiating gastro-vascular canals are never less than eight in number, and they split up into numerous branches, which unite to form an intricate network; lastly, the marginal bodies are concealed from view by a kind of hood.

There still remains another family of the *Lucernarida* (viz., *Rhizostomidae*) in which the reproductive process is carried on in the same way as in the forms we have just described, but the structure of the reproductive zooids is somewhat different. In these, as in *Rhizostoma* (fig. 44), the generative zooid is much like those just men-

Fig. 44.—Generative zooid of *Rhizostoma pulmo*, reduced in size. (After Gosse.)

tioned; but the umbrella is destitute of marginal tentacles; and in place of a single central polypite, there hangs from the under surface of the umbrella a complex tree-like mass, the branches of which end in, and are covered by, small polypites and club-shaped tentacles. The umbrella itself does not exhibit any difference as compared with those already described, but the ova are produced in a genital cavity which is placed on the under surface of the umbrella.

SUB-CLASS GRAPTOLITIDÆ.

We may here notice very briefly a group of extinct organisms which almost certainly belong to this class, and which probably find their nearest allies in the *Sertularians*. The *Graptolitidæ* are without a single living representative, and their antiquity is, indeed, very high, since it is doubtful if they ever pass above the group of rocks known to geologists as the Silurian formation. The most typical forms of the group (fig. 45) agree with the living *Sertularians* in having a horny polypary, and in having the polypites protected by little horny cups or hydrothecæ, all springing from a common stem or coenosarc. The typical *Graptolites*, however, differ from all known *Sertularians* in the fact that the hydrosoma was not fixed to any solid object, but was permanently free. Most of them, also, exhibit a very anomalous and remarkable structure, termed the "solid axis" (fig. 45, B). This is a peculiar, fibrous, apparently

hollow rod, which no doubt served to strengthen the polypary, and which is often prolonged beyond one or both ends of the polypary in a naked state. There is also good evidence that the reproductive process in the Graptolites was carried on in manner somewhat similar to what is seen in the living Sertularians—namely, by means of reproductive buds enclosed in horny capsules. Graptolites most usually present themselves as beautiful silvery impressions, covering the surface of the black shales of various parts of the Silurian system.

SUB-CLASS HYDROCORALLINÆ.

This name has recently been proposed by Professor Moseley for two groups of marine animals which produce a regular skeleton of carbonate of lime, and which have, therefore, been generally placed among the true Corals. Professor Moseley, however, has shown that the forms in question are really referable to the *Hydrozoa*, though they are peculiar, as regards the members of this class, in their power of secreting a regular calcareous skeleton. The best known and most familiar of the animals placed in this group are the Millepores (*Millepora*), the stony skeletons of which contribute so largely to the formation of coral-reefs in the West Indies and Pacific. The skeleton of *Millepora* is an expanded, more or less branched, calcareous mass, studded with minute apertures of two sizes, the mouths of differently-sized tubes. These tubes are divided into chambers by a number of complete transverse partitions (the so-called “tabulæ”), and only the surface-layer of the mass is to be regarded as actually alive. The general calcareous tissue of the skeleton is open and spongy, and allows of a free communication between the different tubes. The larger tubes of the skeleton are occupied in the living condition by zoöids (“gastrozoöids”), which possess a mouth and tentacles, whilst the smaller tubes are tenanted by smaller zoöids (“dactylozoöids”), which possess

Fig. 45 —A, *Graptolites* (*Monograptus*) *priodon*, Bronn, preserved in relief: lateral view slightly enlarged. B, Dorsal view of a fragment of the same species: considerably enlarged. C, Front view of a fragment of the same, showing the mouths of the hydrothecæ: much enlarged. D, Transverse section of the same. All from the Silurian. (Original.)

the latter organs, but are destitute of a mouth. The body-cavities of all the zooids are placed in communication by means of canals which ramify in the spongy skeleton.

Fig. 46.—Enlarged view of a portion of the surface of a living colony of *Millepora nodosa*, showing the expanded zooids of a single system. *a*, Central “gastrozooid”; *b*, One of the mouthless “dactylozooids.” (After Moseley.)

Other living Hydrocorallines are the coral-like *Stylaster*, *Allopora*, &c. Closely allied to the recent types above mentioned is a great series of fossil and wholly extinct organisms, of which *Stromatopora* may be regarded as the central form.

CHAPTER IX.

ACTINOZOA.

THE second great class of the *Cœlenterata* is that of the *Actinozoa*, comprising the Sea-anemones and their allies, the Corals, the Seepens, the Sea-shrubs, and various other organisms. They are all defined as Cœlenterate animals in which there is a *distinct digestive sac which opens below into the general cavity of the body, but is nevertheless separated from the body-walls by an intervening space (the "perivisceral space"), which is divided into a number of vertical compartments by a series of partitions or "mesenteries," to the faces of which the reproductive organs are attached.* The *Actinozoa* (fig. 47), therefore, differ fundamentally from the *Hydrozoa* in this, that whereas in the latter the digestive cavity is identical with the body-cavity, in the former there is a distinct digestive sac, which opens, truly, into the body-cavity, but is nevertheless separated from it by an intervening perivisceral space. The result of this is, that whilst the body of a *Hydrozoön* exhibits on transverse section a single tube only, formed by the walls of the combined digestive and somatic cavity, the body of an *Actinozoön* exhibits *two* concentric tubes, one formed by the digestive sac and the other by the general walls of the body. Further, in the *Actinozoa* the reproductive organs are always internal, and are never in the form of external processes of the body-wall as in the *Hydrozoa*.

In their minute structure the tissues in the *Actinozoa* differ little from those of the *Hydrozoa*. The body is essentially composed of two fundamental layers—an ectoderm and endoderm; but there are often well-developed layers of muscular fibres, somewhat obscuring this simplicity of structure. Thread-cells are most commonly present in abundance. Cilia are very generally developed, especially in the endoderm lining the body-cavity, where they serve to maintain a circulation of the contained fluids. The only digestive apparatus consists of a tubular or sac-like stomach, which opens inferiorly directly into the body-cavity (fig. 47), and communicates with the outer world through the mouth. Definite nerve-centres do not

appear to be present, as a rule; but the mesoderm is usually provided with scattered nerve-cells. No definite organs of the circulation are developed. Distinct reproductive organs are always present, and true sexual reproduction occurs in all the members of the class. In a great many forms, however, of the *Actinozoa*, we have composite organisms or colonies, produced by a process of "continuous" gemmation or fission, the zoöids thus originated remaining attached to one another. In these cases—as in most of the Corals—the separate beings or zoöids thus produced are termed "polypes," the term "polypite" being restricted to the *Hydrozoa*. In the simple *Actinozoa*, however, such as the Sea-anemones, the term "polype" is

Fig. 47.—Diagrammatic vertical section of a Sea-Anemone. *a* Mouth; *s* Stomach; *b* Body-cavity; *c* *e* Convoluted cords ("craspeda") containing thread-cells, and forming the free edges of the mesentery (*m*); *t* *t* Tentacles; *o* Reproductive organ contained within the mesentery. The ectoderm (*e*) is indicated by the broad external line, the endoderm (*e'*) by the thin line and the space between that and the ectoderm.

applied to the entire organism, as consisting of no more than a single alimentary region. It follows from this, that the entire body, or "actinosoma," of any *Actinozoön*, may be composed either of a single polype, or of several such, produced by budding or cleavage, and united to one another by a common connecting structure or coenosarc. Most of the *Actinozoa* are permanently fixed, like most Corals; some, like the Sea-anemones, possess a limited amount of locomotive power; and one order, the *Ctenophora*, is composed of highly active free-swimming organisms. Some of them are unprovided with hard structures or supports of any kind, as the Sea-anemones and *Ctenophora*; but a great many secrete a calcareous or horny skeleton or framework which is known as the "coral" or "corallum."

The *Actinozoa* are divided into four orders—viz., the *Zoantharia*, the *Alcyonaria*, the *Rugosa*, and the *Ctenophora*.

ORDER I. ZOANTHARIA.

The *Zoantharia* comprise those *Actinozoa* in which the polypes are furnished with *smooth, simple, usually numerous tentacles*, which, like the mesenteries, are in multiples of six. The *Zoantharia* are divided into three groups, distinguished from one another by the presence or absence of a coral, and by its structure when present.

The first of these groups is termed *Zoantharia malacodermata*, or “soft-skinned” *Zoantharia*, because the polypes are either wholly destitute of a coral, or if there is one, it consists merely of little

Fig. 48.—*Actinia mesembryanthemum*, one of the Sea-Anemones.
(After Johnston.)

scattered spicules of carbonate of lime or grains of sand. Generally, too, the organism is simple, and consists of no more than a single polype. The best known of the members of this group are the beautiful Sea-anemones or “animal-flowers” (*Actinidæ*), which occur so plentifully on every coast (fig. 48). It will be as well to describe the structure of a sea-anemone somewhat in detail, as in this way a clear notion may be obtained of the general anatomy of the *Actinozoa*. The body of an ordinary sea-anemone (fig. 48) is a truncated cone or short cylinder, termed the “column,” and is of a soft leathery consistence. The two ends of the column are termed respectively the “base” and the “disc,” the former constituting a kind of sucker, by means of which the animal can attach itself at

will, whilst the mouth is placed in the centre of the latter. The mouth is surrounded by a flat space, destitute of appendages, and the circumference of the disc is in turn surrounded by numerous simple tubular tentacles, arranged in alternating rows. The tentacles consist of both ectoderm and endoderm, enclosing a tube which communicates with the body-cavity. By the muscular contraction of the walls of the column, the fluid contained in the body-chamber can be forced into the tentacles, which can be thus protruded to a great length, whilst they can also be usually retracted. In some cases the tentacles are furnished with perforations at their extremities. The mouth (fig. 47) leads directly into the stomach, which is a wide membranous tube, opening by a wide aperture into the body-cavity below, and extending about half-way between the mouth and the base. The wide space between the stomach and body-walls is subdivided into a number of separate compartments by radiating vertical plates, which are called the "mesenteries," and to the faces of which the reproductive organs are attached, in the form of reddish bands, containing either ova or sperm-cells. Below the stomach, the free edges of the mesenteries are thickened, and constitute twisted threads or cords, which are filled with thread-cells, and are termed "craspeda." The Sea-anemones are mostly to be found between tide-marks, in rock-pools, or on ledges of stone, adhering by means of the expanded base. They are not, however, permanently fixed, but can change their place at will. In the nearly allied *Ilyanthus* and *Arachnactis* and in some related forms the base is tapering, and it appears that the animal either lives freely in the sea, or buries itself to the lips in the sand. The true Sea-anemones, as already said, are all simple, each consisting of a single polype; but there are closely related forms (such as *Zoanthus*) in which the organism is compound, consisting of numerous polypites united by a creeping fleshy trunk or *cœnosarc*.

The second group of the *Zoantharia* is termed that of the *Zoantharia sclerodermata*, from the nature of the skeleton or coral. In this group are all the so-called "reef-building" Corals, which are the principal makers of the well-known "coral-reefs." The members of this group all possess the power of secreting carbonate of lime within their tissues, so as to form a more or less continuous skeleton or corallum. From the fact that this corallum is secreted by the inner layer of the polypes, and is therefore truly *within* the body, it is said to be "sclerodermic," in opposition to the kind of coral produced by other forms (such as the Red Coral), in which the coral forms an internal axis, over which the *cœnosarc* is spread, much as the bark encloses the wood of a tree. In this latter case the coral is said to

be "sclerobasic." (For illustrations of these different kinds of corals, see figs. 49 and 56.) In the typical form of sclerodermic coral, the skeleton is in the form of a conical cup (fig. 49), the upper part of which is hollow, and is called the "calice." The lower part is divided into a series of compartments by vertical plates, which are called the "septa," and which correspond to the mesenteries of the living animal. Sometimes the space contained within the walls of the cup or "corallite" is broken up by horizontal plates called "tabulæ"; but when these are present, there are often no septa. In the coral just described we have a single corallite, produced by one polype, and this simple condition may be maintained throughout

Fig. 49.—The skeleton of *Caryophyllia baccalis*, a simple sclerodermic coral, twice the natural size. (After Sir C. Wyville Thomson.)

life. In the great majority of cases, however, the polypes bud or divide, so as to form a colony all bound together by a common flesh or cœnosarc. When such a colony (fig. 50), therefore, produces a sclerodermic coral, in place of a single corallite, we have a composite skeleton composed of a number of little cups or corallites, each of which was produced by one polype, and all of which are united by means of a common calcareous basis, secreted by the cœnosarc. In other cases, the colony is produced simply by the budding forth of new polypes from the sides of the old ones, or by cleavage of the original polypes; so that there is no true cœnosarc. In these cases, the compound skeleton is composed simply of the separate corallites

belonging to the individual zoöids, without any common calcareous basis secreted by a cœnosarc.

As before said, the "septa" are vertical partitions, which divide

Fig. 50.—A compound Coral(*Astræa pallida*) in its living state. (After Dana.)

the space contained within the walls (the so-called "theca") of the coral into a series of compartments. The septa spring from the inner surface of the "theca" (fig. 51), and advance towards its

Fig. 51. A, Transverse section of a simple sclerodermic coral, showing how the space included within the wall or "theca" is subdivided by the radiating septa, the centre being occupied by the columnella; B, Transverse section of a simple Rugose coral, showing the wall and the radiating septa.

centre. Often the septa unite centrally with a calcareous pillar or rod, the "columnella"; and they are of different breadths. A certain number of them extend quite to the centre of the coral, where they

meet the columella (when this is present). These are called the "primary septa." Others, however, fall short of the centre by a greater or less distance; and these are called the "secondary" and "tertiary" septa, according to their breadth (fig. 51).

In accordance with their mode of formation, an ordinary compound sclerodermic coral may be distinguished from a sclerobasic coral by the fact that it would show a number of little cups or calices, in which the polypes were contained, whereas these cups would be absent in the latter. In accordance, also, with the fundamental character of the order *Zoantharia*, the corals of the present group possess septa which are some multiple of six.

When it is understood that compound corals, such as we have been speaking of, are produced by the combined efforts of a number of polypes, essentially the same in structure as our ordinary sea-anemones, it is readily intelligible that under favourable circumstances large masses of coral may be produced in this way. When these masses attain such a size as to be of geographical im-

Fig. 52.—Structure of Coral-reefs. 1. Fringing-reef; 2. Barrier-reef; 3. Atoll: *a* Sea-level; *b* Coral-reef; *c* Primitive land; *d* Portion of sea within the reef, forming a channel or lagoon.

portance, they are spoken of as "coral-reefs," and the phenomena exhibited by these are of such interest as to demand some notice. The coral-producing polypes require for their existence that the average temperature of the sea shall not be less during winter than 66°; and there are therefore no coral-reefs in temperate seas. Reefs, however, abound in all the seas not far removed from the equator, being found chiefly on the east coast of Africa and the shores

of Madagascar, in the Red Sea and Persian Gulf, throughout the Indian Ocean and the whole of the Pacific Archipelago, around the West Indian Islands, and on the coast of Florida. The headquarters, however, of the reef-building corals may be said to be around the islands and continents of the Pacific Ocean, where they often form masses of coral many hundreds of miles in length. According to Darwin, coral-reefs may be distinguished into three principal forms—viz., Fringing-reefs, Barrier-reefs, and Atolls, distinguished by the following characters:—

1. *Fringing-reefs* (fig. 52, 1).—These are reefs, usually of a moderate size, which may either surround islands or skirt the shores of continents. The shore-reefs are not separated from the land by any very deep channel, and the sea on their outward margins is not of any great depth.

2. *Barrier-reefs* (fig. 52, 2).—These, like the preceding, may either encircle islands or skirt continents. They are distinguished from fringing-reefs by the fact that they usually occur at much greater distances from the land, that there intervenes a channel of deep water between them and the shore, and soundings taken close to their seaward margin indicate considerable depths.

As an example of this class of reefs may be taken the great barrier-reef on the N.E. coast of Australia, the structure of which is on a gigantic scale. This reef runs, with a few trifling interruptions, for a distance of more than a thousand miles, with an average breadth of thirty miles, and an area of thirty-three thousand square miles. Its average distance from the shore is between twenty and thirty miles, the depth of the inner channel is from ten to sixty fathoms, and the sea outside is “profoundly deep” (in some places over eighteen hundred feet).

3. *Atolls* (fig. 52, 3).—These are oval or circular reefs of coral enclosing a central expanse of water or lagoon. They seldom form complete rings, the reef being usually breached by one or more openings. They agree in all essential particulars with those barrier-reefs which surround islands, except that there is no central island in the lagoon which they enclose.

The last group of the *Zoantharia* comprises composite organisms in which the *cœnosarc* is supported upon a central axis or sclerobasic skeleton. These *Zoantharia sclerobasica* require no notice, except simply to remark that they are distinguished from other sclerobasic Corals (such as the *Gorgoniæ*) by the fact that each polype possesses tentacles which are a multiple of six in number.

ORDER II. ALCYONARIA.

The second great order of living *Actinozoa* is distinguished by the fact that the polypes are furnished with *fringed* tentacles, and that these, as well as the mesenteries and somatic chambers, are always *eight* in number. With few exceptions, the *Alcyonaria* are composite, their polypes being connected together by a *cœnosarc*. The body-cavities of the polypes are connected with a system of communicating canals which are excavated in the *cœnosarc*, so that a free circulation of nutrient fluids is thus kept up. The structure of

the polypes of the *Alcyonaria* is, in essential anatomical features, the same as in the Sea-anemones, but the organism commonly consists of two sets of polypes, which differ from one another in structure and in function. A regular coral may or may not be present, and when present, varies much in its character; but most Alcyonarians possess numerous microscopic spicules of lime in their tissues.

Of the various different organisms included under this order, one of the best known is the "Dead-men's-fingers," or *Alcyonium*, which occurs commonly on both sides of the North Atlantic. It forms spongy-looking masses of a yellow or orange colour, attached to shells and other marine objects. The whole mass is covered with little star-shaped apertures, through which the delicate polypes can be

Fig. 53. — Colony of *Veretillum cynomorium*, of the natural size, with the polypes protruded.

Fig. 54. — *Pennatula sulcata*, seen from the dorsal side. Slightly reduced, after Kölliker.

protruded and retracted at will. Another well-known member of this order—the type of another family—is the "Sea-rod" (*Virgularia*), which has the form of a long rod-shaped body of a light flesh colour, supported upon a calcareous rod (sclerobasis), somewhat like a knitting-needle, which is covered by the cœnosarc. From the cœnosarc are given out lateral processes, each of which bears numerous polypes. Closely allied to *Virgularia* is the "Cock's-comb" (*Pennatula*); but in this the lower end of the cœnosarc is naked and fleshy (fig. 54),

and the polype-bearing fringes are considerably longer, giving the whole organism very much the appearance of a feather. In *Verecillum* (fig. 53) the upper part of the colony is short and club-shaped, and bears the polypes all round its circumference.

Another family of the *Alcyonaria* is represented by the so-called "Organ-pipe corals," of which *Tubipora musica* is a well-known example (fig. 55). In this there is a well-developed sclerodermic coral consisting of numerous cylindrical tubes, which are not divided by vertical partitions (septa), but which are connected by strong transverse plates. The coral is bright red in colour, and the polypes are usually bright green. In its minute structure, the corallum is composed of microscopic spicules fused together.

Fig. 55.—A, Portion of the corallum of *Tubipora musica*, of the natural size, showing the tubular corallites and their connecting floors; B, Polype of the same, greatly enlarged, showing the mouth and tentacles.

The best known group, however, of the *Alcyonaria* is that of the *Gorgoniidae*, represented by the Sea-shrubs, Fan-corals, and the Red Coral of commerce. A few of the members of this family are British, but they attain their maximum in point of size and numbers in the seas of the tropics. In all the *Gorgoniidae* the organism consists of a composite structure made up of numerous polypes united by a common flesh or cenosarc (fig. 56, B), the whole supported by a central branched axis or coral. The coral varies in composition, being sometimes calcareous—as in Red Coral—sometimes horny, and sometimes partly horny and partly calcareous, as in *Isis*. In all cases, however, the corallum differs altogether from the sclerodermic corallum, which has been described as so characteristic of the reef-building Corals. The coral in the present instance is always what is called "sclero-basic"—that is to say, it always forms an internal axis, covered by the cenosarc with the polypes produced therefrom. It is therefore

outside the polypes, and bears to the cœnosarc the same relation that the trunk of a tree bears to its investing bark. This is well shown in fig. 56, B, where there is represented one of these sclerobasic corals in which the corallum consists of a branched horny stem. The polypes of all the *Gorgonidæ* agree, of course, with their order in having eight tentacles each, and by this they are distinguished from the few *Zoantharia* in which there is a sclerobasic coral. The tissues of the cœnosarc and polypes are usually charged with microscopic spicules.

The best known of the *Gorgonidæ* is the *Corallium rubrum*, or "Red Coral" of commerce, which is largely imported from the Mediterranean. In this species (fig. 57) there is a bright red, finely

Fig. 56.—A, Portion of a compound sclerodermic Coral (*Dendrophyllia*), showing the cups (*a a*) produced by the separate polypes, united by a common calcareous tissue. B, Portion of a branched sclerobasic Coral (*Gorgonia*), showing the hard horny skeleton in the centre, surrounded by a fleshy bark or rind (mostly removed in the figure), in which the little polypes are embedded.

grooved, calcareous sclerobasis, usually more or less repeatedly branched. The corallum is invested by a bright red cœnosarc or bark, which is studded with numerous little apertures. The polypes can be protruded from these openings at will, and are milk-white in colour, with eight fringed tentacles each. The entire cœnosarc is excavated into a number of communicating canals, with which the cavities of the polypes are connected, the whole system being filled with a nutritive fluid known as the "milk."

Another group of the *Alcyonaria* has recently been constituted under the name of *Helioporidæ* for the singular stony corals belonging to the genus *Heliopora*, formerly believed to belong to the *Zoantharia*. In this genus, the corallum is compound, and is formed

of tubular corallites, furnished with both tabulæ and radiating septa, and separated from one another by an assemblage of smaller tabulate

Fig. 57.—Red Coral (*Corallium rubrum*), of the natural size, and a portion enlarged.

tubes, occupied by rudimentary polypes. Along with the living *Heliopora* of the Pacific and Indian Oceans, various ancient corals (*Heliolites*, &c.) have been placed.

ORDER III. RUGOSA.

This order merely requires mention, as almost all, or all, its members are extinct, and are therefore only known to us by their hard parts or skeletons; while the true characters and limits of the group are not completely worked out. They agree with the *Zoantharia sclerodermata* in having a well-developed sclerodermic corallum, but differ from them in the fact that the septa are typically in four systems; and there are generally transverse plates or tabulæ combined with the vertical plates or septa. On the other hand, they agree with the *Acyonaria* in having their parts in multiples of four, but differ from them in having a well-developed sclerodermic corallum in which septa are present. They are chiefly known as fossils in the older rocks of the earth's crust, and they have no undoubted representatives at the present day.

ORDER IV. CTENOPHORA.

The fourth and last order of the *Actinozoa* is that of the *Ctenophora*, comprising a number of free-swimming oceanic creatures, very different in appearance from any of the forms which we have hitherto been considering, and often placed among the *Hydrozoa*. They are all transparent, gelatinous, glassy-looking creatures, which are found near the surface in the open ocean, swimming rapidly by means of bands of cilia. The cilia are arranged in a series of transverse ridges, which are disposed in longitudinal bands, the whole constituting loco-

Fig. 58.—Adult of *Pleurobrachia rhododactyla*, in a natural attitude and of the natural size. (After A. Agassiz.) *c* One of the ciliated bands or ctenophores; *t* One of the tentacles.

motive organs which are known as “ctenophores” (fig. 58, *c*). In none are there any traces of a corallum or skeleton, and thread-cells, or cells which represent these, are generally present. As the type of the order, we may take *Pleurobrachia* or *Cydidpe* (fig. 58). The body of *Pleurobrachia* is transparent, colourless, gelatinous, and melon-shaped, and exhibits two poles, at one of which is placed the mouth. The globe-like body is divided into a number of crescentic lobes by eight ciliated bands or ctenophores, which proceed from near the mouth to near the opposite pole of the body. Besides the

cilia there are two very long and flexible tentacular processes, which are fringed on one side by smaller secondary branches. The tentacles arise each from a kind of sac, one placed on each side of the body, and they can be instantaneously and completely retracted within these sacs at the will of the animal. The mouth of *Pleurobrachia* opens into a spindle-shaped digestive sac or stomach, which in turn opens below into a wider and shorter cavity termed the "funnel"; from this there proceed in the axis of the body two small canals, which open at the opposite pole of the body. The funnel communicates with a complicated system of canals, which are ciliated internally, and are filled with a nutrient fluid. In the angle between the two canals which run from the base of the funnel to the surface is a little vesicle or sac, believed to be a rudimentary organ of hearing, and placed upon this is a little mass which is generally believed to be of a nervous nature. The reproductive organs are developed in the walls of the canal-system.

Fig. 59. Ctenophora. *Cestum Veneris*, reduced in size.

The only other form of the *Ctenophora* which deserves mention is the "Venus's girdle" (*Cestum Veneris*), which agrees in essentials with *Pleurobrachia*, but is greatly elongated in a direction at right angles to the alimentary canal, till we have a ribbon-shaped body produced (fig. 59), four or five feet in length and two or three inches high. *Cestum* is not uncommon in the Mediterranean, and has the power of phosphorescence, appearing at night as a moving and twisting band of flame.

SUB-KINGDOM III. ECHINODERMATA.

CHAPTER X.

ECHINODERMATA.

THE *Echinodermata* may be defined as *simple marine organisms, which are mostly bilaterally symmetrical when young, but which in the adult condition have this bilateral symmetry more or less extensively masked by a radial (usually pentamerous) arrangement of their parts. An alimentary canal, with or without a distinct anus, and separate from the proper body-cavity is present. A system of water-vessels, often communicating directly with the exterior, and generally connected with protrusible tubes ("feet"), is present. The nervous system is radiate, consisting of an œsophageal ring and radiating branches. The integument is characteristically hardened by the deposition in it of carbonate of lime in the form of plates, granules, or spicules.*

The members of this sub-kingdom are popularly known as Sea-urchins, Star-fishes, Brittle-stars, Feather-stars, Sea-cucumbers, &c., and derive their name of *Echinodermata* (Gr. *echinos*, a hedgehog; and *derma*, skin) from the generally prickly nature of their integuments. In all, the skin is possessed of the power of secreting carbonate of lime, but in very different degrees. In the Sea-urchins this goes so far that the body becomes enclosed in a kind of box, composed of numerous calcareous plates firmly jointed together. In the Star-fishes and their allies the skin is rendered prickly by grains, tubercles, or spines of calcareous matter, and the body is either destitute of regular plates or is only partially enclosed by them. In the Sea-cucumbers, again, the calcareous matter is only present in the form of minute grains scattered in the skin. When adult, they all show a more or less distinctly radiate structure, which is most conspicuous in the star-shaped Star-fishes and Sand-stars, but can be detected in all the members of the class. When young, however, they almost always exhibit what is called "bilateral symmetry"—that is to say, they show similar parts on the two

sides of the body. In all Echinoderms there is a water-vascular system of tubes, which is termed the "ambulacral system," which generally communicates with the exterior, and which in most cases is used in locomotion. An alimentary canal is always present, and is always completely shut off from the general cavity of the body. There are always distinct organs of reproduction, which are almost always placed in different individuals, so that the sexes are distinct. The nervous system is in the form of a ring surrounding the gullet and sending branches in a radiating manner to different parts of the body.

One of the most characteristic points about the Echinoderms is their mode of development. In most cases, namely, the embryo is a little oval body covered all over with cilia; but in the course of growth the cilia become restricted to transverse bands or to definite outgrowths of the body. The embryo is now often somewhat conical or pyramidal in shape, with long projecting processes, and may be supported by a provisional internal skeleton (fig. 60). An ali-

Fig. 60.—Larva of *Echinus*. (After J. Muller.) A, A, Front arms with their internal skeleton; F, F, Arms of the mouth-process; B, B, Posterior side-arms; a Mouth; a' Oesophagus; b Stomach; b' Intestine; d Ciliated bands; f f Ciliated epaulets; c Disc of the future *Echinus*.

mentary canal with a distinct mouth and anus is present, and the embryo is thus divided into two bilaterally symmetrical halves. This singular embryo was originally described, in the case of the Sea-urchins, as an independent animal, under the name of "*Pluteus*." The special peculiarity of the further development of the embryo is that the adult animal is ultimately developed out of a mass of active, growing protoplasm which appears on one side of the stomach of

the Pluteus, and finally envelops that organ; while a new mouth is formed, and a large part of the provisional embryo is absorbed. The adult further produces a fresh skeleton for itself, and now exhibits conspicuous radial symmetry.

The *Echinodermata* are divided into seven orders, as follows:—

1. *Echinoidea* (Sea-urchins).
2. *Asteroidea* (Star-fishes).
3. *Ophiuroidea* (Sand-stars and Brittle-stars).
4. *Crinoidea* (Feather-stars).
5. *Cystoidea* (extinct).
6. *Blastoidea* (extinct).
7. *Holothuroidea* (Sea-cucumbers).

ORDER I. ECHINOIDEA.

The animals included in this order vary from the shape of a sphere or globe to that of a disc, and they are all commonly known as “Sea-urchins” or “Sea-eggs.” They are all characterised by the fact that the body is encased in a “test” or “shell” (fig. 61) composed of numerous calcareous plates, usually immovably jointed together so as to form a kind of box. The intestine is convoluted, and there is a distinct vent, or anal aperture.

The test of a Sea-urchin, as just said, consists of many calcareous plates accurately fitted together, and united by their edges, or, in a few cases, overlapping one another. In all living forms the test is composed of ten zones of plates, each zone consisting of a double row. In five of these zones (fig. 61, A, *i*) the plates are of large size, and are perforated by no apertures. These are termed the “interambulacral areas.” In the other five zones (fig. 61, A, *a*) the plates are of small size, and are perforated by little apertures for the emission of delicate locomotive suckorial tubes (the so-called “ambulacral tube-feet”). These zones are therefore called the “ambulacral areas.” Besides these main rows of plates, which collectively make up the greater part of the test, there are other plates placed in the leathery skin round the mouth and vent. The most important of these form a kind of disc, which is placed at the summit of the shell. This disc (fig. 61) is composed of two sets of plates—one called the “genital plates,” perforated for the ducts of the reproductive organs; the other set smaller, carrying each a little “eye,” and known by the name of “ocular plates.” One of the genital plates is also larger than the others, and carries a spongy mass which is called the “madreporiform tubercle,” and which protects the entrance of the water-vascular or ambulacral system. The whole of

the test is covered with numerous tubercles of different sizes, which carry longer or shorter spines (fig. 61, E). The spines are jointed to the tubercle by a sort of "ball-and-socket" or "universal" joint, and they are completely under the control of the animal, so as to be used both in locomotion and apparently as defensive weapons. In most of our British species the spines are short, but in many tropical forms they attain a very great length. Besides the spines, the outer

Fig. 61.—Morphology of Echinoidea. A, Young specimen of *Strongylocentrotus Dröbachiensis*, viewed from above; B, Small portion of the test of the same magnified; C, Summit of the test of *Echinus sphæra*, magnified; D, *Clypeaster subdepressus*, viewed from above, showing the petaloid ambulacra; E, Spine of *Porocidaris purpurata*; F, Pedicellaria of *Toxopneustes ligidus*. a a Ambulacral areas; i i Interambulacral areas; q Genital plate; o Ocular plate; m Madreporiform tubercle; p Membrane surrounding the anus. (Figs. A, B, and D are after A. Agassiz.)

surface of the test is furnished with curious little bodies called "pedicellariæ" (fig. 61, F), which were long believed to be parasitic. They consist of two or three blades mounted upon a flexible stalk, and constantly employed in snapping together like the beak of a bird. They occur in many other *Echinodermata*, and their use is obscure.

Locomotion is effected in the Sea-urchins by a curious system of contractile tubes which are known as the "ambulacral tubes" or "tube-feet," and which are appendages of the water-vascular system.

The following is essentially the arrangement of the whole aquiferous system (see fig. 62). From the madreporiform tubercle on the largest of the genital plates there proceeds a membranous canal, the "sand-canal" (*s*), by which the outer water is conducted to a central tube (*r*), which forms a ring round the gullet. The tubercle is spongy, and is perforated with little holes, and its function is probably to act as a filter, and prevent foreign particles gaining access to the interior. The "circular canal" carries five little bladders of unknown function, termed the "Polian vesicles" (*p*). From the "circular canal" round the gullet proceed also five "radiating canals" which take their course towards the summit of the shell, underneath the ambulacral areas (*a*). In its course each radiating canal gives off numerous short lateral tubes (*t*)—the ambulacral tubes or tube-feet—which gain the exterior of the shell by passing through the apertures in the ambulacral plates of the shell, and which terminate in little sucking-discs. The tube-feet can be distended with water by means of a series of little muscular bladders or "ampullæ" (*v*) placed at their bases, and they can thus be thrust far out beyond the shell, into which they can be again withdrawn at the will of the animal. However long the spines may be, the animal can protrude the tube-feet to a still greater length; and by the combined action of the little suckers at their extremities locomotion is effected with moderate rapidity, considering the bulk of the body.

Fig. 62.—Diagram of the ambulacral system of *Echinus*. *m* Madreporiform tubercle; *s* Stone-canal; *r* Central oesophageal ring; *p p* Polian vesicles; *a a* Radiating ambulacral vessels. Only the bases of four of the radiating vessels are shown; and a few of the tube-feet (*t*), with their secondary vesicles or "ampullæ" (*v*), are shown on one side of one of the radiating canals.

The digestive system in *Echinus* consists of a mouth armed with a curious apparatus of calcareous teeth, which opens into a gullet, which in turn conducts to a long intestinal tube. The teeth form a singular pyramidal structure known as "Aristotle's lantern"; but many Sea-urchins are without teeth. The long and convoluted intestine is attached to the interior of the shell by a delicate membrane or "mesentery," and terminates in a distinct vent. The surface of the mesentery, as well as that of the lining membrane of the shell, is richly ciliated, and thus serves to distribute the fluid which fills the general cavity of the body, and

Fig. 63.—*Cidaris papillata*. (After Gosse.)

which corresponds with the blood, to all parts of the body. It is doubtful if any true blood-system is present, but there is present a system of tubes, of which the principal portion is a long fusiform vessel running parallel with the sand-canal, and which have been regarded as blood-vessels. The nervous system consists of a gangliated cord placed round the gullet, and sending five radiating branches along the ambulacral areas. The two sexes are distinct, but in both the reproductive organs are in the form of five membranous sacs placed in a radiating manner in the interambulacral areas, and opening at the genital plates.

The majority of the Sea-urchins are found at moderate depths in the sea, especially in the neighbourhood of oyster-banks. Others spend their existence buried in the sand; and one species excavates holes for itself in the solid rock, apparently by some mechanical action.

ORDER II. ASTEROIDEA.

As the structure of the Sea-urchins may be taken as embodying the most important anatomical peculiarities of the *Echinodermata*, and as this has been described at some length, it will not be necessary to do more than briefly indicate the more important characteristics of the remaining orders. In the present order are included all the true Star-fishes; the Sand-stars and Brittle-stars being now regarded as a distinct group. The body in all the *Asteroidea* is

Fig. 64.—The Common Star-fish (*Uroaster rubens*), natural size, viewed from above.

more or less obviously star-shaped (fig. 64), consisting of a central disc surrounded by five or more lobes or arms, which radiate from the body, are hollow, and contain prolongations from the stomach. The body is not enclosed in an immovable box or test, as in the Sea-urchins, but the integument is of a leathery nature, and is richly furnished with calcareous plates, tubercles, and spines. The true Star-fishes are distinguished from the nearly allied Brittle-stars (*Ophiuroidea*) by the fact that the arms or "rays" are direct prolongations of the body, that they contain prolongations of the

stomach, and that they are deeply grooved on their under surfaces for the radiating vessels of the water-vascular system, which are further protected by a sort of internal skeleton. The upper surface of the body and arms is richly furnished with calcareous matter, in the form of prickles, tubercles, spines, and pedicellariæ, these last being peculiarly modified spines. The upper surface, also, exhibits the madreporiform tubercle in the form of a concentrically striated disc placed at the angle between two of the rays; and also the aperture of the anus, when this is present. The mouth is placed in the centre of the lower surface, and is not furnished with teeth. It leads into a pouched stomach and very short intestine, which usually terminates on the upper surface by an anal aperture; but the anus is occasionally wanting. From the upper end of the stomach in all the *Asteroidea* proceeds a series of much-branched membranous sacs, two of which are prolonged into each ray. These sacs are of a brown or greenish colour, and are often called the "hepatic cæca," as they are supposed to correspond with the liver. The water-vascular or ambulacral system is in most essential respects identical in structure with that of the Sea-urchins, making due allowance for the different shape of the body. The madreporic plate leads into a short sand-canal, which opens into a circular ring round the gullet. The circular ring carries Polian vesicles, and gives off the radiating ambulacral vessels, one of which is prolonged to the extremity of each ray, running at the bottom of the deep ambulacral groove on the under surface of the arms. The ambulacral groove is formed by a double row of calcareous plates (the "ambulacral ossicles"), and the radiating ambulacral vessel with its tube-feet lies underneath these plates. On the other hand, the "ampullæ," or little bladders which distend the tube-feet, are situated *above* the ambulacral ossicles, and therefore in the interior of the arm; and the ampullæ become connected with their respective tube-feet by passing through a series of pores formed between successive pairs of ambulacral ossicles. The nervous system consists of a gangliated ring surrounding the mouth and sending branches along each of the arms. The reproductive organs, like the nervous system, exhibit a radiate condition, being arranged in pairs in each ray.

The Star-fishes are found on almost all shores, but many forms are properly inhabitants of deep water. They differ much in the general shape of the body. In the common Cross-fishes (*Craster* or *Asterias*) the disc is small, and is furnished with long finger-like rays, which are properly five in number. In the *Cribellæ* the general shape is much the same. In the Sun-stars (*Solaster*) the disc is large and well marked, and the rays are from twelve to fif-

teen in number, and shorter than the diameter of the disc. In the Cushion-stars (*Goniaster*) the body is in the form of a five-angled disc, more or less flattened on both sides, the rays being only marked out by the ambulacral grooves upon the lower surface.

ORDER III. OPHIUROIDEA.

This order comprises the common Brittle-stars and Sand-stars (*Ophioglypha*, *Ophiura*, *Ophiothrix*, *Ophiocoma*, &c.) The body in

Fig. 65.—Ophiuroidea. *Ophioglypha lacertosa*: A, Outline, of the natural size; B, The disc viewed from above, twice the natural size; C, The disc viewed from below, showing the mouth and genital fissures, twice the natural size. (Original.)

the *Ophiuroidea* consists of a circular central disc covered with small calcareous plates, and giving off five long slender arms (fig. 65),

which may be simple or branched, but which do not contain any prolongations from the stomach, nor have their under surfaces excavated into grooves for the protrusion of ambulacral tube-feet. The arms, in fact, are not prolongations or lobes derived from the body itself, but are special appendages added for purposes of locomotion and prehension. The arms are very much longer than the diameter of the disc, and are protected by four rows of calcareous plates—one above, one below, and one on each side. In the centre of each arm is a row of calcareous pieces which form a kind of internal axis or skeleton, below which is placed the radiating ambulacral vessel. The main internal organs are contained within the disc, and none of them pass into the arms except the nerve-cords and ambulacral vessels. The mouth is placed in the centre of the under surface of the disc, and opens into a globular, simple stomach, which is not furnished with an anal aperture, all indigestible particles being got rid of through the mouth. In various points of their anatomy the *Ophiuroidea* differ considerably from the true Star-fishes, to which they are most nearly related, but these differences do not require further notice.

The habits of the Brittle-stars and Sand-stars are various, but many of them may be found in rock-pools or under stones at low water on most shores. One of the most remarkable types is the Medusa-head Star, in which the arms are divided from the base, first dichotomously and then into many branches.

ORDER IV. CRINOIDEA.

In this order are comprised *Echinodermata*, in which the body is fixed, during the whole or a portion of the existence of the animal, to submarine objects by means of a jointed flexible stalk or column. The *Crinoidea* were formerly very numerous, both individually and in types, but they are represented at the present day by but a small number of living forms, of which one group only (viz., that of the Feather-stars) is at all of common occurrence. The body in the Crinoids consists of a central disc or cup formed of calcareous plates, and protecting the body of the animal. From the margins of this cup spring five or more arms which are arranged in a radiating manner, so as to form a more or less feathery crown. In one of the living groups (*Comatula* or *Antedon*), the animal, when full grown, is free; but in all other living types, and in the great majority of fossil forms, the body was attached throughout life to the seabottom by means of a jointed stalk fixed to the lower surface of the cup (fig. 67).

The commonest living group is that of the Feather-stars (*Comatula*

or *Antedon*), species of which are found in almost all seas. In this group the organism consists of a central body or disc, from which proceed five radiating arms, which divide almost directly after their origin into two secondary branches, so that ultimately there are produced ten long and slender rays. Each arm is furnished on both sides with a number of little jointed lateral processes or "pinnæ," so as to assume a feather-like appearance, from which its

Fig. 66.—Crinoidea. *Comatula rosacea*, a free Crinoid, viewed from its dorsal or aboral aspect.

popular name is derived (fig. 66). The digestive system is furnished with both a mouth and a vent; the water-vascular or ambulacral system appears to take no part in locomotion, and the reproductive organs are lodged in the lateral processes of the arms. The most remarkable point, however, about a Feather-star, is the manner in which development takes place. When fully grown (fig. 66) it presents no small superficial resemblance to some of the *Ophiuroidea*.

When young, the *Comatula* is so different in appearance from the adult, that it was originally described as a distinct animal. It consists now of a little cup-shaped disc with ten radiating arms above,

Fig. 67. - *Rhizocrinus lofotensis*, a living stalked Crinoid (after Wyville Thomson), four times the natural size. *a* Stem; *b* Cup; *c* *c* Arms.

produced by the splitting into two of five primary rays, and furnished inferiorly with a little flexible column or stalk composed of a number of calcareous joints. By this jointed stem the body is at this period of life fixed to sea-weeds or other submarine objects. When sufficiently mature, however, the body drops off its stalk, and then only requires to grow in size to become a fully developed *Comatula*.

The stalked condition which we have just seen to constitute a merely temporary stage in the life-history of *Comatula* is, on the other hand, the permanent state of parts in all the "Stone-lilies" and in most other fossil *Crinoidea*, and in a few living forms. Of the living stalked Crinoids the ones with which naturalists have been longest acquainted are the species of *Pentacrinus*, from the seas of the West Indies. Recently a number of stalked Crinoids have been obtained from great depths in the sea, showing that these ancient types still survive, though in much diminished numbers. One of the most interesting of these deep-sea

Crinoids is the little *Rhizocrinus lofotensis* (fig. 67), which seems to be distributed over the whole of the deeper portions of the North Atlantic.

ORDERS V. AND VI. CYSTOIDEA AND BLASTOIDEA.

These orders merely require to be mentioned here, as all the forms included in them are extinct, and are unrepresented at the present day by living species. In both, the body is enclosed in a kind of box formed by jointed calcareous plates, and it was in most cases permanently fixed to the sea-bottom by a jointed stalk or column. The arms, which form so conspicuous a feature in the true *Crinoidea*, were either absent or very rudimentary. Both orders are in many respects closely allied to the *Crinoidea*, and they constitute probably the least highly developed sections of the whole class of the *Echinodermata*.

ORDER VII. HOLOTHUROIDEA.

In this order are comprised the highest of the *Echinodermata*, all very different in outward appearance from any of the forms we have hitherto considered. They are commonly known as Sea-cucumbers or Trepangs, but, except in warm seas, they are rare and inconspicuous animals at the best. They are all more or less worm-shaped or snail-like in form, and they are not provided with any regular shell. The skin is leathery, and generally contains calcareous matter in the form of microscopic plates or spicules, or more rarely in the form of larger overlapping plates. The body is capable of great changes of form in the way of extension or contraction, being provided with exceedingly powerful longitudinal and transverse muscles. Locomotion is effected by the alternate extension and contraction of the vermiform body, or by rows of ambulacral tube-feet, like those of the Sea-urchins, protruded through the integument. Typically, the tube-feet are arranged in five longitudinal zones, as in the Sea-urchins (fig. 68); but, in other cases, the tube-feet are irregularly distributed over the whole body, and in a few cases they are emitted from the lower surface of the body alone. In some forms (*Synapta*), there are no tube-feet, and locomotion is effected by numerous minute anchor-shaped spicules of lime, attached to plates sunk in the skin (fig. 70). The water-vascular or ambulacral system is sometimes quite rudimentary, but in other cases its internal arrangement much resembles that of the Sea-urchins, except that the madreporiform tubercle is not placed on the outside of the body, but hangs down freely in the interior of the body. The circular œsophageal ring carries generally one very long Polian vesicle (fig. 69, *p*); and the tube-feet are provided with "ampullæ." The mouth is situated at the anterior end of the body, and is provided with a crown of branched tentacles

(fig. 68). It opens into a long convoluted digestive tube, which is attached to the body-walls by a delicate mesentery, and terminates in a large muscular chamber or "cloaca" (fig. 69), which in turn communicates with the exterior by the anal aperture. Springing from the cloaca in many Holothurians are two much-branched tubes, which run forward towards the anterior end of the body, and which are filled with sea-water from the exterior. These tubes seemingly act as respiratory organs, and are usually spoken of as the "respiratory tree" (fig. 69, *ll*). The Holothurians have a nearly world-wide distribution, and are found from between tide-marks up to great

Fig. 68. — *Cucumaria frondosa*, showing the crown of feathery tentacles round the mouth and the rows of tube-feet.

Fig. 69. — *Holothuroidea*. Semi-diagrammatic longitudinal section of a Holothurian. *t* Tentacles; *r* Calcareous ring at the base of the tentacles; *p* Polian vesicle; *s* Sand-canal; *i i i* Alimentary canal; *g* Duct of the reproductive organs; *cl* Cloaca; *a* Anus; *ll* Respiratory tree.

which run forward towards the anterior end of the body, and which are filled with sea-water from the exterior. These tubes seemingly act as respiratory organs, and are usually spoken of as the "respiratory tree" (fig. 69, *ll*). The Holothurians have a nearly world-wide distribution, and are found from between tide-marks up to great

depths in the sea. Many of the deep-sea forms exhibit singular modifications of structure. Some Holothurians (*e.g.*, *Synapta*) burrow in sand or mud; others are free. Many attain a considerable size.

Fig. 70.—Anchor-shaped spicules of *Synapta*, and the plates to which these are attached. Magnified greatly.

SUB-KINGDOM IV. ANNULOSA.

CHAPTER XI.

GENERAL CHARACTERS OF THE ANNULOSA—DIVISIONS OF THE ANNULOSA—CHARACTERS AND ORDERS OF THE SCOLECIDA.

THE Annulose animals are characterised by the possession of a *usually more or less elongated body, which is bilaterally symmetrical, instead of being radially disposed. Commonly the body is divided into similar segments, which may be definite or indefinite, and are arranged along an antero-posterior axis. Lateral appendages may be present or absent, and when present are bilaterally disposed. A nervous system is present, and consists of one or two ganglia placed in the anterior part of the body, or of a ventrally placed double gangliated chain.*

The sub-kingdom *Annulosa* may be divided into the following three primary sections, each of which admits of sufficiently definite characterisation :—

I. SCOLECIDA.—This division includes the parasitic Worms (*Entozoa*), the Wheel-animalcules, and some allied forms, and is characterised by the fact that the body is flattened, and either unsegmented or imperfectly segmented, though the integument may be annulated. A water-vascular system is present, but the water-vessels are not concerned with locomotion. There is no true blood-system ; and the nervous system consists of one or two cephalic ganglia, and never has the form of a gangliated ventral chain. Lateral appendages are almost universally wanting.

II. ANARTHROPODA.—This division includes the Spoon-worms (*Gephyrea*) and the Ringed Worms (*Annelida*), and is characterised by the fact that the body is composed of a number (often indefinite) of similar or nearly similar segments arranged longitudinally. A "pseudohæmal" system of vessels is generally present. The nervous system is placed ventrally, and consists typically of a double chain of ganglia, united by longitudinal commissures, and forming an œsophageal collar. Cilia are generally developed. Lateral locomo-

tive appendages are usually present, but are never jointed or articulated to the body.

III. ARTHROPODA.—This division includes the Crustaceans (*Crustacea*), the Spiders, Scorpions, &c. (*Arachnida*), the Centipedes and their allies (*Myriapoda*), and the Insects (*Insecta*). The body (fig. 71) is composed of a series (usually definite) of distinct rings or

Fig. 71.—Diagram of the anatomy of an Insect. *an* Antennæ; *e* Eye; *m* Mouth; *g* Gullet; *sg* Salivary gland; *s* Stomach; *f* Tubes supposed to represent the kidneys; *i* Intestine; *c* Chamber (cloaca) into which the intestine opens; *v* Vent; *h* Heart; *n* Nervous system; *l* Bases of the legs.

“somites,” arranged along a longitudinal axis. A true blood-vascular system is normally present, and the heart is placed dorsally. The nervous system consists primitively of a double chain of ganglia, placed ventrally, and traversed anteriorly by the œsophagus. Limbs are almost always present, and are jointed and articulated to the body. The integument is more or less extensively hardened by the deposition in it of chitine, with or without salts of lime; and ciliated epithelium is not developed.

SCOLECIDA.

The *Scolecida* are characterised, as compared with the higher Annulose Animals, by their *unsegmented or imperfectly segmented bodies*; by the *general absence of lateral appendages*; by the *possession of branched water-vessels, filled with a watery fluid, and usually communicating with the exterior*; and by the *fact that the nervous system consists of one or two ganglia situated in the anterior part of the body*.

A large number of the Scolecids are internal parasites, and are commonly known by the name of *Entozoa*. Many forms, however, lead a permanently free existence. The *Scolecida* are often divided into two great sections—viz., (1) the *Platyelmia* or Flatworms, including the Tape-worms (*Tæniada*), the Fluke-worms (*Trematoda*), and the Turbellarian Worms; and (2) the *Nematelmia*

or Round Worms, comprising the Thorn-headed Worms (*Acanthocephala*), the Hair-worms (*Gordiacea*), and the typical Round-worms and Thread-worms (*Nematoidea*). A third division must be constituted for the reception of the Wheel-animalcules (*Rotifera*).

SECTION A. PLATYELMIA.

ORDER I. TENIADA.

This order comprises the singular animals known as Tapeworms, all of which are found living as parasites within the alimentary canal of other animals; the young (often called "Cystic worms" or "Bladder-worms") being also parasitic, but usually inhabiting the solid tissues. As a general rule, the adult tapeworm inhabits the alimentary canal of an individual of some one species of the higher animals; while the young of the same tapeworm inhabits the tissues of an individual belonging to some other species of animal. As a rule, therefore, each tapeworm is, at different times of its life, parasitically related to two different animals, belonging generally to different species. In its early stages each tapeworm inhabits the tissues of what may be called its "intermediate bearer," while in its adult condition it inhabits the intestine of what we may term its "final host." As a rule, the "intermediate bearer" and the "final host" are not only different individuals, but they belong to different kinds of animals—the two, however, being so far related to each other that the "intermediate bearer" is liable to be eaten by the "final host."

Many animals are infested by tapeworms; but all the leading points of interest in the order will be brought out by a consideration of one of the commonest of the tapeworms to which man is subject—namely, the Pork-tapeworm, or *Tenia solium*. The Pork-tapeworm is found inhabiting the intestines of man, one only being generally present in the same individual. In shape (fig. 72) it is an extremely elongated, flattened, tape-like body, many feet in length, and composed of a number of flattened joints all loosely united to one another. At one extremity the joints, technically called the "proglottides," become much smaller and narrower, till ultimately a point is reached where the organism is firmly fixed to the mucous membrane of the intestine by means of a minute rounded head (fig. 72, *a*). The organs by which attachment is effected are, in this species, a crown of recurved hooks and four suckers. In other types only the suckers are present (fig. 73, *c*). The head is in reality the true animal, and all the long, jointed, tape-like body which

follows this is really produced by a process of budding from the head. The head contains no reproductive organs, and is not furnished with a mouth or digestive organs of any kind, its nutrition

Fig. 72.—A, *Tænia solium*, of the natural size: *a* “Head” or “nurse;” *b* One of the proglottides from the sexually mature part of the worm. B, A single mature proglottis of the same, showing the genital pore (*p*) and the branched uterus (*u*).

being entirely effected by imbibition of the nutritive fluids elaborated by its host. A nervous system, in the form of two ganglia, united by a transverse commissure, and sending filaments backwards, is

present. The water-vascular system consists of two long vessels which run down each side of the body and communicate at each articulation by a transverse vessel, the whole opening in the last joint into a contractile vesicle. Each joint, or "proglottis," is sexually perfect, or hermaphrodite, containing both male and female reproductive organs, which open on the surface by a small raised aperture, the "generative pore" (fig. 73, *h*). Almost the whole of each of the mature joints is filled up by a much-branched uterus. As the head is the true animal, and the numerous joints are only produced by budding, it follows that the entire organism is to be regarded as a kind of colony, constituted by a single sexless zoöid

Fig. 73.—Morphology of *Taeniada*. *a* Head and a few following segments of *Taenia mediocanellata*; *b* A few segments of the same further removed from the head; *c* and *d* Segments progressively further removed from the head,—all of the natural size; *e* Head of the same, enlarged; *h* A single proglottis of the same, with its branched uterus and lateral genital pore, enlarged two diameters; *f* Embryo of *Taenia bacillaris*, with six hooklets; *g* *Cysticercus cellulosæ*, the "cystic" young of *Taenia solium*, with its hooklets and suckers, its wrinkled neck, and its caudal vesicle, enlarged. (After Leuckart, Van Beneden, and Weinland.)

or "nurse" and numerous sexual zoöids, produced by budding from the former.

The process of development—that is to say, the process by which this composite organism, commonly known as the tapeworm, is produced—is a very remarkable one, and is briefly as follows: Each generative segment or joint, as already said, is hermaphrodite, and contains innumerable ova. These eggs, however, cannot be developed within the body of the animal infested by the tapeworm itself, but they are compelled to gain access to the body of some different species of animal, if development is to proceed. To secure this end, the mature joints of the colony break off, and are expelled

from the alimentary canal of the host. The joints thus expelled die and decompose, and their contained eggs are thus set free. Each egg is covered with a little leathery capsule which protects it from injury, and contains a minute embryo in its interior. If this microscopically small egg be swallowed—as in many ways it easily may be—by another warm-blooded animal (in this particular case by the pig), then a fresh series of changes ensues. The leathery case of the ovum is dissolved in the stomach of the new host, and the embryo, or “pro-scolex” (fig. 73, *f*), is set free, when it bores its way through the walls of the stomach by means of little hooks or spines with which it is provided. Having reached a suitable locality, the young tapeworm proceeds to surround itself with a kind of cyst, and it develops from its hinder end a kind of bladder or vesicle filled with a clear watery fluid. The young tapeworm is now what is technically called a “scolex,” and it constitutes what used to be termed a “Cystic Worm” (fig. 73, *g*). It consists not only of the caudal bladder, but also of a short neck carrying an oval “head,” which is furnished with four suckers and a little crown of hooklets. The “scolex” of the *Tænia solium* is generally about a fourth of an inch in length, and is found embedded in the muscles of the pig, when the pork is said to be “measly.” When first discovered, the young tapeworm was regarded as a distinct species of worm, and was described under the name of *Cysticercus celluloſe* (fig. 73, *g*). In this cystic stage the young tapeworm may remain for an apparently indefinite period, being quite incapable of developing eggs. For its further development it is necessary that it should now be introduced into the alimentary canal of man. If a portion of measly pork be eaten, with these cystic worms embedded in it, then the young tapeworm is liberated from its cyst: it fixes itself by means of its suckers and hooklets to the mucous membrane of the intestine, and its caudal bladder drops off. It is now converted into the head of the adult tapeworm. It finally commences to throw out buds from its hinder extremity, and in these buds or joints the reproductive elements are produced, so that ultimately we get the long flattened jointed colony with which we started.

A like extraordinary series of phenomena is now known to occur in other cases, but these can be merely alluded to here. Thus, another of the common tapeworms of man—viz., the Beef-tapeworm (*Tænia mediocanellata*)—lives as a “scolex” or “cystic worm” in the muscles of the ox. The tapeworm of the cat (*Tænia crassicollis*) spends its “cystic” stage in the tissues of the mouse. One of the tapeworms of the dog (viz., *Tænia serrata*) inhabits in its early life the bodies of hares and rabbits. Another tapeworm of the dog (viz., *Tænia cænurus*) is found as a “cystic worm” inhabiting the brain of

the sheep, in which animal it produces the disease known as the "staggers." Lastly, another curious tapeworm of the dog (viz., the *Tenia echinococcus*) lives in its young stages in the human body, giving rise to what are known as "hydatid tumours." The adult tapeworm of this species is only about a quarter of an inch in length, and consists only of three joints besides the head. The so-called "hydatid tumour" consists of one or more bladder-like tumours, varying greatly in size, embedded in the liver, lungs, brain, or other solid organ of the human body. The bladder is filled with a watery fluid, and its inner surface carries a vast number of little buds, which are mostly similar in structure to an ordinary "cystic worm." Similar little "cystic worms" are often found floating in the fluid itself, and are commonly spoken of as "*Echinococci*." In reality, the "hydatid tumour" is the result of the development of the young or "scolex" of the *Tenia echinococcus* of the dog. In this particular case the "scolex," or young tapeworm, has the power of throwing out buds, and thus of forming a composite organism or colony. Hence, in this case, instead of remaining harmlessly embedded in the tissues, as is usual among the young of the tapeworms, the "scolex" goes on constantly growing and increasing in size, by the production of new buds in its interior. For this reason, also, "hydatid tumours" usually give rise to serious or fatal results by the pressure which they exert upon the tissues or organs amongst which they lie.

ORDER II. TREMATODA.

The "suctorial" worms, or "flukes," as the members of this order are commonly called, are internal parasites, inhabiting various situations in different animals, but especially affecting birds and fishes. They are almost all more or less flattened and leaf-like in shape, and are furnished with one or more ventral suckers, by which they adhere. They are distinguished from the *Teniada* by always possessing an alimentary canal, which is often much branched, and which is simply hollowed out of the tissues of the body. No anal opening is present; and there is no body-cavity. The integument is not ciliated, and the sexes are generally united.

The best known of the Trematode worms is the common Liver-fluke (*Distoma hepaticum*) which inhabits the gall-bladder and bile-ducts of the sheep and other domestic animals, and sometimes occurs in the same situation in man. In the sheep it gives rise to the prevalent and often fatal disease known as the "rot." In *Distoma hepaticum*, or in such a form as *Distoma lanceolatum* (fig. 74), the body is ovate and leaf-like, half an inch or more in length,

and furnished with two ventral suckers. One of these is placed anteriorly (fig. 74, *a a*), and is perforated by the aperture of the mouth. The hinder sucker (*ap*) is imperforate, and is the main organ of adhesion. Between the two suckers are the openings of the male and female organs of reproduction (*c*). The mouth opens into a short gullet, which divides into two primary branches which are continued backwards. In *Distoma lanceolatum*, the divisions of the intestine are simple (fig. 74, *i*), but in *D. hepaticum* they are furnished with numerous secondary lateral branches. Dorsally is placed a more or less complex system of water-vessels, which open posteriorly by a caudal pore (fig. 74, *p*), and are filled with a watery fluid. The nervous system consists of a pair of cephalic ganglia, giving off branches backwards. A large portion of the body is further occupied by the very complicated reproductive organs, the animal being hermaphrodite.

Fig. 74.—A Trematode Worm (*Distoma lanceolatum*), enlarged. *a a* Anterior sucker, with the mouth at its bottom; *ap* Posterior sucker; *o* Gullet, dividing behind into the two branches of the intestine, which are unbranched, and terminate behind in blind extremities (*i i*); *p* External opening of the water-vessels, which divide above so as to cross the blind ends of the intestine. The remaining letters refer to the different parts of the reproductive organs.

Most Trematode worms pass through a remarkable series of changes, usually accompanied by migrations, in their earlier stages; but these changes are in many cases only imperfectly known. In the case of the common Liver-fluke (*Distoma hepaticum*), the eggs are expelled from the intestine of the sheep which is infected by the adult worm, and give exit to a little ciliated embryo, which swims about actively in water. This bores its way ultimately into the tissues of a particular kind of Water-snail (*Limnæa truncatula*), where it becomes encysted. It then passes through a series of extraordinary changes, which cannot be described here, the ultimate result of which is the production of a number of little tadpole-like embryos, known as “cercariæ.” These escape from the body of the snail, and swim about actively for a

time in the water ; but they finally attach themselves to a blade of grass, and surround themselves with a horny capsule. If now, the encapsuled embryo should be swallowed by the sheep, along with

the grass on which it feeds, the embryo escapes from its horny covering, and makes its way from the stomach of the sheep into the bile-ducts, where it becomes developed into the adult Liver-fluke.

ORDER III. TURBELLARIA.

The Turbellarian worms differ altogether from the preceding orders of Scolecids in being mostly aquatic in their habits and in being non-parasitic. They never possess sucking-discs or cephalic hooks, and their integument is always furnished with vibrating cilia. A water-vascular system is always present, but it appears sometimes not to communicate with the exterior. The alimentary canal is sometimes simply hollowed out of the tissues and destitute of an anus, as in the *Trematoda*, and at other times suspended in a free space (body-cavity) and furnished with an anus. It may be simple or much branched.

The best known of the members of this order are certain little, soft-bodied, ovate, or elliptical creatures, which are commonly found

in fresh water or on the sea-shore, or in moist earth, and are known as *Planarians*. The skin in these curious little animals (fig. 75) is richly furnished with cilia, and also contains

numerous cells which have been compared to the "nettle-cells" or "cnidæ" of the *Cœlenterata*. The intestine may be either straight or branched, but always terminates behind in blind pouches, and is never provided with an anus. The water-vascular system communicates with the exterior. The nervous system consists of two ganglia, placed in front of the mouth, and united by a cord. There are generally rudimentary eyes or pigment-spots, which vary in number from two to sixteen.

The remaining members of the *Turbellaria* are known as Ribbon-worms (*Nemertidæ*), and are not uncommonly found in the sea, sometimes between tide-marks, sometimes at great depths, sometimes near the surface of the open ocean: occasionally they occur in moist earth. They differ from the Planarians in being worm-like in shape, by the fact that the alimentary canal is furnished with a distinct anus, and by the possession of a definite body-cavity.

SECTION B. NEMATELMIA.

ORDER I. ACANTHOCEPHALA.

The "Thorn-headed Worms" included in this order are all internal parasites. They are worm-like in shape, marked with transverse wrinkles, and destitute of any mouth or alimentary canal. The anterior extremity of the body (fig. 76) forms a kind of proboscis or snout, which is armed with recurved hooks, and has placed at its base a single nervous ganglion. Beneath the skin is a network of canals, containing a clear fluid, and believed to represent the water-vascular system. The Thorn-headed Worms include some of the most formidable parasites with which we are as yet acquainted, the best known being the various forms of *Echinorhynchus*, which are found inhabiting the alimen-

Fig. 76.—Acanthocephala. A, *Echinorhynchus gigas*, slightly enlarged. B, Head of the same, still further enlarged.

tary canal in many Mammals, birds, and fishes. About one hundred and twenty species of *Echinorhynchus* are known, but it is doubtful if any mature example has been found in the human subject.

ORDER II. GORDIACEA.

The *Gordiacea*, or "Hair-worms," are elongated, worm-like, or hair-like Scolecids, in which the alimentary canal is without an anus, and the sexes are in separate individuals.

The best known representative of this group is the common Hair-worm (*Gordius aquaticus*, fig. 77) of Europe and North America. This curious worm is often found in ponds and rivers, and may be two or three feet long when mature. Other examples are found coiled up round the intestine of ground-beetles or grasshoppers; but it is not clear whether these are in a natural position, so to speak, or whether they may not be wandered individuals. In such cases, however, the worm ultimately leaves its insect-host, and betakes itself to water, where it lays long chains of white eggs. The embryo is at first free and locomotive, with three pairs of cephalic hooks (fig. 77, B), and a little protrusible snout. It passes its next stage encysted in the larvæ of water-insects, into which it has bored its way, and then it gains access to the bodies

Fig. 77.—Gordiacea. A, A small individual of *Gordius aquaticus*, of the natural size. B, Larva of *Gordius sulfuratus*, with its piercing proboscis and two rows of hooks, enlarged.

of fishes which eat these larvæ. Ultimately, however, it becomes free, and makes its way to land.

ORDER III. NEMATOIDEA.

The order *Nematoidea* includes the typical "Round-worms" and "Thread-worms," some of which are parasitic, while others lead a permanently free existence. The body is cylindrical, the integument being often annulated, but never ciliated. The mouth is placed anteriorly (fig. 78), and leads through a gullet (*g*) to a strong

muscular pharynx (*v*). The intestine is freely suspended in the body-cavity, and a distinct anus is present. There are two lateral water-vessels which open ventrally in front by a common pore. The nervous system is a gangliated cord surrounding the gullet. The sexes are generally in separate individuals; and the males are usually fewer in number and smaller in size than the females.

Considerably more than a thousand species of Nematoid worms are known, of which a large number are permanently free. Good examples of the free Nematoids are the little "Vinegar-eel" (*Anguillula aceti*), the "Paste-eel" (*Anguillula glutinis*), and the common *Anguillula fluviatilis* of impure water.

A large number of the Nematoid worms are internal parasites, inhabiting the alimentary canal, the air-passages, the solid organs and tissues, or the blood-tubes of various animals; but it will be sufficient here to mention some of the commonest forms of these. The most abundant and familiar of these parasitic types is the common Round-worm (*Ascaris lumbricoides*), which may be six or eight inches in length, and is found inhabiting the small intestine of all races of men, but principally of children, often in great numbers. Another almost equally common type is the small Thread-worm (*Oxyuris vermicularis*), which is less than half an inch in length, and is found inhabiting the large intestine, generally near its termination. It is generally found in children; but an allied type (*Trichocephalus dispar*) is often found in the large intestine of adults. Less common than any of the preceding is the singular Guinea-worm (*Filaria medinensis*), which is confined to the intertropical regions of both

Fig. 78.—Nematoidæ. A, *Rhabditis bioculata*, female, enlarged. B, Portion of the alimentary tract of *Oxyuris vermicularis*, enlarged. *g* Gullet; *v* Muscular gizzard; *s* Chylific stomach, or anterior end of the intestine (*i*); *o o* Ovaries; *p* Genital pore.

hemispheres, and which spends a portion of its existence buried in the cellular tissue which separates the muscles. It may attain a length of several feet, and has an extraordinary but still incompletely understood history. Equally famous is the little "Muscle-worm" or *Trichina*, which attacks man, pigs, &c., and exists in two conditions. In one stage it is found buried in vast numbers in the muscles, each little worm—a thirtieth of an inch or less in length—being enclosed in a little whitish capsule. When thus encysted, the *Trichinae* have no reproductive organs and are comparatively harmless. If, however, a portion of the infected muscle be eaten by another suitable animal, the little *Trichinae* escape from their cysts and develop reproductive organs. They then produce young, in vast numbers, within the intestine of their new host; and the young bore their way through the walls of the intestine, and travel into the muscles, where they surround themselves each with a little capsule, and become quiescent. When this stage has been reached, the animal attacked is in safety; but the migration of the worms from the intestine into the muscles usually gives rise to extremely serious or even fatal constitutional disturbance.

SECTION C. ROTIFERA.

The *Rotifera*, or "Wheel-animalcules," derive their popular name from the fact that the anterior end of the body is furnished with one or two circlets of cilia (fig. 79) which, when in motion, vibrate so rapidly as to produce the illusory impression of a quickly rotating toothed wheel. The *Rotifera* are all aquatic, and are mostly inhabitants of fresh water. They are all microscopic in size, none attaining a greater length than 1-36th of an inch. In the females there is a distinct mouth, intestinal canal, and anus. A nervous system is also present, consisting of ganglia placed near the anterior extremity of the body and sending filaments backwards. There is, finally, a well-developed water-vascular system.

Most of the *Rotifera* are free-swimming active little animals (fig. 79, A), but some are permanently fixed, as in *Melicerta* (fig. 79, B) or in the Crown-animalcule (*Stephanoceros*). They are usually simple, but they are sometimes composite, forming colonies. As a rule, the male and female *Rotifera* differ greatly from one another, the males being smaller than the females, devoid of any masticatory or digestive apparatus, and more or less closely resembling the young forms of the species. The males, in fact, merely lead a transient existence, and die as soon as they have succeeded in fertilising the females. The body in most cases is very distinctly ringed or annulated (fig. 79, A), but is not composed of distinct rings separated by

partitions. The integument is usually provided with bundles of muscular fibres taking a longitudinal and transverse direction. In the free forms the anterior ciliated disc acts somewhat like the propeller of a screw-steamer in driving the organism through the water—in all cases it has the action of producing currents in the water by which particles of food are brought to the mouth. The posterior end of the body is usually developed in the free forms into a kind of tail or foot (fig. 79, A), which may take the shape of a kind of pincers or of a little suckorial disc.

As regards their internal anatomy, in the females of almost all

Fig. 79.—Rotifera. A, Diagrammatic representation of *Hydatina senta* (generalised from Pritchard): *a* Depression in the ciliated disc leading to the digestive canal; *b* Mouth; *c* Pharyngeal bulb with masticatory apparatus; *d* Stomach; *e* Cloaca; *f* Contractile bladder; *g g* Respiratory or water-vascular tubes; *h* Nerve-ganglion, giving filament to ciliated pit (*k*); *o* Ovary. B, *Melicerta ringens* (after Gosse).

the *Rotifera* there is a well-developed alimentary canal, which is completely shut off from the general cavity of the body. The mouth (fig. 79, A, *b*) opens into a dilated chamber or “pharyngeal bulb” (*c*), which contains a complicated apparatus of horny teeth. The pharynx opens into a capacious stomach (*d*), continued into an intestine which terminates by a chamber known as the “cloaca” (*e*), which forms the common outlet for the water-vascular and generative systems. In both sexes there is a well-developed water-vascular system consisting of a contractile chamber or bladder (*f*), opening into the cloaca, and giving origin to two complicated tubes which

are known as the "respiratory tubes" (*g g*), and which terminate near the anterior end of the body, apparently by blind extremities. The nervous system is in the form of a large double ganglion placed above the gullet, and having one or two eye-specks placed upon it. The ovaries (*o*) constitute conspicuous organs in the female *Rotifera*, but in summer the young Rotifers appear to be produced by the females without having access to the males.

The *Rotifera* were long confounded with the *Infusoria*, in consequence of their great similarity in external appearance. They are, however, fundamentally distinguished from the Infusorians by their possession of a definite body-cavity, the presence of a well-developed alimentary canal, and the possession of a nervous system and of proper reproductive organs, while their development is also quite different.

CHAPTER XII.

ANARTHROPODA.

THE *Anarthropoda* or higher groups of the Worms have the body distinctly segmented, but the segments are generally numerous (often indefinite in number), and are mostly similar to each other except at the two extremities of the body. Lateral appendages may be wanting ; but when they are present, they are not articulated, nor are they jointed to the body. The nervous system has the form of

Fig. 83.—Gephyrea. *Sipunculus Indicus*, of the natural size. (After Keferstein.)

a ventral chain of ganglia, the first pair of ganglia lying above the gullet. Cilia are generally developed. There is no proper heart or system of blood-vessels ; but there is generally a system of tubes, filled with a coloured fluid, often furnished with contractile dilata-tions, and sending branches to the breathing organs, which take the

place of the proper vascular system, and which are known as the "pseudohæmal" vessels.

The two principal groups included in this division of Annulose animals are the *Gephyrea* (Spoon-worms) and the *Annelida* (Ringed Worms).

CLASS I. GEPHYREA.

This is a small group, including a number of worm-like animals, commonly called Spoon-worms, which in many respects resemble the Annelides, and have at the same time certain relationships with the Holothurians among the Echinoderms. They differ from the Annelides in not having the body definitely segmented, though the skin is annulated (fig. 80), and also in the fact that the ventral nerve-chain is not gangliated. There are no lateral appendages, except occasionally bristles. They differ from the Holothurians in the want of an ambulacral system and the non-radiate character of the nervous system. The Spoon-worms are all marine, and the most widely distributed genus is *Sipunculus* (fig. 80), which ranges from between tide-marks down to a depth of 2500 fathoms.

CLASS II. ANNELIDA.

The *Annelida* or *Annulata*, commonly known as Ringed Worms, are distinguished by the possession of definite segmentation, the body being composed of a number of rings which are all similar to each other except at the two ends of the body. All the *Annelida* are more or less worm-like in shape, and in all except the Leeches, the segments are (some or all) provided with lateral appendages which mostly subserve locomotion, but which are never jointed to the body. In the typical *Annelida* each segment (fig. 81) consists of two arches, termed, from their position, respectively the "dorsal arc" (*d*), and the "ventral arc" (*v*). Each segment carries a lateral process on each side, which are known as the "foot-tubercles" (*parapodia*). Each foot-tubercle in turn may consist of an upper piece or "dorsal oar" (*a*), and a lower piece or "ventral oar" (*b*), both carrying a tuft of bristles and a soft jointed filament (the "cirrus").

The nervous system consists essentially of a double gangliated chain placed along the ventral surface of the body, and traversed in front by the gullet, so that the first pair of ganglia lie above the gullet. The digestive system consists of a mouth, generally with a protrusible proboscis, and sometimes horny jaws, a gullet, stomach, intestine, and a distinct anus. As a rule, the alimentary canal runs straight from one end of the body to the other without describing

any convolutions in its course. In almost all cases the alimentary tube is placed in a distinct perivisceral cavity, which contains a fluid with solid particles in it, corresponding to the blood of the higher animals. In most, if not all, there is further a system of vessels which carry a coloured fluid, which are contractile, and which send branches to the respiratory organs, when these exist. This system is believed not to correspond to the blood-vascular system of the higher animals, and it has therefore been termed the "pseudo-hæmal" system (Gr. *pseudos*, falsity; and *haima*, blood). It is believed, on the other hand, to be truly homologous with the water-vascular system of the *Scolecida*. Respiration is effected by the general surface of the body, or by distinct gills or branchiæ. In

Fig. 81.—Diagrammatic transverse section of an Annelide. *d* Dorsal arc; *v* Ventral arc; *n* Branchiæ; *a* Notopodium, or dorsal oar; *b* Neuropodium, or ventral oar, both carrying setæ and a jointed cirrus (*c*).

most cases, also, there exists a series of peculiar tubular involutions of the integument, which are known as the "segmental organs." The segmental organs open on the surface of the body by minute apertures, and generally have the form of coiled or folded tubes, which may terminate blindly internally (Leeches), or which open at their inner ends into the perivisceral cavity. In the latter case, the internal openings of the "segmental organs" are usually funnel-shaped and ciliated, and they often serve to convey the generative products to the exterior. The "segmental organs" correspond, in a general way, with the kidneys of the higher animals. The sexes in the *Annelida* are sometimes distinct, sometimes united in the same

individual. The embryos are almost always ciliated, and many of them pass through a metamorphosis.

The so-called "Abranchiate" Annelides are the Leeches and Earth-worms, in which respiration is carried on principally through the soft moist integument. On the other hand the marine Tube-worms and Sand-worms possess, as a rule, external processes adapted for respiration in water, and these are known as the "Branchiate" Annelides.

ORDER I. HIRUDINEA.

The *Hirudinea* or *Discophora* are well known under the name of Leeches, some forms being marine, while others inhabit fresh water, and a few live in moist places on land. The Leeches are characterised

Fig. 82.—Hirudinea. *a* The Medicinal Leech (*Sanguisuga officinalis*), natural size; *b* Anterior extremity of the same magnified, showing the sucker and triradiate jaws; *c* One of the jaws detached, showing the semicircular toothed margin.

by the fact that the body is destitute of lateral bristles or foot-tubercles, but is provided with a sucking-disc at one or both extremities. In the typical forms, as in the common Medicinal Leech (fig. 82), there are sucking-discs at both ends of the body, and in those in which only the hinder sucker is present, the head can be converted into a suctorial cavity. Locomotion is effected either by means of the alternate fixation and detachment of the suckers, or by a serpentine bending of the body.

The body is obviously ringed or annulated, but none of the rings carry lateral appendages of any kind. The mouth is sometimes destitute of teeth, but is sometimes armed with complex jaws. The alimentary canal is short, with lateral pouches, and united to the skin by means of a spongy vascular tissue, so that the body-cavity is obliterated. The pseudo-hæmal system is well developed, and consists essentially of four great longitudinal vessels. The segmental organs are partially tubular and partially saccular, and open on the lower surface by minute pores, while they terminate blindly internally. The nervous system has its usual form, and the ganglia in front of the gullet ("pre-oesophageal" ganglia) give off branches to a number of simple

eyes which are placed on the head. The sexes are united in the same individual.

The most familiar of the Leeches are the common Horse-leech (*Hæmopsis*), and the Medicinal Leech (*Sanguisuga officinalis*). The latter is provided with three semicircular toothed jaws (fig. 82, *b*, *c*), which meet in a point, and are sufficiently powerful to cut through the human skin. The Medicinal Leech is a native of fresh waters throughout the south and east of Europe, and it is imported in large numbers from Hungary, Bohemia, and Russia.

In the Horse-leech the jaws are comparatively blunt, and the animal has only the power of cutting through the soft mucous membranes. It derives its name from the fact that it attaches itself to the mucous membrane of the mouth in horses whilst drinking at ponds or marshes.

ORDER II. OLIGOCHÆTA.

• • In this order are included the Earth-worms (*Lumbricidæ*), and the Water-worms (*Naïdidae*). They are all distinguished from the preceding by the fact that the body is furnished with rows of bristles (fig. 83, *A*), which take the place of the foot-tubercles of the higher *Annelida*, and which are the organs of locomotion. They are distinguished from the higher forms by the fact that the locomotive bristles are comparatively few in number, hence the modern name of the order (Gr. *oligos*, few; and *chaîté*, a bristle). In the common Earth-worm (*Lumbricus terrestris*, fig. 83, *B*), the body is cylindrical, attenuated at both ends, and furnished with eight rows of short locomotive bristles. The mouth is destitute of teeth, and opens into a gullet which leads to a muscular crop, succeeded by a second muscular dilatation or gizzard. The intestine is continued straight to the anus, and is constricted in its course by numerous transverse partitions springing from the walls of the body-cavity, and corresponding with the successive segments of the body. The pseudohæmal system is well developed, and the dorsal vessel carries a series of contractile dilatations or "hearts." The segmental organs are long coiled tubes, which open by minute apertures on the ventral surface, and communicate internally with the body-cavity. The *Naïdidae* are chiefly noticeable on account of the power which many of them possess of producing fresh individuals by a process of budding before they attain sexual maturity. One of the commonest of them is a little worm (*Tubifex rivulorum*, fig. 83, *A*), which occurs abundantly in many of our pools and streams, and which exhibits a fine red colour, owing to the

pseudohæmal system being visible through the transparent integument.

Fig. 83. Oligochaeta. (After Lankester.)

ORDER III. POLYCHAETA.

In the so-called Polychætous Annelides, the animal is furnished with locomotive organs in the form of "foot-tubercles," carrying tufts of bristles (fig. 81). Branchiæ are generally present, in the form of outgrowths of the integument, richly supplied with branches of the pseudohæmal vessels. The Polychætous Annelides are all marine, and are of very varied habits. They may be con-

veniently divided into two groups, according as they secrete for themselves a protective tube (*Tubicola*), or live a free life (*Errantia*); but the general organisation in these two sections is essentially the same.

The Tubicolous Annelides or Tube-worms derive their name from the fact that they have the power of protecting themselves by means of tubes (Lat. *tuba*, a tube; and *colo*, I inhabit). In some cases (fig. 84) the tube is composed of carbonate of lime, and is a genuine secretion from the body. In other cases, the tube is composed of grains of sand or pieces of broken shell, cemented together by a glutinous secretion from the surface of the body. In all the *Tubicola* the respiratory organs are in the form of branched filamentous external gills, in which the fluid of the pseudohæmal system is subjected to the action of the outer water. They are therefore "Branchiate" Annelides. As they live in tubes, however, and do not voluntarily expose more than the anterior end of the body, the branchiæ are all placed on or near the head. The filaments of which the gills are composed (fig. 84, *a*) are richly ciliated, and as the pseudohæmal fluid is usually red, they have generally a beautiful scarlet colour.

The most familiar of the *Tubicola* is the *Serpula* (fig. 84, *a*), the contorted and winding tubes of which must be known to every one as occurring on shells or stones on the sea-shore. One of the cephalic filaments in *Serpula* is much developed, and its extremity forms a kind of conical plug or "operculum," which serves to close the mouth of the tube when the animal is retracted within it. In *Spirorbis* (fig. 84, *b*) the shelly tube is coiled into a flat spiral, which is fixed to some solid object. It is of extremely common occurrence on the fronds of sea-weed, and on other submarine objects.

The so-called "Errant" Annelides (Lat. *erro*, I wander) are so called because of their "roving" habits, the animal leading a free existence, and not being confined in a tube (fig. 85). They have always lateral unjointed appendages, or foot-tubercles, which carry tufts of bristles, and a soft jointed filament or cirrus. The anterior rings of the body are usually so modified as to form a sort of head,

Fig. 84.—*Tubicola*. *a* *Serpula contortuplicata*, showing the branchiæ and operculum; *b* *Spirorbis communis*.

which is provided with eyes and with two or more feelers, which differ from the antennæ of Insects and Crustaceans in not being jointed. The mouth is placed on the inferior surface of the head, and is sometimes furnished with one or more pairs of horny jaws which work from side to side. The upper part of the alimentary canal is muscular, and can be turned inside out, or protruded beyond the true opening of the mouth. The pseudohæmal system is well developed, and its contained fluid is mostly red. Respiration is

Fig. 85.—*Cerrothulus grandis*, an "Errant Amelide," in its living condition.
(After Verrill.)

effected by external processes, gills or branchiæ, arranged in tufts placed along the sides or back of the body, and not confined to the immediate neighbourhood of the head, as in *Tubicola*. The sexes are in different individuals, and the young pass through a metamorphosis.

Amongst the best known and commonest of the Errant Amelides are the common Lob-worm (*Arenicola piscatorum*); the Sea-centi-

pedes (*Nereis*); and the Sea-mice (*Aphrodite* and *Polynoe*), some of which attain a large size, and are conspicuous for their iridescent bristles. Other less abundant forms may be readily obtained by searching under stones at low water. In one remarkable Annelide, from the Philippine Islands, the body is branched, and thus becomes truly composite. A few of the Errant Annelides live in the open ocean.

CHAPTER XIII.

ARTHROPODA.

1. GENERAL CHARACTERS OF THE ARTHROPODA. 2. CHARACTERS AND DIVISIONS OF THE CRUSTACEA.

THE remaining members of the sub-kingdom *Annulosa* are distinguished by the possession of *jointed appendages, articulated to the body*; and they form a great primary division—often called by the name *Articulata*. As this name, however, has been employed in a wider sense than is understood by it here, it is perhaps best to adopt the more modern term *Arthropoda*.

The members of this division, comprising the *Crustacea* (Lobsters, Crabs, &c.), the *Arachnida* (Spiders and Scorpions), the *Myriapoda* (Centipedes), and the *Insecta*, are distinguished as follows:—

The body (fig. 71) is composed of a series of segments, arranged along a longitudinal axis; each segment or “somite,” occasionally, and some almost always, being provided with articulated appendages. Both the segmented body and the articulated limbs are more or less completely protected by a chitinous exoskeleton, formed by a hardening of the cuticle. The appendages are hollow, and the muscles are prolonged into their interior. The nervous system in all, at any rate in the embryonic condition, consists of a double chain of ganglia, placed along the ventral surface of the body, united by longitudinal commissures, and traversed anteriorly by the œsophagus. The blood-system, when differentiated, is placed dorsally, and consists of a contractile cavity, or heart, provided with valvular apertures, and communicating with a perivisceral cavity, containing corpusculated blood. Respiration is effected by the general surface of the body, by gills, by pulmonary sacs, or by tubular involutions of the integument, termed “tracheæ.” In no member of the division are vibratile cilia known to be developed.

The *Arthropoda* are divided into four great classes—viz., the

Crustacea, the *Arachnida*, the *Myriapoda*, and the *Insecta*; which are roughly distinguished as follows:—

1. CRUSTACEA.—*Respiration by means of gills, or by the general surface of the body. Two pairs of antennæ. Locomotive appendages more than eight in number, borne by the segments of the thorax, and, usually, of the abdomen also.*

2. ARACHNIDA.—*Respiration by pulmonary vesicles, by tracheæ, or by the general surface of the body. Head and thorax united into a cephalothorax. Antennæ (as such) absent. Legs eight. Abdomen without articulated appendages.*

3. MYRIAPODA.—*Respiration by tracheæ. Head distinct; remainder of the body composed of nearly similar somites. One pair of antennæ. Legs numerous.*

4. INSECTA.—*Respiration by tracheæ. Head, thorax, and abdomen distinct. One pair of antennæ. Three pairs of legs borne on the thorax. Abdomen destitute of limbs. Generally two pairs of wings on the thorax.*

CLASS I. CRUSTACEA.

The members of this class are commonly known as Crabs, Lobsters, Shrimps, Prawns, King-crabs, Barnacles, Acorn-shells, Wood-lice, &c. They are nearly allied to the succeeding class of the *Arachnida* (Spiders and Scorpions), but are distinguished by their adaptation to a more or less purely aquatic life, by having jointed appendages upon the hinder segments of the body (abdomen), and by the possession of two pairs of antennæ. As a class, the *Crustacea* are distinguished by being usually furnished with branchiæ, or respiratory organs adapted for breathing air dissolved in water, by having more than four pairs of legs, by having a well-developed chitinous or partially calcareous “crust” or external skeleton, by the fact that some of the appendages are generally so modified as to act as organs of mastication, and by passing through a metamorphosis before attaining their adult condition.

The body in a typical Crustacean is composed of *twenty-one* distinct segments or somites, placed one behind the other. These segments are distributed in three distinct divisions, known respectively as the “head,” the “thorax” and the “abdomen” or tail, each of which is usually regarded as being composed of seven segments. In very many cases, however, the fourteen segments belonging to the head and thorax are amalgamated together into a single mass, which is termed the “cephalothorax,” thus leaving seven segments to the abdomen.

Each segment or “somite” (fig. 86) may be regarded as com-

posed of a convex upper plate (*t*) and a flatter ventral arch (*s*), and each may support a single pair of appendages. Typically, each appendage in a Crustacean consists of a short basal portion or "protopodite" (fig. 86, *a*), which

Fig. 86.—The third abdominal segment of the Lobster. *t* Dorsal arch; *s* Ventral arch of the segment; *a* Protopodite; *b* Exopodite; *c* Endopodite.

gives origin to an outer and an inner branch or division, known respectively as the "exopodite" (*b*) and the "endopodite" (*c*). Very commonly one of the two divisions of the appendage may be wanting; or in some cases both are absent, and the appendage may be reduced to the protopodite only. A certain number of the appendages of the anterior segments are usually converted into masticating organs, some of which may be proper biting jaws (mandibles and maxillæ), while others are merely limbs so far modified as to act as subsidiary jaws ("foot-jaws" or maxillipedes).

The last segment of the body—known as the "telson"—carries no appendages, and is often regarded as not being properly a segment, but an unpaired appendage.

The *Crustacea* form an extremely large group of animals divided into many orders, and it will be sufficient to merely notice many of these in the briefest manner. It will also be as well to commence with the consideration of the higher sections of the class first.

ORDER DECAPODA.

The *Crustacea* included in this order derive their name from the fact that they all possess five pairs of legs (Gr. *deka*, ten; *podes*, feet). They belong to a large section known as the "stalk-eyed" Crustaceans (*Podophthalmata*), from the fact that the eyes are supported by long, movable stalks. They all further have the cephalothorax covered by a great shield or "carapace," under which the gills are carried. They include the Lobsters, Shrimps, Cray-fish, Crabs, Hermit-crabs, and other forms, and are the most highly organised and most familiar of the whole class of the *Crustacea*. They are divided into three very well marked groups or tribes, all of which can be exemplified by familiar types.

A. Macrura.—The name of *Macrura* (Gr. *makros*, long ; and *oura*, tail) is given to those ten-footed Crustaceans which have a long and well-developed tail or abdomen. Amongst these are the Lobster, Shrimp, Prawn, and Cray-fish, of which the Lobster or Cray-fish may be selected as a good typical example.

In the Lobster or Cray-fish (fig. 87) the body is at once seen to be composed of two parts, familiarly called the “head” and “tail.”

Fig. 87.—The common Cray-fish (*Astacus fluviatilis*), viewed from below. *a* Antennules; *b* Large antennae; *c* Eyes; *d* Opening of auditory sac; *e* Last pair of foot-jaws; *f* One the great chelæ; *g* Fifth thoracic limb; *h* Swimmerets; *i* The last pair of swimmerets; *j* The opening of the anus below the telson.

Fig. 88.—Masticatory organs of the Cray-fish (*Astacus fluviatilis*). *a* Mandibles; *b* Maxillae; *c* Second pair of maxillae; *d* First pair of foot-jaws; *e* Second pair of foot-jaws; *f* Third pair of foot-jaws.

The so-called head is covered by a great shield termed the “carapace,” and it is in reality the cephalothorax, being composed of the amalgamated segments which belong to the true head and to the thorax. The so-called tail is really the abdomen, and it is composed of a number of segments which are not immovably united together,

as in the cephalothorax, but are movably jointed together. The various appendages of the animal are arranged in pairs on the under surface of the body ; and where the segments are completely amalgamated (as in the cephalothorax), their existence may nevertheless be determined by the presence of the successive pairs of appendages. The first segment of the head carries a pair of compound eyes, made up of a number of simple lenses aggregated together, and supported upon long and movable eye-stalks. Behind these come two pairs of jointed organs of touch, which are known as the "antennæ." The front pair is much smaller than the hinder pair, and they are known respectively as the "lesser antennæ," or "antennules" (fig. 87, *a*), and the "great antennæ" (*c*). Behind these, again, comes the mouth, which is placed on the under surface of the head, and is provided with a complicated series of masticatory organs. It is unnecessary to describe these minutely, but it should be noticed that they are all modified limbs, and therefore differ altogether from the jaws of the Vertebrate animals. That this is their real nature is shown most obviously in the hindermost pairs of these jaws, which are so little altered from ordinary legs that they are known as "foot-jaws" (fig. 88, *f*). The last five segments of the thorax carry five pairs of walking-legs, hence the name *Decapoda* applied to the order. Of these legs, the first three pairs have their extremities converted into nipping-claws or "cheke," and the first pair is much larger than the others, and constitutes the well-known great claws of the Lobster. The last two pairs of legs simply terminate in pointed extremities, and not in pincers. The segments of the abdomen, with the exception of the first and the hindmost, carry each a pair of paddle-like appendages, which are used in swimming, and are called the "swimmerets." The last pair of swimmerets are attached to the last segment but one, and are very greatly expanded, so as to form a very powerful tail-fin (fig. 87, *i*). The last segment of all is known as the "telson" (*j*), and is not provided with any lateral appendages.

The mouth in the Lobster leads by a short gullet into a globular stomach, which is furnished with a calcareous apparatus for grinding down the food, commonly called the "lady in the lobster." The intestine is continued backwards from the stomach without convolutions, and opens by a distinct anus placed in front of the telson. A well-developed liver is also present. The heart is placed dorsally, and is filled with aerated blood derived from the gills, which it propels through every part of the body. The gills, or branchiæ, are pyramidal bodies attached to the bases of the legs, and placed in a kind of chamber formed beneath the great shield, or carapace, on each side of the body. They consist each of a central stem support-

ing numerous lateral branches, and they are richly supplied with blood. The water which fills the gill-chambers is constantly renewed by the movements of the legs, and thus the gills are kept constantly supplied with fresh water. The nervous system is placed along the ventral surface of the body, and has its usual form. The organs of sense are the two pairs of feelers or antennæ, the compound eyes, and two organs of hearing.

B. Anomura.—The most familiar members of this tribe are the Hermit-crabs (*Paguridæ*) which occur so commonly on every shore.

Fig. 89.—Brachyura. The Spiny Spider-crab (*Maia squinado*).

They are distinguished by the fact that the abdomen is quite soft, and is not protected by a chitinous crust. The animal, therefore, is compelled to protect the defenceless part of the body in some artificial manner, and this it effects by appropriating the empty shell of some dead Mollusc, such as the common periwinkle or whelk. The abdomen is provided with special appendages to enable the intruder to retain firm hold of his borrowed dwelling, at the same time that he can change it at will when too small or otherwise inconvenient.

The first pair of legs are developed into pretty powerful nipping-claws or chelæ, and one of them is always much larger than the other, and acts as a kind of plug, blocking up the entrance of the shell when the animal is retracted within it.

C. Brachyura.—The Decapod Crustaceans included in this tribe are familiarly known as Crabs, and they derive their name of *Brachyura* (Gr. *brachus*, short; and *oura*, tail) from the rudimentary condition of the abdomen. The abdomen, in fact, is not only extremely short, but it is always tucked up beneath the greatly developed cephalothorax, so that it is not visible at all, except when the animal is looked at from below (fig. 89). The Crabs have very various habits, but they are mostly denizens of the shore, hiding beneath stones or sea-weed, in cracks of rock, or in pools near the line of low-water. Some of them, however, can swim with tolerable activity, and some

of them (the Land-crabs) even live habitually inland. One group, that of the "Pea-crabs," is distinguished by the singular habit of living semi-parasitically within the shells of bivalve Molluscs, such as the great horse-mussel or the oyster.

The young or larval Crab is exceedingly unlike the adult, and has a long and well-developed abdomen, thus approximating to the type of structure which is permanently retained in the *Macrura*.

Fig. 90. —*Squilla mantis*, the Locust-Shrimp.

ORDER STOMAPODA.

The Stomapod Crustaceans are nearly allied to the Decapods, but they have six or eight pairs of legs, and the gills are not placed in chambers on the under surface of the thorax, but are usually suspended beneath the abdomen. They are almost all marine, and the Locust-Shrimp or *Squilla* (fig. 90) may be taken as the type of the order. In

this Crustacean the abdomen is well developed, and its terminal appendages form a broad swimming-tail. The front pairs of legs are hooked, and the gills are attached to the first five pairs of abdominal feet.

ORDER ISOPODA.

In this order are a number of Crustaceans, of which some inhabit the sea, others are parasitic in their habits, and others are terrestrial. Of the terrestrial forms the common Wood-lice (*Oniscus*) are familiar examples. Of the aquatic types, the Water-slaters (*Asellus*) inhabit fresh waters; but the Rock-slaters (*Ligia*) and Box-slaters (*Idotea*) are marine, as are many others. The parasitic forms live upon fishes or other Crustaceans, and have often become much altered by retrograde metamorphosis.

Fig. 91.—Isopoda. A, *Idotea entomon*, enlarged. B, *Arcturus longicornis*, enlarged. C, *Serolis Scythei*. a Antennules; an Antennae. (After Gerstaecker, Spence Bate and Westwood, and Lütken.)

The Isopod Crustaceans all belong to a section of the class *Crustacea*, in which the eyes are not supported upon movable stalks, and they are therefore said to be “sessile-eyed” (*Hedriophthalmata*). The head is distinct, and the thorax carries *seven* pairs of legs; while the branchiæ are attached to the under surface of the abdomen, the segments of which are often coalescent.

ORDER AMPHIPODA.

This order comprises small Crustaceans, in which the breathing-organs are in the form of membranous vesicles attached to the bases

of the thoracic legs. There is a well-developed abdomen, and there are seven pairs of thoracic legs, directed partly forwards and partly backwards. Good examples are the Sand-hoppers (*Talitrus*, fig. 92, A) and the "Fresh-water Shrimps" (*Gammarus*, fig. 92, B).

The Sand-hoppers and *Gammarus* swim on their side when in the water, and the former leap with great activity on land.

Fig. 92.—Amphipoda. A, *Talitrus locusta*, the "Sand-hopper," enlarged. B, *Gammarus locusta*, enlarged about four times. (After Spence Bate and Westwood.)

Nearly related to the Amphipods are a number of little Crustaceans (*Leiodipoda*), in which the abdomen is quite rudimentary. Some of these (e.g., the Whale-lice) are parasitic in their habits, and all inhabit the sea.

ORDER MEROSTOMATA.

In this order are only the living King-crabs (*Limulus*), and some large extinct forms nearly allied to them. They are all distinguished by the fact that the appendages which are placed round the mouth act by their bases as jaws, but have their extremities developed into swimming-paddles, walking-feet, or nipping-claws.

The King-crabs (fig. 93) constitute a special group called *Xiphosura* (Gr. *xiphos*, a sword ; and *oura*, tail), from the fact that the end of the abdomen is furnished with a long sword-like spine (fig. 93, *t*). The mouth is surrounded by six pairs of appendages, the bases of which are spinous and act as jaws, whilst their free extremities are developed into nipping-claws or chelæ. The whole of the upper sur-

Fig. 93.—Xiphosura. *Limulus polyphemus*, viewed from below.

Fig. 94.—Eurypterida. *Pterygotus Anglicus*, restored. (After H. Woodward.)

face of the body is protected by a kind of buckler, composed of an anterior semicircular shield, and a posterior somewhat hexagonal plate, the under surface of which carries branchial plates, whilst the sword-like telson is jointed to its hinder margin. The King-crabs attain a large size, and are often called “Molucca crabs” from their occurrence in the Moluccas. Both the eggs and the flesh are eaten by the Malays.

Closely allied to the King-crabs is the extinct sub-order of the *Eurypterida*, an example of which is figured above (fig. 94). This particular species is supposed to have attained a length of probably six feet, but other forms were very much smaller.

ORDER TRILOBITA.

The Trilobites constitute a wholly extinct order of the *Crustacea*, and deserve a short notice from their great geological importance. They derive their name from the fact that the body exhibits a more or less conspicuous division into a central and two lateral lobes (fig. 95). The entire shell or crust is composed of an anterior semi-

Fig. 95.—*Olenus micurus*.
(After Salter.)

circular shield, covering the head, a series of movable rings constituting the thorax, and a tailpiece composed of amalgamated segments, and representing the abdomen. On the under surface of the shell nothing had until lately ever been discovered except the upper lip, but recently limbs and branchiæ have been made out. The cephalic shield usually bears a pair of compound eyes, but these are sometimes wanting. It is known that most of the Trilobites possessed the power of rolling themselves up into a ball, much as our modern wood-lice.

The Trilobites are only known as occurring in the older rocks of the earth's crust, and they are chiefly characteristic of the period known to geologists as the "Silurian."

ORDER PHYLLOPODA.

This is a small order comprising a number of Crustaceans, which are principally found in inland waters, whether fresh or salt, only one form inhabiting the sea. These Crustaceans (fig. 96) have

Fig. 96.—Phyllopus. Fairy Shrimp (*Chirocephalus*, or *Branchipus diaphanus*).
(After Baird.)

numerous feet, never less than sixteen in number, and the feet are mostly expanded and leaf-like, and serve as gills or breathing-organs. The body may be naked, or the head and thorax may be covered by

a shield, or the animal may be enclosed within a bivalve shell. To this order belong the curious "Brine-shrimps" (*Artemia*), which are found in the brine-pans of salt-works, or in salt lakes.

ORDERS CLADOCERA, COPEPODA, AND OSTRACODA.

These orders deserve mention more from the extreme abundance of their commoner forms than for any other reason. They include a number of minute Crustaceans, most of which are commonly called "Water-fleas," and which abound both in fresh and in salt water, in almost all regions of the globe. They are, however, mostly so small that, though visible to the eye, they can only be satisfactorily examined under the microscope. As an example of the *Cladocera* may be taken the "Branched-horned Water-flea" (*Daphnia pulex*, fig. 97, *b*), thousands of which may be captured in any pond in summer. In this pretty little species the whole body is enclosed in a bivalve shell, which is so transparent that the whole organisation

Fig. 97.—Fresh-water Entomostraca. *a* *Cypris tris-striata*; *b* *Daphnia pulex*; *c* *Cyclops quadricornis*.

of the animal is clearly visible through it. The head is distinct, and carries a single eye. The greater antennæ are branched. The males are smaller than the females, and much fewer in number; and it appears to be a well-established fact that the female, when once fertilised by the male, can not only lay eggs for the rest of her life, but can transmit the power of producing fertile ova to her young for several generations. Of the *Copepoda* one of the commonest is the *Cyclops* (fig. 97, *c*), in which the cephalothorax is covered by a shield, and there is a well-developed abdomen. The female carries on either side a kind of pouch or ovisac, in which the eggs remain till they hatched. The little *Ostracoda* (fig. 97, *a*), are all minute

Crustaceans, which occur in both fresh and salt water. They are distinguished by the fact that the body is entirely enclosed in a shell, which is made up of two lateral halves or valves. The valves of the shell are united by a membrane along the back, but can be opened below, so as to allow of the protrusion of the feet.

Fig. 98.—Female of *Achtheres Carpenteri*, magnified. The line placed alongside of the figure shows the real size. *a* Abdomen; *d* Disc of attachment developed upon the last pair of thoracic limbs; *o* Ovisac.

Very closely related to the Copepods is a group of curious Crustaceans, which are often called "Fish-lice" (*Ichthyophthira*), because in their adult condition they are attached parasitically to the skin, eyes, or gills of fishes. The males, however, are usually free.

In its parasitic condition (fig. 98), the animal is more or less swollen and deformed, its limbs being often rudimentary, and the segmentation of its body obscured or lost. They are firmly fixed, in various ways, to their hosts, and the females carry large external bags of eggs (ovisacs). The young of

the Fish-lice, however, have well-developed limbs and eyes, and lead an active locomotive existence.

ORDER CIRRIPEdia.

The last order of *Crustacea* is that of the *Cirripedia* (Lat. *cirrus*, a curl; and *pes*, foot), comprising the so-called Barnacles and Acorn-shells, both extremely unlike Crustaceans to look at. All the Cirripedes are distinguished by the fact that, whilst they are quite free when young, and very similar to some of the little Crustaceans just described, when adult they are immovably fixed by their heads to some solid object. In this fixed condition the body and internal organs are, in most cases, protected by means of a calcareous shell, composed of many pieces, and the only part of the body which remains movable is the legs, which are constantly thrust out of the shell and again drawn in in quest of food. The *Cirripedia* were formerly described as: "multivalve" shell-fish (*Mollusca*), owing to

their common possession of a regular calcareous shell. Two distinct types of structure are known amongst the *Cirripedia*, constituting the two families of the Barnacles (*Lepadidæ*), and the Acorn-shells (*Balanidæ*).

In the Barnacles (fig. 99), the anterior end of the body is much elongated, and is converted into a kind of stalk, by means of which the animal is attached to some solid object, such as a rock, a floating log of timber, or even some marine animal. In the Acorn-shells (fig. 100) which occur in myriads upon every solid object between tide-marks, there is no stalk, but the head is firmly cemented to the

Fig. 99.—Two fully-grown individuals of the common Barnacle (*Lepas anatifera*), growing upon a foreign body. *p* The stalk of attachment; *c* The body of the animal enclosed in a shell, from which the legs can be protruded.

Fig. 100.—A, Acorn-shell (*Balanus balanoides*), of the natural size, viewed from above. B, *Balanus*, with the shell on one side removed, to show the animal inside; *a* and *b* Two of the plates forming the lid of the shell.

centre of a membranous or shelly plate. The body is enclosed in a limpet-shaped or conical shell, composed of several pieces, and having an aperture at its summit. This opening is closed by a movable lid, and from it the animal can protrude its delicate legs or “cirri,” which look like a “glass hand,” and are constantly employed in sweeping the water in search of food.

In accordance with the fixed condition of the adult, almost all the *Cirripedia* are hermaphrodite, possessing both male and female organs of reproduction. In some cases, however, males exist, but

these are much smaller than the females, and quite different from them in appearance, and they spend their existence within the shell of the female.

Greatly as the Cirripedes are metamorphosed, when compared with the typical Crustaceans, they are not so entirely altered as are the nearly allied animals known as the *Rhizocephala*. These singular Crustaceans are fixed parasitically to the under side of the abdomen of crabs and hermit-crabs, the body being a mere muscular sac, with no indications of limbs or of segmentation, attached to its host by means of branched root-like processes of attachment, which sink deeply into the tissues of the latter. The young of these degraded Crustaceans have, however, limbs and organs of vision, and swim about actively in the water.

CHAPTER XIV.

ARACHNIDA.

CLASS II. ARACHNIDA.

THIS class includes the Mites, Ticks, Scorpions, and Spiders, and, as a whole, is very nearly related to the preceding. The *Arachnida*, however, are distinguished from the *Crustacea* by being adapted in most cases for a strictly terrestrial life, so that when any distinct breathing-organs are present these are never in the form of gills, but are always either pulmonary sacs or air-tubes (*tracheæ*). In none of the *Arachnida*, further, are there ever more than four pairs of legs, and *the segments of the abdomen never carry locomotive limbs of any sort*. The eyes are sessile, and are never supported upon stalks; *the antennæ are converted into jaws or pincers; and the head is always amalgamated with the thorax, so as to form a cephalothorax*.

The integument usually produces chitine more or less abundantly, so as to constitute a resistant shell; but in some cases the skin remains permanently soft. The mouth is situated in the anterior portion of the body, and in the higher forms is furnished with a pair of prehensile jaws, called "mandibles," a pair of chewing-jaws, called "maxillæ," and a lower lip. In the Scorpions an upper lip is present as well. In the true Spiders each mandible terminates in a sharp movable hook (fig. 104, B), perforated by a canal which communicates with a poison-gland situated near its base. By means of this poison apparatus the spiders kill such animals as they capture. In the Scorpions the mandibles are short, and terminate in strong pincers (fig. 101, c). In them, too, the maxillæ are furnished with enormously developed nipping-claws or *chelæ*. In all the *Arachnida* the mandibles are believed to correspond to the antennæ of the *Crustacea*. In the lower *Arachnida*, such as the Ticks, the organs of the mouth are modified partly for piercing, and partly for suction.

The mouth in the *Arachnida* opens into a pharynx, which is of very small diameter in the true Spiders, which live simply on the

juices of their prey. The intestinal canal is usually short and straight, and is continued without convolutions to the aperture of the anus. Salivary glands are also present, as well as ramified tubes ("Malpighian tubes") which are believed to act as kidneys.

The circulation is maintained by means of a dorsal heart, which is situated above the alimentary canal. The typical *Arachnida*

Fig. 101.—Pedipalps. A, *Scorpion ofer*, viewed from above, and somewhat reduced in size. B, Front portion of the head of the same, viewed from above, and enlarged. C, *Butkus Kochii*, with the terminal segments and the ends of the appendages on one side omitted. *m* Maxillary palpi (behind these are the four pair of ambulatory legs); *c* Chelicerae; *t* Telson; *o* Lateral ocelli; *o'* Central, larger ocelli; *g* Opercular plate, covering the opening of the reproductive organs; *r* One of the "combs;" *s* One of the openings into the pulmonary sacs. (C is after Prof. Ray Lankester.)

breathe air directly, and the function of respiration is performed by the general surface of the body (as in the lowest members of the class), or by branched air-tubes termed "tracheæ," or by distinct pulmonary chambers or sacs, or, lastly, by a combination of tracheæ with pulmonary sacs. The tracheæ are essentially similar in struc-

ture and function to the breathing-tubes of the *Myriapoda* and *Insecta*, and consist of tubes, which open on the surface of the body by distinct apertures called "spiracles," or "stigmata," and ramify through the tissues internally. The walls of the tubes are prevented from collapsing by means of a spirally coiled thread or filament of chitine, which is wound round their walls within their inner lining. The pulmonary sacs which occur in the *Arachnida* are simple chambers formed by an inversion of the skin, which constitutes a number of closely set plates or folds. The whole of the interior of the pulmonary sacs is richly supplied with blood, and air is admitted by means of external openings (fig. 101, C).

The nervous system is of the regular Articulate type, but the ganglia of the ventral chain are often massed together in particular situations. In no case are compound eyes present; and when distinct organs of vision exist, these are in the form of from two to eight or more simple eyes.

ORDERS OF THE ARACHNIDA.

ORDER I. Podosomata.

In this order are included the "Sea-spiders" (*Pycnogonum*, *Nymphon*, &c.), which are wholly marine, and are often regarded as referable to the *Crustacea*. They possess four pairs of legs, and upon this ground they have been generally placed in the *Arachnida*. In some forms the legs attain an extraordinary length, and contain prolongations from the stomach. They are all grotesque-looking animals, found at low water upon stones or marine plants, or parasitically attached to marine animals.

ORDER II. ACARINA.

The most familiar members of this order are the Mites and Ticks (fig. 102). They are distinguished by the fact that the abdomen is amalgamated with the cephalothorax to form a single mass. Respiration is effected by the general surface of the body or by air-tubes (tracheæ). The mouth-organs are usually adapted for piercing and for suction (fig. 102, C), but some Mites have biting mandibles.

The habits of the Mites are extremely varied. Some are found upon different plants; others are parasitic upon water-insects when young, but swim about freely when adult; others are parasitic upon other animals, such as sheep, dogs, insects, &c.; and others inhabit decaying provisions, as is the case with the well-known "Cheese-mite" (*Acarus domesticus*). Two species have a considerable medical

interest as attacking man. One of these causes the skin-disease which is known as the "itch," and the other is found inhabiting

Fig. 102.—Acarina. A, *Tegeocranus elongatus*, one of the Mites, enlarged 65 times. B, *Ixodes ricinus*, one of the Ticks, greatly enlarged. C, Mouth-organs of a Tick (*Ixodes albipictus*), enlarged: *l* Labium; *m* Mandibles; *mp* Maxillary palpi. (After Michael, Packard, and Cuvier.)

certain glandular follicles of the skin, probably without an exception even in favour of the most cleanly people.

ORDER III. PEDIPALPI.

In this family are the most formidable of all the *Arachnida*—namely, the Scorpions (fig. 101). They are all distinguished by the fact that the abdomen is divided into distinct segments, and is continued into the cephalothorax without any well-marked boundary or constriction. In the true Scorpions the end of the abdomen (fig. 101, *t*) is composed of a hooked telson, which is perforated for the duct of a poison-gland, situated at its base. It is by means of this that the Scorpions sting; and the poisonous fluid which they secrete is sufficiently powerful to render their wounds painful or even dangerous. The mandibles in the Scorpions, as already said, are developed into pincers, and the so-called "maxillary palpi" constitute powerful nipping-claws. The respiratory organs are in the form of pulmonary sacs, four on each side, opening on the under

surface of the abdomen by as many distinct apertures or spiracles (fig. 101, C).

The Scorpions live in the warmer regions of the temperate zone and in tropical countries, and are generally found hiding under stones or in the crevices of walls. They live upon insects, which they catch with the great nipping-claws, and sting to death with the telson.

Related to the true Scorpions, though belonging to a special group, are the little "Pseudo-scorpions" or "Book-scorpions" (fig. 103, A). These are small Arachnidans, which are commonly found among old books, and which look very like Scorpions in miniature, this being due to the fact that the maxillary palpi are of great size and terminate in pincers. Related to these, again, are the "Harvest-men" (*Phalangium*, fig. 103, B), which are distinguished by the great length and slenderness of their legs.

Fig. 103.—A, Book-scorpion (*Chelifer*), magnified; B, *Phalangium copticum*, of the natural size.

ORDER IV. ARANEIDA.

In this order are the true Spiders, readily distinguished from the Insects, with which they are popularly confounded, by having four pairs of legs, as well as by other characters. In all the true Spiders (fig. 104) the segments of the thorax and head are united to form a single mass or cephalothorax, to which the soft and unsegmented abdomen is joined by a constricted stalk or neck. Respiration is effected by means of pulmonary sacs, conjoined with tracheæ. The pulmonary sacs are two or four in number, and open on the under surface of the abdomen by as many apertures. The head bears from two to eight simple eyes; the mandibles (fig. 104, B) are hooked, and carry the duct of a poison-gland; and the maxillary palpi are not developed into nipping-claws. The Spiders are all predacious and rapacious animals, and many of them possess the power of constructing webs, either for the capture of their prey, or

simply for lining their habitations. For the production of the web, Spiders are furnished with special glands situated at the extremity of the abdomen. The secretion of these glands is a viscid fluid, which hardens rapidly on exposure to air, and which is cast into its proper thread-like shape by passing through what are called the "spinnerets." These are little conical or cylindrical organs, from

Fig. 104.—A, The male of the common House-Spider (*Tegenaria civilis*) considerably magnified; *c* Front portion of the body, consisting of the amalgamated head and thorax; *p* Maxillary palpi; *a* Abdomen. B, Front portion of the head of the same, showing the eight eyes (*f*) and the mandibles (*n*). C, Under side of the head and trunk, showing the true jaws (*m*), the lower lip (*l*), and the horny plate to which the legs are attached. D, Diagram of one of the air-chambers or breathing-organs. (Figs. A, B, and C are after Blackwall.)

two to eight in number, placed at the end of the abdomen, and perforated by a number of extremely minute tubes, through which the secretion of the gland has to pass before reaching the air. Many Spiders, however, do not construct any web, unless it be for their own habitations, but simply hunt their prey for themselves.

The Spiders are oviparous, and their young pass through no metamorphosis, but they cast their skin or "moult" repeatedly before they attain the size of the adult.

CHAPTER XV.

MYRIAPODA.

CLASS III. MYRIAPODA.

THIS class is a small one, and includes only the Centipedes and the Millepedes. In all the *Myriapoda* the head is distinct, and not amalgamated with the thorax. There is no clear boundary-line between the thorax and the abdomen, both being composed of nearly similar segments. The body (except in the genus *Pauropus*) always consists of more than twenty rings; and the hinder segments, which correspond to the abdomen, always carry locomotive appendages, whereas the abdominal rings in *Arachnida* and *Insecta* are always destitute of locomotive appendages. One pair of antennæ is present, and the number of the legs is always more than eight pairs. Respiration is carried on by branched air-tubes or tracheæ.

In most of their characters the *Myriapoda* closely resemble the true Insects, with which, indeed, they are not uncommonly classed. The true Insects, however, always have the head, thorax, and abdomen distinct from each other, and have never more than three pairs of legs. In most of the *Myriapoda* the young or "larvæ" are more like insects than the adult, since they have only three pairs of legs, or are altogether destitute of feet. In some cases, however, the young Myriapod, on escaping from the egg, possesses nearly all the characters of the parents, except that the number of body-rings, and consequently of legs, is smaller, and increases with every change of skin ("moult"). The class is divided into two leading groups or orders, represented by the common Centipedes (*Chilopoda*) and Millepedes (*Chilognatha*).

The Centipedes (fig. 105) are carnivorous in their habits, and the organs of the mouth are adapted for a life of rapine. In addition to the parts of the mouth proper, they have two pairs of "foot-jaws," of which the second is hooked and perforated for the discharge of a poisonous fluid. The bite of the common European species is perfectly harmless to man, but some of the tropical forms attain a

length of half a foot or more, and are consequently able to inflict extremely severe and even dangerous bites. The true Centipedes are further distinguished by the number of legs not being indefinitely

Fig. 105.—Centipede (*Scolopendra*).

great (usually from fifteen to twenty pairs), and by the fact that the antennae are composed of not less than fourteen joints each.

The Millepedes (fig. 106) are repulsive-looking but perfectly innocent animals, which feed principally upon decaying vegetable matter. The body in the ordinary Millepedes is rounded and worm-like; and the segments are so amalgamated that each apparent body-ring

Fig. 106.—Millepede (*Lulus maximus*), a small example, of the natural size.

gives origin to *two* pairs of minute thread-like feet. The mouth is destitute of the powerful jaws which are found in the Centipedes, the legs are indefinitely numerous, and the antennae are short, and are composed of no more than six or seven joints each.

The European Millepedes are all of small size, but some tropical species attain a length of from six to ten inches.

A third group, under the name of *Pauropoda*, has been established for a curious little creature called *Pauropus*. In this, the body consists of only ten segments, and there are no more than nine pairs of legs. The antennae are five-jointed, forked, and provided with jointed appendages. There are no tracheae, and respiration is carried on by the skin. It is very small, and is found inhabiting decayed leaves and damp situations.

Lastly, a fourth group, termed *Onychophora*, containing only the curious animals of the genus *Peripatus* (fig. 107), must be admitted, provisionally at any rate, amongst the *Myriapoda*. The species of *Peripatus* are worm-like animals found in moist situations or under

stones in the West Indies, South Africa, South America, and New Zealand. They are so worm-like that they have often been placed among the Annelides ; but the recent researches of Prof. Moseley

Fig. 107.—Onychopoda. *Peripatus Capensis*. (After Moseley.)

have shown that the animal breathes by tracheæ, so that it must be placed in or near the *Myriapoda*.

CHAPTER XVI.

INSECTA.

CLASS IV. INSECTA.

THE true Insects are distinguished from the preceding classes of Articulate animals by the fact that *the three divisions of the body—namely, the head, thorax, and abdomen—are always distinct from one another; there are never more than three pairs of legs in the adult, and these are borne upon the thorax; the abdomen is destitute of locomotive appendages.* Respiration is effected by means of air-tubes or tracheæ, and in most Insects two pairs of wings are developed from the back of the second and third segments of the thorax.

The integument in insects is more or less hardened by the deposition of chitine in it, and the body is deeply cut into segments (hence the name *Insect*, from the Latin *insectus*, cut into). The head in insects (fig. 108, *a*) is composed of several segments amalgamated together, and carries a pair of jointed feelers or antennæ, a pair of eyes, usually compound, and the appendages of the mouth. The thorax in insects (*b, c, d*) is composed of three segments, which are amalgamated together, but are generally prettily easily recognised. Each of the segments of the thorax carries, in perfect insects, a single pair of jointed legs, so that there are three pairs in all. To the back of the two hinder segments of the thorax, in most insects, there are also attached two pairs of wings. In their typical form the wings are membranous expansions, supported by more or less numerous hollow tubes, known as the “nervures.” One or both pairs of wings may be wanting, and when both are present the anterior pair may be much modified by the deposition of chitine in it. These modifications will be treated of in speaking of the orders of Insects. The abdomen in insects (*e*) is properly composed of eleven segments, which are usually more or less freely movable upon one another, and which never carry locomotive limbs, as is so commonly the case in the *Crustacea*. The extremity of the abdomen is, however, often furnished with appendages which are

primarily connected with reproduction, but which are often converted into weapons of offence and defence. Of this nature are the "ovipositors" of Ichneumons, the stings of Bees and Wasps, and the forceps of the common Earwig.

The organs of the mouth in insects require a brief consideration, as being in the closest possible relation with their habits and mode

Fig. 108.—Diagram of the external anatomy of an Insect: *a* Head carrying the eyes (*o*) and antennæ (*an*); *b* First segment of the thorax, with the first pair of legs; *c* Second segment of the thorax, with the second pair of legs and the first pair of wings; *d* Third segment of the thorax, with the third pair of legs and the second pair of wings; *e* Abdomen, without limbs, but carrying terminal appendages concerned in reproduction; *f* Femur; *t* Tibia; *ta* Tarsus.

of life. Two chief types of mouth are recognisable in insects, termed respectively the "masticatory" and the "suctorial," according as the mouth is fitted for biting and chewing, or simply for imbibing fluids. The masticatory mouth is seen in perfection in the Beetles, in which the following organs are present (fig. 109, A): 1. An upper lip or "labrum" (*l*), attached below the front of the head. 2. A pair of biting-jaws (*m*) or "mandibles." 3. A pair of chewing-jaws or "maxillæ" (*mx*) provided with jointed filaments, called the

“maxillary palpi” (*mp*). 4. A lower lip or “labium” (*la*), which also carries a pair of jointed filaments, known as the “labial palpi” (*lp*). In the typical suctorial mouth, as seen in the Butterflies and Moths (fig. 109, B), the following is the arrangement of parts. The upper lip and mandibles are quite rudimentary; the maxillæ (*mx*) are greatly lengthened, and form a spiral tube fitted for sucking up the juices of flowers; and the labial palpi are much developed, and form two hairy cushions, between which the trunk can be coiled up when not in use. In many insects (fig. 109, C) the organs of the mouth are essentially adapted for suction, but are also fitted for piercing solid substances, such as the skin of animals or the stems

Fig. 109.—Organs of the mouth of Insects, enlarged; (A) of a Beetle (*Curabius*); (B) of the Small Cabbage White Butterfly (*Pontia rapæ*); (C) of the Bed-bug (*Cimex lectularius*), the mandibles and maxillæ being displaced to one side. *l* Labrum; *m* Mandible; *mx* Maxilla; *mp* Maxillary palpus; *la* Labium; *lp* Labial palpus; *an* Base of one of the antennæ. (Fig. B. is slightly altered from Westwood.)

of plants. In these the lower lip forms a kind of sucking-tube or sheath, within which are contained the maxillæ and mandibles, which are modified so as to form piercing organs or lancets. In the common Bee the masticatory and suctorial types of mouth are combined. The mandibles or biting-jaws are retained, to enable the honeycomb to be manufactured, and there is also a tubular trunk fitted for sucking up the juices of flowers. In the Butterflies, too, in which the mouth of the adult is strictly adapted for suction, the caterpillar is furnished with a masticating mouth, so that it can feed upon leaves, or other solid substances.

The mouth in the masticating insects (fig. 110, *a*) leads into a membranous and often folded cavity, termed the “crop” (*b*), from which the food passes to a second muscular cavity or “gizzard” (*c*).

The gizzard is adapted for crushing the food, and often has plates or teeth of chitine developed in its walls. It is succeeded by the true digestive cavity (*d*), which is termed the "the chylific stomach." From this there proceeds an intestine (*f*), of variable length, which usually terminates in a chamber called the "cloaca" (*g*), into which the ducts of the reproductive organs open. The commencement of the gullet is furnished with glandular appendages, which discharge

Fig. 110.—Digestive apparatus of a Beetle (*Carabus curatus*). *a* Gullet; *b* Crop; *c* Gizzard; *d* Chylific stomach; *e* Malpighian tubes; *f* Intestine; *g* Cloaca; *h* Anal glands.

the functions of salivary glands. Immediately behind the posterior aperture of the stomach are a variable number of cæcal convoluted tubes (*e*), which are known as the "Malpighian vessels," after their discoverer Malpighi, and which correspond with the kidneys of higher animals.

The circulation in insects is mainly carried on by a long contractile tube placed along the back, and termed the "dorsal vessel." The blood collected from the various tissues and organs of the body, enters the dorsal vessel from behind, and is driven forwards to the anterior extremity of the body. Respiration is effected by means of

air-tubes or tracheæ (fig. 111), which commence at the surface by so many apertures or spiracles, and branch repeatedly as they proceed inwards through the tissues. They have the same structure as in the *Arachnida*, consisting of membranous tubes strengthened by

Fig. 111.—Ideal transverse section of an Insect. *h* Dorsal vessel; *i* Intestine; *n* Ventral nerve-cord; *t t* Stigmata leading into the branched tracheal tubes; *w w* wings; *a* Coxa of one leg; *b* Trochanter; *c* Femur; *d* Tibia; *e* Tarsus. (After Packard.)

means of a spirally coiled filament of chitine. The tracheæ are prolonged into the wings, so that these structures likewise assist in respiration.

The nervous system in insects, though sometimes somewhat modified, has essentially the regular Annulose form of a ventral chain of ganglia, traversed in front by the gullet. The organs of sense are the eyes and antennæ. The eyes are usually “compound,” and are composed of numerous six-sided lenses, united together, and each supplied by a separate nervous filament. As many as eight thousand of these lenses have been counted in one of the eyes of the common Cockchafer, and this number is sometimes greatly exceeded. Besides these compound eyes there are sometimes “simple” eyes, identical in structure with the single lenses of the compound eyes; and in rare cases these are the only organs of vision. The feelers or antennæ, with which all insects are furnished, are jointed filaments attached close to the eyes, and assuming very different shapes in

different insects. They appear to be certainly organs of touch, but they very probably minister to other senses as well, and there is some reason to suppose that they are connected with the sense of hearing in particular.

The sexes in insects are distinct, and most of them are oviparous. Generally speaking, the young insect is extremely different in external characters from the adult, and it requires, before reaching maturity, to pass through a series of changes which collectively constitute what is called the "metamorphosis." In some insects, however, there is no proper metamorphosis, and in some the changes which take place are not so complete and striking as in others. By the absence of metamorphosis, or by its completeness when present, insects are divided into three convenient, though perhaps not strictly natural, sections, as follows :—

Section I. Ametabolic Insects.—The insects belonging to this section are said to be "Ametabolic" (Gr. *a*, without ; *metabole*, change), because they pass through no metamorphosis. The young, on their escape from the egg, resemble the adult in every respect, except in size, and they undergo no alteration in reaching maturity, except that they grow larger. All the insects of this section are destitute of wings in the adult state, and they are therefore often called "Aptera" (Gr. *a*, without ; *pteron*, a wing).

Section II. Hemimetabolic Insects.—In the insects belonging to this section (Gr. *hemi*, half ; and *metabolé*, change), there is a metamorphosis consisting of three stages, but these stages do not differ much from one another in appearance (see fig. 117). The young, on escaping from the egg, is known as the "larva," and it is not only much smaller than the adult, but is destitute of wings. After several changes of skin, the larva enters into the second stage, when it is termed the "pupa." The pupa is active and locomotive, and rarely differs much from the larva, except that it is bigger, and that rudimentary wings have now appeared on the back of the thorax. After a certain period, and after some changes of skin, the wings burst from their sheaths, and the pupa is now converted into the third and final stage, when it is known as the "imago" or perfect insect. In all the insects belonging to this section—such as Grasshoppers, Dragon-flies, &c.—the second stage, or pupa, is active and locomotive ; and for this reason the metamorphosis is said to be "incomplete."

Section III. Holometabolic Insects (Gr. *holos*, entire ; and *metabolé*, change).—The insects belonging to this section—such as Butterflies,

Moths, and Beetles—pass through three stages, just as do the preceding, but these stages differ from one another very much in appearance, and the metamorphosis is therefore said to be “complete” (fig. 112). In these insects the larva is worm-like, segmented, and usually furnished with locomotive feet, which do not correspond with the three pairs proper to the adult (see figs. 123, 124), though these are usually present as well. Sometimes feet are wanting altogether. The larva is also provided with masticating organs, and eats voraciously. In this stage of the metamorphosis, the larvæ constitute what are popularly known as “caterpillars” or “grubs.”

Fig. 112.—Metamorphosis of the Magpie-moth (*Phalena grossulariata*).

Having remained in this condition for a longer or shorter time, and having undergone repeated changes of skin, necessitated by its rapid growth, the larva passes into the second stage, and becomes a pupa (fig. 123—see also fig. 112). In this stage the insect remains quiescent, unless irritated, and it is very often attached to some foreign object, so as to be quite incapable of changing its place. In the case of the Butterflies and Moths, the pupa constitutes what is familiarly known as the “chrysalis.” The body is protected by a chitinous pellicle, and in some cases this is still further protected by the dried skin of the larva; whilst in other cases the larva—immediately

before entering the pupa stage—spins for itself a protective case of silken threads, which surrounds the chrysalis, and is known as the “cocoon.” Having remained for a variable time in this inanimate, quiescent pupa-stage, during which rapid changes have been going on in the interior of the animal, the insect now frees itself from the envelope which obscured it, and appears as the perfect winged adult or imago.

CHAPTER XVII.

ORDERS OF INSECTS.

THE known number of insects is so enormous, their forms are so various, and their habits and instincts are not only so remarkable, but have been so fully described, that it were hopeless to attempt here to do more than give the briefest possible outline of the leading characters which distinguish the different orders. The student desirous of further information on this head must have recourse to treatises specially devoted to entomology.

SECTION I. AMETABOLIC INSECTS.—*Young not passing through a metamorphosis, and differing from the adult in size only. Perfect insect or imago destitute of wings; eyes simple, sometimes wanting.* Owing to the fact that the adult ametabolic insects have no wings, they are often grouped together as a common assemblage, under the name of *Aptera*.

ORDER I. ANOPLURA.

The insects comprised in this order are parasitic upon man and other animals, and they are commonly known as Lice (*Pediculus*, fig. 113, A). They are all very minute in size, destitute of wings in the adult state, having a mouth formed for suction, and having either two simple eyes or none.

ORDER II. MALLOPHAGA.

These are known as "Bird-lice," and are all minute parasites on different birds or quadrupeds (fig. 113, B). They are distinguished from the true Lice by not living upon the juices of their host, but upon the more delicate and tender appendages of the skin. The mouth is, consequently, not suctorial, but fitted for biting.

ORDER III COLLEMBOLA.

These are Apterous insects, which attach themselves to foreign bodies by means of a ventral suctorial tube. They are commonly called "Spring tails," in allusion to the fact that the abdomen carries a long forked appendage, which is employed as an elastic

Fig. 113.—Types of Aptera. A, *Pediculus humanus capitis*, one of the *Anoplura*; B, *Docophorus hamatus*, one of the Bird-lice; C, *Campodea*, one of the *Thysanura*; D, *Degeeria*, one of the *Poduridæ*; E, Scale of a Podurid, as seen under the microscope; F, *Degeeria purpurascens*. All the figures are greatly enlarged. (After Packard and Gervais.)

spring, and which enables the insect to effect extensive leaps (fig. 113, D and F). The best-known members of the group are the *Poduræ*, which are generally found in moist dark places in gardens and in similar situations.

ORDER IV. THYSANURA.

This order comprises insects such as *Lepisma* and *Campodea* (fig. 113, C), which are nearly related to the preceding, but are distinguished by the possession of a masticatory mouth, and by the fact

that the bristles which terminate the abdomen do not form a "spring." The body is often covered with delicate scales, which are shown under the microscope to be beautifully marked and striated.

SECTION II. HEMIMETABOLIC INSECTS.—*Metamorphosis incomplete; the larva differing from the perfect insect chiefly in the absence of wings and in size; pupa usually active, or, if quiescent, capable of movement.*

ORDER V. HEMIPTERA.

In this order the mouth is formed for suction (fig. 109, C); the eyes are compound, but simple eyes are often present in addition. Two pairs of wings are always present.

FIG. 114.—Hemiptera. Bean Aphis (*Aphis fabae*); winged male and wingless female.

A

B

FIG. 115.—Hemiptera. A, *Pentatoma rutilans*, with the wings closed. B, *Rhaphigaster incarnatus*, with the wings expanded in flight: a Anterior wing (hemelytron), with its basal portion hardened by chitine; b Posterior membranous wing.

The *Hemiptera* live upon the juices of plants or animals, which they are enabled to obtain by means of their suctorial mouths. All

the four wings are present, but the condition of these varies in different sections of the order. In one group all the four wings are membranous (fig. 114); but in the other the posterior wings and the tips of the anterior wings alone are membranous. The inner portions of the anterior wings are hardened by chitine (fig. 115), and they are known as "hemelytra" (Gr. *hemi*, half; and *elutron*, a sheath). Amongst the more familiar examples of the *Hemiptera* are the numerous species of Plant-lice (*Aphides*), the Field-bugs (*Pentatoma*, fig. 115), the Boat-fly, the *Nepa* or Water-scorpion (fig. 116), the Cochineal insects, and the Cicadas.

The Cochineal insects are of considerable commercial importance, as the dried and powdered bodies of the female constitute the substance known as Cochineal, from which is obtained the brilliant pigment, carmine. The male insect is winged, and is smaller than the female, which is wingless. They live upon different species of Cactus (*Opuntia*), and are mainly imported from Mexico, Algeria, and the Canary Islands.

Numerous species of *Aphides* or Plant-lice (fig. 114) are known, and they are among the greatest pests of the gardener and farmer, as they are extraordinarily prolific, and live upon the juices of plants. One of the most curious points about the Plant-lice is that they secrete a sweet and sticky fluid, which is expelled from the body by two little tubular filaments placed near the end of the abdomen. Ants are excessively fond of this fluid, and hunt after *Aphides* in all directions in order to obtain it.

Fig. 116.—*Nepa cinerea*, the "Water-scorpion," showing the semi-membranous anterior wings ("hemelytra").

ORDER VI. ORTHOPTERA.

The mouth in this order is strictly masticatory; there are four wings present, but the anterior pair are smaller than the posterior, and of a different texture. The posterior wings are membranous and are folded lengthwise, like a fan; the anterior wings are leathery, and constitute cases (elytra) for the posterior wings. This order includes the Crickets (*Achetidae*), Grasshoppers (*Acridiidae*), Locusts (*Locustidae*), Cockroaches (*Blattidae*, fig. 118), and others. Some of them are formed for running, all the legs being nearly equal in size; others have the first pair of legs greatly developed, and constituting powerful organs of prehension; whilst others, such

as the Locusts and Grasshoppers, have the hindmost pair of legs much longer than the others, giving them a considerable power of leaping. All the *Orthoptera* are extremely voracious, and every one is acquainted with the terrible ravages occasionally caused in hot countries by swarms of locusts.

Fig. 117. Different stages in the metamorphosis of a Grasshopper. A, Larva; B, Pupa, with the rudimentary wings; C, Adult or imago, with the fully developed wings.

The most destructive species is the Migratory Locust (*Edipoda migratoria*), which is very abundant in Africa, India, and throughout the whole of the East. Owing to the rapidity with which they devour everything they can possibly eat, and owing to their enormous numbers, the Locusts are compelled to be constantly on the

move, looking for "fresh fields and pastures new." It is from these migrations in vast bodies in search of food that the Migratory Locust

Fig. 118. —Orthoptera. The common Cockroach (*Blatta orientalis*), male and female.

takes its name. When one of these destructive hosts visits a district, it only needs a few hours to convert the most fertile country into a howling wilderness. In an incredibly short space of time every green

thing on their line of march is destroyed, every leaf is stripped from every tree, every blade of grass and corn is eaten down, and it is not until the ground is utterly bare and brown that the Locusts take wing and seek out some fresh region to devastate. Nearly or quite as destructive as the Eastern Locust are various species which inhabit North America, and are particularly abundant in the far West.

ORDER VII. NEUROPTERA.

The mouth in this order is fitted for mastication ; the wings are four in number, generally nearly equal in size, all membranous, and traversed by numerous delicate nervures, which interlace so as to form a delicate network (fig. 119). The metamorphosis is generally incomplete, but is sometimes complete.

This order includes the well-known and rapacious Dragon-flies (*Libellulidæ*), the Caddis-flies (*Phryganeidæ*), the May-flies (*Ephemeroideæ*), the Ant-lion (*Myrmeleo*), the Aphis-lion (fig. 119), Termites, &c. The last of these—namely, the Termites or White Ants (fig.

Fig. 119.—Neuroptera. Aphis-lion (*Chrysopa perla*), imago, larva, and eggs.

120)—are social insects, living in organised communities, and exhibiting many remarkable phenomena. They are mostly inhabitants of hot countries, and cause immense mischief by destroying wood-work of all descriptions. Though called “White Ants,” it is to be remembered that they are not related in any way to the true Ants. They build mounds of different shapes and sizes, sometimes several feet in height, formed of “particles of earth worked into a material as hard as stone.” Each family of Termites possesses a king and queen, which are always kept together closely guarded in

a chamber placed in the centre of the nest. Both are without wings and are much larger than the bulk of the community, the queen immensely so, owing to the enormous distension of her abdomen with eggs. The ordinary Termites are all sexless, incapable of laying eggs, and they are divided into two distinct sets or "castes,"

Fig. 120.—Different individuals of the colony of one of the Termites. A, The queen, before the wings are shed; D, The queen, after the wings are thrown off and the abdomen has become greatly distended with eggs; C, Worker; B, Soldier.

both destitute of wings, and differing in the armature of the head. The one class includes the so-called "workers," who perform all the ordinary work of the colony, whilst the "soldiers" have greatly developed jaws, and are simply occupied in defending the nest against all enemies.

SECTION III. HOLOMETABOLA.—*Metamorphosis complete; the larva, pupa, and imago differing greatly from one another in external appearance. The larva worm-like, and the pupa quiescent.*

ORDER VIII. APHANIPTERA.

In this order are only the Fleas (*Pulicidae*) in which the mouth is suctorial, the metamorphosis is complete, and the wings are rudi-

mentary, being represented by four minute scales placed on the last two segments of the thorax (fig. 121). The larva of the common Flea is a footless grub, which in about twelve days spins a cocoon

Fig. 121.—A, The common Flea (*Pulex irritans*); B, Larva of the same; C, Pupa of the same. All the figures are greatly magnified. (After Westwood.)

for itself, and becomes a quiescent pupa, from which the imago emerges in about a fortnight more.

ORDER IX. DIPTERA.

The insects of this order, as implied by its name, have only a single pair of wings—namely, the anterior pair. The posterior wings are rudimentary, and are represented by two clubbed filaments called “balancers” or “poisers” (fig. 122). The mouth in the *Diptera* is suctorial. It consists of a tubular lower lip, enclosing the other parts of the mouth, and placed on the under surface of the head. The antennæ are generally small and three-jointed, sometimes many-jointed, sometimes feathery. The metamorphosis is complete, the larva being usually a soft fleshy grub, with an indistinct head, and generally destitute of legs.

The common Gnat (*Culex pipiens*) deposits its eggs upon the surface of water, the eggs being cemented together to form a sort of raft, and each having an inferior lid which allows the escape of the larva (fig. 122, A). The larval Gnat (fig. 122, B) is vermiform, with a large head and thorax, and with lateral tufts of bristles, which it uses in swimming. The last abdominal segment carries a bunch of leaf-like fins, with which the larva can keep itself suspended, head downwards, in the water; and the last segment but one carries a long tube, into which the tracheæ open, and which the larva thrusts above the surface of the water for the purpose of obtaining air. In its pupal condition (fig. 122, C) this abdominal tube has disappeared, though the abdomen still acts as a swimming-organ. The head and thorax are now fused together, and the dorsal aspect of the thorax is furnished with two tubes, which project above water when the

insect comes to the surface, and which convey air to the tracheæ. Though active, the pupa does not eat; and when the time comes for the completion of the metamorphosis it approaches the surface, above which it raises its back. The skin then splits dorsally, and, drying,

FIG. 122. — The common Gnat (*Culex pipiens*). A, A few of the eggs, attached together to form a raft, which floats on the water; B, The larva, suspended in the water head downwards, and showing the antennæ (*a*), the terminal respiratory tube (*r*), and the fins attached to the extremity of the body (*f*); C, The pupa, with the two respiratory tubes attached to the thorax; D, The adult insect, with the well-developed front wings, the rudimentary hind wings or "balancers" (*h*), the antennæ (*a*), and the proboscis (*p*). All the figures are greatly enlarged.

forms a boat, in which the insect floats until its wings are fit for use.

The *Diptera* constitute one of the largest orders of insects; the House-flies and Flesh-flies (*Musca*), the Gnats and Mosquitoes (*Culicidæ*), the Crane-flies (*Tipula*), the Forest-flies (*Hippobosca*), and the Gad-flies (*Tabanidæ*) constituting good examples.

ORDER X. LEPIDOPTERA.

This well-known and most beautiful of all the orders of insects comprises the Butterflies and Moths, the former being active by day (*diurnal*), and the latter mostly towards twilight (*crepuscular*), or at night (*nocturnal*). In all the *Lepidoptera* the mouth of the adult insect is purely suctorial, and is provided with a spiral trunk fitted for imbibing the juices of flowers, and formed out of the elongated

and metamorphosed maxillæ (fig. 109, B). The wings are four in number, and are covered more or less completely with modified hairs or scales, which are pretty objects under the microscope, and from which the wings derive their beautiful colours. The larvæ of the *Lepidoptera* (fig. 123) are generally known as caterpillars. They

Fig. 123.—Large Cabbage White Butterfly (*Pontia brassica*). *a* Larva or caterpillar; *b* Pupa or chrysalis; *c* Imago or perfect insect.

are worm-like, provided with masticatory organs fitted for dividing solid substances, possessing false legs ("prolegs") in addition to the three pairs proper to the adult, and having attached to the under lip a tubular organ or spinneret, by which silken threads can be manufactured.

The Butterflies or Diurnal *Lepidoptera* are characterised by being active during the daytime, by keeping their wings mostly erect when at rest (fig. 123, *c*), by generally having club-shaped antennæ, and by having a chrysalis (*b*), which is almost always naked and angular, and is generally attached to some solid object by silken threads variously disposed.

The Moths (fig. 124) are mostly active during the night-time, when they are said to be "nocturnal." Many of them, however, are "crepuscular"—that is to say, they are active during the hours of twilight; and a few come out in broad daylight and in the brightest sunshine. The pupæ or chrysalides are never angular, as in the case of the Butterflies.

In the Crepuscular *Lepidoptera*, including those forms which are active during the twilight, the antennæ are usually fusiform, or grow gradually thicker from the base to the apex; the wings are

horizontal or little inclined when the insect is at rest; and the pupæ are never angular. Amongst the best known of the Crepuscular *Lepidoptera* are the Hawk-moths (*Sphingidae*), comprising some of the largest examples of the whole order.

The Nocturnal *Lepidoptera* have the antennæ setaceous, or diminishing gradually from the base to the apex, often serrated or pec-

Fig. 124.—Goat-moth (*Cossus ligniperda*) and caterpillar.

tinated (fig. 124); the wings in repose are horizontal or deflexed; the pupæ are mostly smooth, sometimes spiny, and often enclosed in a cocoon. This group includes most of the ordinary moths. Certain groups of these comprise Moths of very small size, which are often spoken of as *Microlepidoptera*.

ORDER XI. HYMENOPTERA.

In this order all the four wings are present, as a rule, and they are all membranous in texture, with few nervures (fig. 125). The mouth is always furnished with biting-jaws or mandibles, but often is adapted for suction as well. The females have the extremity of the abdomen furnished with an instrument connected with the process of laying eggs (ovipositor); and in very many cases this becomes

the powerful defensive weapon known as the sting. The metamorphosis is complete.

The *Hymenoptera* form a very extensive order, comprising the Bees (*Apidae*), the Wasps (*Vespidæ*), the Ants (*Formicidæ*), the Gall-flies (*Cynipidæ*), the Saw-flies (*Tenthredinidæ*, fig. 125), the Ichneumons, and many other forms. The Bees, Wasps, and Ants are well known as forming social communities, though solitary members of the two former families are very common.

In both groups these organised communities consist of a vast number of undeveloped females, or "neuters"—the so-called "workers"—presided over by a single fertile female, or "queen," or containing several such. The males are only produced at certain seasons,

Fig. 125.—Hymenoptera. *a* Winged male of Ant; *b* Wingless worker of Ant; *c* Pupa of Ant; *d* Larva of Ant, enlarged; *e* The Great Saw-fly (*Sirex gigas*).

and they constitute the so-called "drones" of a hive of bees. The workers discharge all the duties necessary for the preservation of the colony, such as procuring food, building the nests, and feeding the young. As there is only one set, or "caste," of neuters, the duty of defending the nest falls to the lot of all the workers, and is not delegated to a special class of soldiers. The queen is the founder of the colony, and her sole function, after starting the community, is to lay eggs. The drones, or males, do no work, as a rule, and they either die, or are killed by the workers, as soon as the female is fertilised.

The Ants likewise form communities, consisting of males, females, and neuters. The males and females, like those of the very different "White Ants," or Termites, are winged (fig. 125, *a*), and are pro-

duced in great numbers at particular times of the year. They then quit the nest and pair, after which the fecundated females lose their wings and form fresh societies. The workers (fig. 125, *b*) are sometimes all of one kind, but they are often divided into two, or even three, distinct classes or "castes." The Ants exhibit many most extraordinary and interesting instincts and habits, of which their custom of "milking" the little Plant-lice has been already mentioned. Another very singular habit of some Ants may be just alluded to—their habit, namely, of capturing the pupæ of other species of Ants and bringing them up as slaves. The relations, however, between the masters and slaves vary a good deal in different cases. In the case, for instance, of the Russet Ant (*Formica rufescens*) the masters are so entirely dependent upon their slaves that they cannot even feed themselves, and the only work which they perform unassisted is the capturing of fresh slaves. In the Blood-red Ant (*Formica sanguinea*), on the other hand, the slaves are much fewer in number, and the masters are much less dependent upon their good offices. In all cases, the slaves exhibit the greatest devotion to their masters, and are invariably taken the greatest care of by their captors.

ORDER XII. STREPSIPTERA.

This is an extremely small order of insects, which merely requires to be mentioned. It includes only certain minute parasites, which are found on bees and other *Hymenoptera*. The females are desti-

Fig. 126.—Strepsiptera. *Stylops Spencii*, greatly magnified (after Westwood).

tute of wings or feet, and are merely soft worm-like grubs. The males (fig. 126) are active, and possess a single pair of large membranous wings. Unlike the *Diptera*, it is the *posterior* pair of wings which is present, and the *anterior* pair is quite rudimentary, and is

only represented by curious twisted filaments, from which the name of the order is derived.

ORDER XIII. COLEOPTERA.

The twelfth and last order of insects is that of the *Coleoptera*, including the well-known insects familiar to every one under the name of "Beetles." The leading peculiarity of the *Coleoptera* is to be found in the fact, that though all the four wings are present, only the posterior pair are membranous, and perform the function of wings. The anterior pair of wings (figs. 127, 128) are no longer capable of being used in flight, but are hardened by the deposition of chitine, and constitute protective cases, which cover the hind-wings, and are known as "elytra" (Gr. *elutron*, a sheath). The mouth in all the Beetles is masticatory, and is furnished with biting and chewing jaws (fig. 109, A).

The larvæ of the Beetles are all worm-like grubs, with masticatory mouths, and they all pass through a complete metamorphosis, generally requiring a protracted period for its completion. The known

Fig. 127.—Coleoptera. A, *Cicindela campestris*, the Tiger-beetle, enlarged. B, Larva of the same, enlarged. C, *Dytiscus marginalis*, male.

Fig. 128.—a, Rose-chaffer (*Cetonia aurata*) and larva.

number of different kinds of Beetles cannot be estimated with any certainty, but it may be safely said that the order is one of the largest of all the groups of Insects. They are, as a general rule, remarkable for their hard chitinous skin, their glittering, often

metallic, colours, and their voracious habits, though many of them feed upon vegetable matters.

Of the enormous number of known Beetles, the only one which can be said to be of any decided use to man is the so-called Blister-beetle," or "Spanish Fly" (*Cantharis vesicatoria*). This handsome insect is a native of Southern Europe, especially of Italy, Spain, and France, and lives upon the leaves of the ash, lilac, elder, and poplar. It is largely collected and exported for medicinal purposes, as it yields one of the most generally used and efficient of blisters.

Many of the *Coleoptera* inflict great injury upon wild or cultivated plants, some of them being most destructive in their adult condition, while others do most harm in their larval state. It is to be remembered, however, that the *Coleoptera*, like the *Diptera*, discharge important and highly beneficial functions by destroying vast quantities of decaying organic matter, which would otherwise prove injurious to man.

SUB-KINGDOM V. MOLLUSCA.

CHAPTER XVIII.

SUB-KINGDOM MOLLUSCA.

THE *Mollusca* (Lat. *mollis*, soft), as implied by their scientific name, are mostly soft-bodied animals ; but their popular name of "shell-fish" expresses the fact that their soft body is usually protected by an external skeleton or "shell." All the *Mollusca* are furnished with a distinct alimentary canal, which is completely shut off from the general cavity of the body. There is sometimes no distinct blood-circulatory apparatus ; but when there is, its central portion (*i.e.*, the heart) is placed upon the dorsal aspect of the body. The chief peculiarity, however, of the *Mollusca* is found in the nature of the nervous system. In the lower forms (fig. 132, 2, *d*), the nervous system consists essentially of a single ganglionic mass, giving off filaments in various directions. In the higher *Mollusca* (fig. 129), the nervous system consists of three scattered pairs of ganglia, united to one another by nervous cords. One of these pairs is placed above the gullet or œsophagus, and is known as the "supra-œsophageal" or "cerebral" ganglia. A second pair supplies nerves to the great locomotive organ of most Molluscs, the "foot," and is therefore called the "pedal" ganglia. The third pair is known by the cumbersome name of the "parieto-splanchnic" ganglia, because it supplies nervous filaments to the walls (*parietes*) of the body, and also to the internal organs (*splanchna*). In all the higher Molluscs it is this scattered condition of the nervous masses which distinguishes them so sharply from all other animals. Distinct respiratory organs may or may not be present, and they may be adapted for breathing air directly or through the medium of water. All the higher *Mollusca* are simple animals, and perpetuate their kind by means of the sexes ; but many of the lower forms have the power of producing colonies by continuous gemmation, much as we have formerly seen in the Hydroid Zoophytes.

The digestive system in all the *Mollusca* consists of a mouth,

gullet, stomach, intestine, and anus (fig. 129), with the exception of a few forms in which the intestine ends blindly. In some the

Fig. 129.—Diagram of the structure of a typical Mollusc (the Common Whelk). *f* The muscular "foot"; *op* The operculum; *t* One of the tentacles, or feelers, with an eye at its base; *p* The proboscis, retracted, with the mouth at its extremity; *oe* Gullet; *g* Stomach; *i* Intestine, terminating in the anus; *n* *n* Salivary glands; *l* The liver and the ovary; *h* The heart; *bc* The gill, contained in a hood of the mantle; *s* Breathing-tube or siphon; *c* and *c'* The main nerve ganglia, the one above the gullet being the cerebral ganglia, and the one below the gullet being the combined pedal and parieto-splanchnic ganglia.

mouth is surrounded by ciliated tentacles (*Polyzoa*, fig. 132); in others it is furnished with two long ciliated arms (*Brachiopoda*, fig.

Fig. 130. — *Terrebratula vitrea*. 1. Showing the ciliated "arms"; 2. Showing the shell with its loop for the support of the arms. (After Woodward.)

130); in the Bivalves (*Lamellibranchiata*), it is mostly furnished with four membranous processes or "palpi" (fig. 139, *p*); in others

it is furnished with a complicated toothed organ or "odontophore" (*Gasteropoda*, fig. 141, and *Pteropoda*); and lastly, the *Cephalopoda*, in addition to an odontophore, possess horny mandibles, forming a kind of beak, very like that of a parrot.

The blood is colourless, or nearly so. In the lowest class of the *Mollusca* (*Polyzoa*) the circulation is carried on by means of cilia, and there is no distinct heart nor any definite course of the circulating fluid. In the Sea-squirts (*Tunicata*) there is a distinct heart, but the structure of this is very simple, consisting of a mere tube, open at both ends, so that the course of the circulation is periodically reversed. In the higher *Mollusca* there is a distinct heart, consisting of two chambers, of which one (the *auricle*) receives the aerated blood from the gills, while the other (the *ventricle*) drives it through the body.

Respiration is very variously effected amongst the *Mollusca*. In the *Polyzoa* (fig. 132) respiration is discharged mainly by the crown of ciliated tentacles surrounding the mouth. In the Sea-squirts (fig. 134) respiration is effected by a greatly developed pharynx, which is perforated by numerous ciliated apertures. In the Lamp-shells and their allies (*Brachiopoda*, fig. 135) the long ciliated arms which spring from the sides of the mouth seem to be the main agents in respiration. In the Bivalve shell-fish, the Cuttle-fishes, and most of the Univalves, the breathing-organs are in the form of gills or branchiæ, adapted for breathing air dissolved in water. In the remainder of the Univalves (*e.g.*, Snails and Slugs) the breathing-organs are adapted for breathing air directly, and have the form of an air-chamber or pulmonary sac, produced by the folding of a portion of the mantle. The air is admitted to the chamber by a round opening situated on the side of the neck, and capable of being closed at will. The lining membrane of the chamber is richly supplied with blood-vessels, and thus the necessary purification of the blood is carried out.

In accordance with the scattered or rudimentary condition of the nervous system, the *Mollusca* are not characterised by acuteness of senses, nor by any great power of locomotion. Organs of sight exist in some of the lower and many of the higher *Mollusca*, attaining in the Cuttle-fishes (fig. 148) an extremely high type of organisation. Some of the common Bivalve shell-fish, such as the Scallop, possess numerous simple eyes placed along the margins of the mantle, but in many cases even these are absent. Locomotion is very variously effected, but seldom with much vigour or activity. The lowest classes of the *Mollusca* are in the great majority of instances fixed when adult. The common Univalve shell-fish, such as Whelks, Snails, Slugs, &c, creep about slowly by means of a flattened disc,

developed on the under surface of the body, and known as the "foot." Other Univalves and many Bivalves can effect short leaps by means of the foot; but many of the latter are permanently fixed to solid objects, or buried in the sand. The minute *Mollusca*, known as the *Pteropoda* (fig. 147), swim freely at the surface of the ocean by means of two fins, formed by a modification of the foot, and attached to the sides of the head. The only Molluscs which enjoy really active powers of locomotion are the predaceous Cuttle-fishes, which swim rapidly by means of fins, or by ejecting a jet of water from the cavity of the mantle, and which can also creep about by means of the "arms" placed round the mouth (fig. 148).

The last feature in the *Mollusca* which requires to be mentioned is the "shell." The shell is not invariably and universally present in the *Mollusca*, many being either destitute of a shell altogether, or having one so small that it would not commonly be recognised as such. In these cases, as in the common Slugs, the animal is said to be "naked." In all the *Mollusca* which possess a shell, this is secreted by the integument, or by what is technically called the "mantle"; and in all cases it is composed of carbonate of lime. The methods in which the lime is arranged differ in different cases; but all living shells have an outer covering of animal matter, which is known as the "epidermis." In a great many of the higher *Mollusca*, such as the Whelks, Periwinkles, Snails, and others, the shell consists of only a single piece, when it is said to be "univalve." In many others, such as Oysters, Mussels, Scallops, &c., the shell is composed of two pieces, and is then said to be "bivalve." In a few forms the shell consists of several pieces, and it is then said to be "multivalve." The more important variations in the shells of the *Mollusca* will be noticed in speaking of the different classes of the sub-kingdom.

In accordance with the nature of the nervous system, the *Mollusca* are divided into two great divisions, known respectively as the *Molluscoida* and *Mollusca proper*. In the *Molluscoida* the nervous system consists of a single ganglion, or principal pair of ganglia, and there is either no circulatory organ or an imperfect heart. In this division are included the three classes of the Sea-mosses (*Polyzoa*), the Sea-squirts (*Tunicata*), and the Lamp-shells and their allies (*Brachiopoda*). In the *Mollusca proper* the nervous system consists of three principal pairs of ganglia, and there is a well-developed heart, consisting of at least two chambers. Under this head come all the ordinary forms of Shell-fish.

CHAPTER XIX.

MOLLUSCOIDA.

CLASS I. POLYZOA.

THE members of this class are the lowest of all the *Mollusca*, and they are generally known by the popular names of "Sea-mosses"

Fig. 131.—*Flustra foliacea*, one of the Sea-mats. *a* Portion of the colony, natural size; *b* A fragment magnified, to show the cells in which the separate polypides are contained.

and "Sea-mats." They are invariably compound, forming associated growths or colonies, often more or less plant-like in form (fig. 131),

each consisting of a number of distinct but similar zoöids, produced by gemmation from a single primordial individual. The colonies thus produced are very generally protected by a horny or chitinous integument, and they are so like the Hydroid Zoophytes that they were long described as such. Indeed, the only absolute distinction between the two classes is to be found in the internal structure of the zoöids of each. The separate beings or zoöids which collectively constitute the colony of any *Polyzoön* are spoken of as "polypides"—the term *polypite* being only used in connection with the *Hydrozoa*, and the term *polyp.* being similarly restricted to the *Actinozoa*.

Each polypide in a typical *Polyzoön* has the following structure (fig. 132, 2): The body of the animal is enclosed in a double-walled sac, of which the outer layer is usually chitinous or calcareous, and constitutes a "cell" in which the zoöid is contained. This outer layer is known as the "ectocyst" to distinguish it from the ecto-

Fig. 132.—Morphology of Polyzoa. 1. Fragment of one of the Sea-mats (*Flustra truncata*) magnified to show the cells. 2. Diagram of a single polypide of a Polyzoön (after Allman): *a* Mouth surrounded by the ciliated tentacles; *b* Alimentary canal; *c* Anus; *d* Nerve-ganglion; *e* Investing sac or "ectocyst"; *ff* Reproductive organs; *g* Muscle. 3. Bird's-head process.

derm of the *Celenterata*. The cell, thus formed, is lined by a much more delicate membranous layer, which is known as the "endocyst." This membranous sac, formed by the endocyst, is pierced by two openings. One of these is the mouth, and it is always surrounded by a circle or crescent of hollow ciliated processes or tentacles (fig.

132, 2, *a*). These ciliated tentacles serve partly as respiratory organs, and partly to set up a current of water by which floating particles of food are brought to the mouth. The mouth and tentacular crown can be partially or completely pulled into the sac by means of a muscle which is fixed to the gullet (2, *g*). The mouth leads into a gullet, and that again into a stomach, sometimes with a muscular gizzard between. From the stomach proceeds an intestine of variable length, which terminates by a distinct anus at the upper part of the sac (2, *c*). On one side of the gullet, between it and the anus, is placed a single nerve-ganglion (*d*). Distinct reproductive organs (*f f*) are also present, and the whole cavity of the sac is filled with fluid. From the above description it will be evident that the typical polypide of a *Polyzoön* differs from the polypite of a *Hydrozoön* in having a distinct alimentary canal suspended freely in a body-cavity, in having both a mouth and vent, in having a distinct nervous system, and in having the reproductive organs contained in the body.

The foregoing gives the essential structure of the polypide of any *Polyzoön*, but in nature this simplicity is lost. In all cases in nature the primitive polypide possesses the power of producing fresh zoöids by a process of budding; and these zoöids remain attached to one another, so that ultimately there is produced a compound growth or colony. Further, in almost all the *Polyzoa*, the ectocyst or outer layer of the polypide is more or less hardened by the deposition in it of chitine or of carbonate of lime. The skeletons thus formed are the parts of the colony which are most familiarly known, and in the case of the common Sea-mats (fig. 131), they are very well known to seaside visitors, and are generally regarded as sea-weeds. Examined in its dead state, such a skeleton only shows a number of little horny chambers or cells (fig. 132, 1), each with a little aperture. When alive, however, each of these cells was tenanted by a single zoöid or polypide, capable of protruding its ciliated head from the aperture, and of again retiring within it if alarmed. The skeleton is, in some cases, furnished with curious organs, which are known as "bird's-head processes" (*avicularia*, fig. 132, 3), from their resemblance to the beak of a bird. The parts of this beak keep constantly snapping together, very much like the little pincer-like organs called "pedicellariæ" in the Sea-urchins and Star-fishes; but it is difficult to see what service they perform. They continue their movements long after the death of the polypides, and this appears, in some cases, at any rate, to be due to a peculiar system of nerves known as the "colonial" nervous system. In addition, namely, to the single ganglion with which each polypide is furnished, it has been shown that, in some forms, the zoöids composing the colony are

united together by a well-developed nervous system, and are thus brought into organic connection with one another.

The vast majority of the *Polyzoa* are fixed, and thus assume a very plant-like appearance. There is one fresh-water type, however (viz., *Cristatella*), in which the colony can creep about upon a flattened base very like the foot of a slug. In this same form, also, alone of all the *Polyzoa*, there is not any outer covering or ectocyst to the polypides.

The *Polyzoa* are partly inhabitants of the sea and partly of fresh water, and they are thus divided into two groups which, as a

Fig. 133.—1. Fragment of *Flustra truncata*, one of the Sea-mats, natural size. 2. A single polypide of *Valerka*, magnified, showing the circular crown of tentacles. 3. A polypide of *Lophopus crystallinus*, a fresh-water Polyzoan, highly magnified, showing the horse-shoe-shaped crown of tentacles; a Tentacular crown; b Gullet; c Stomach; d Intestine; e Anus; g Gizzard; k Endocyst; l Ectocyst.

general rule, differ from one another considerably in anatomical structure. In most of the fresh-water *Polyzoa* the tentacles are borne upon a crescentic disc or stage (fig. 133, 3), so that the crown of tentacles assumes the shape of a horse-shoe. In almost all the marine forms, on the other hand, the tentacles (fig. 133, 2) are simply arranged in a circle.

All the *Polyzoa* are hermaphrodite, each polypide being furnished with the reproductive organs proper to the two sexes. The eggs are simply liberated into the perivisceral cavity, where they are

fertilised ; but it is uncertain how the fertilised ova escape into the external medium. Besides true sexual reproduction, and besides the power of producing colonies by continuous budding, fresh individuals can be produced in many cases by a process of discontinuous gemmation.

CLASS II. TUNICATA.

The members of this class are not uncommonly called *Ascidian Molluscs* (Gr. *askos*, a wine-skin), from the resemblance which many of them exhibit in shape to a two-necked leather bottle (fig. 134, C). They are popularly known as "Sea-squirts," from their power of

Fig. 134.—Morphology of *Tunicata*. A, Diagram of the structure of a simple Tunicate : *t* Test; *t'* Second muscular tunic; *s* Branchial sac; *b* Branchial aperture; *a* Atrial aperture; *c* Atrium; *o* Opening of the gullet; *g* Stomach, leading into the intestine; *an* Anal aperture; *n* Nerve-ganglion. B, *Botryllus smaragdus*, a "compound" Tunicate—a small portion of a colony of the natural size, and a single system of the same enlarged; *ca* Common atrial aperture; *br* Branchial aperture of one of the zooids. C, *Molgula Manhattensis*, a simple Ascidian. The arrows in A and C show the direction of the water-currents.

forcibly ejecting water from the orifices of the bottle. Their scientific name, again, of *Tunicata*, is derived from the fact that the body is enveloped in a leathery elastic integument, which consists of different layers, and which takes the place of a shell. The outer covering of the animal is of a gristly or leathery consistence, and is known as the "test." It is remarkable for containing a considera-

ble proportion of a substance apparently identical with *cellulose*, which is one of the most characteristic of all vegetable products. The test is lined by a second coat, which is highly muscular, and confers upon the animal its power of contracting itself and squirting out water. Of the two necks which are placed at the anterior end of a simple Ascidian (fig. 134, C'), one is perforated by the aperture of the mouth, whilst the other serves as an excretory aperture. These two apertures are known respectively as the "oral," or "branchial," and the "atrial" apertures.

The oral aperture (*a*) is usually furnished with a circle of small non-retractile tentacles, and opens into a great chamber known by various names, but best as the "respiratory sac" or "branchial sac." This sac occupies the greater part of the cavity of the body (fig. 134, A, *s*), and has its walls perforated by numerous apertures, the sides of which are ciliated. At the bottom of the respiratory sac is a second opening (the *mouth* of some writers) which leads by a short gullet into a capacious stomach (*g*). From the stomach an intestine is continued to terminate by a distinct anus, which does not communicate directly with the exterior, but opens into a second great chamber, known as the "cloaca" or "atrium" (*c*). The cloaca, in turn, opens on the exterior by the second or atrial aperture in the test (*a*). These two great chambers—namely, the respiratory sac and the cloaca—occupy the greater part of the body-cavity, and where their walls come into contact, a free communication is established between the two by means of the ciliated apertures already spoken of as perforating the respiratory sac. The cilia which fringe these apertures all work towards the cloaca, and thus a constant current of water is caused to set in by the oral aperture, through the respiratory sac, into the cloaca, and out again by the atrial aperture. In this way respiration is effected, the walls of the respiratory sac being almost made up of blood-vessels. A distinct heart is present in all the *Tunicata*, but it has a very simple structure. It consists of a simple tube, open at both ends, and not provided with valves. In consequence of this, the circulation in the majority of Tunicaries is periodically reversed, the blood being driven for a certain number of contractions in one direction, and then propelled for a like period in an opposite direction; so that "the two ends of the heart are alternately arterial and venous."

The nervous system in the *Tunicata* consists of a single ganglion placed on one side of the oral aperture (fig. 134, A, *n*).

With one or two exceptions all the *Tunicata* are hermaphrodite, the organs of reproduction being situated in a fold of the intestine, and opening into the cloaca. The embryo is usually at first free, and swims about by means of a long tail, so that it presents con-

siderable resemblance to the tadpole of a frog. The tail of the larval Tunicate also possesses in its interior a singular axial rod, which presents a remarkable resemblance to the embryonic backbone or "notochord" of Vertebrate animals. There are, further, other points of likeness between the embryo Tunicates and the *Vertebrata*; and the Tunicates are, therefore, sometimes regarded as degenerate Vertebrate animals.

The Tunicata are all marine, but differ a good deal from one another in form. In the so-called "simple" Ascidians the animal has the shape figured above (fig. 134, C), and is fixed to some solid object by one end of the test. In the "social" Ascidians the organism consists of a number of zooids, produced by continuous budding, and connected together by a common tube, through which the blood circulates. In the so-called "compound" Ascidians (fig. 134, B) the tests are fused together into a common gelatinous mass, in which the individuals are embedded in groups. Some of the *Tunicata* are oceanic—that is to say, are found floating or swimming at the surface of the open ocean—and some exhibit the phenomenon of phosphorescence.

CLASS III. BRACHIOPODA.

The members of this class, sometimes called "Lamp-shells," are little known to the general public, being all marine, often inhabiting considerable depths in the sea, and being much more abundantly represented by fossil forms than by living examples. They are often placed with the ordinary Bivalve shell-fish (*Lamellibranchiata*), in consequence of their universally possessing a shell composed of two pieces or valves (fig. 135), but they are really of a much lower organisation. In their essential structure they show many points of affinity to the *Polyzoa*, but they are always simple animals, never forming colonies, and they always have a bivalve shell. The two pieces of which the shell is composed are always placed one in front and one behind, so that they are "ventral" and "dorsal," and not "right" and "left" as in the true Bivalves. The two valves of the shell are also always slightly, and sometimes greatly, different from one another in size, so that the shell is said to be "inequivalve." The ventral valve is usually the largest, and often possesses a prominent curved beak, which is generally perforated by an aperture through which there passes a muscular stalk by means of which the shell is attached to some solid object. In some cases, however, as in *Lingula* (fig. 136), the stalk of attachment simply passes between the valves, and is not transmitted through a distinct aperture. In other cases the shell is simply attached by the substance of the ventral valve.

The inner surface of the valves of the shell is lined by expansions of the integument, which are called the "mantle-lobes," and which secrete the shell. The digestive organs and muscles occupy a small space near the apex or "beak" of the shell, which is partitioned off by a membranous partition, perforated by the aperture of the mouth. The remainder of the cavity of the shell is almost filled by two long processes, derived from the sides of the mouth, fringed with lateral

Fig. 135. *Terebratulina* (*Waldheimia*) *funebris*. A, The shell viewed from behind, showing the dorsal valve, and the perforated summit of the ventral valve above it. B, Inner view of the dorsal valve, showing the shelly loop (*l*) which supports the spiral arms. C, Inner view of the ventral valve, showing the foramen or aperture (*f*) in the beak, through which the muscular stalk of attachment passes. D, Longitudinal and vertical section of the animal, showing the spiral arms (*a*), the stomach (*s*), and the liver (*h*). At *f* is the opening in the beak, with the stalk of attachment (*p*) passing through it. (After Davidson and Owen.) Some details have been omitted in figs. B, C, and D, for the sake of clearness.

branches, and termed the "arms" (fig. 135, D). These arms are usually closely coiled up, and serve to obtain food for the animal. It is from these organs that the name of the class is derived (Gr. *brachion*, arm; and *podes*, feet). The arms also serve as respiratory organs, and in many forms they are supported on an internal calcareous framework or skeleton, sometimes called the "carriage-spring apparatus."

The mouth is placed between the bases of the arms, and is not furnished with any apparatus of teeth. It conducts by a gullet into a distinct stomach, surrounded by a well-developed granular liver. The intestine may or may not be furnished with a distinct anus, but in no case does it open into the body-cavity. Within the lobes of the mantle there is a remarkable system of branched tubes, which commence by blind extremities, and finally communicate with the mantle-cavity by means of certain organs which were formerly believed to be hearts, and are now known as "pseudo-hearts." This system of tubes appears to be mainly, if not entirely, connected with reproduction. A true heart, however, is present in most, if not in all, of the *Brachiopoda*.

The nervous system consists of a single principal ganglion, in some cases connected with others so as to form a collar round the commencement of the gullet. In some cases, however, the nervous system appears to be very rudimentary.

The sexes appear to be sometimes distinct and sometimes united in the same individual. The embryo, in some cases, at any rate, is locomotive, moving from place to place by means of the ciliated arms or by ventral spines.

Fig. 136. — *Lingula anatina*, showing the muscular stalk by which the shell is attached (*p*). (After Cuvier).

CHAPTER XX.

MOLLUSCA PROPER.

THE higher *Mollusca* or *Mollusca Proper* comprise those members of the sub-kingdom in which *the nervous system consists of three principal pairs of ganglia; and there is always a well-developed heart consisting of at least two chambers.*

In this division are included the following classes:—

1. <i>Lamellibranchiata</i> ,	without a distinct head.
2. <i>Gasteropoda</i> ,	} with a distinct head and a masticatory
apparatus or "odontophore."
3. <i>Pteropoda</i> ,	
4. <i>Cephalopoda</i> ,	

CLASS I. LAMELLIBRANCHIATA.

These are well known as Bivalve shell-fish, such as Mussels, Oysters, Scallops, &c., and they are all either marine or inhabitants of fresh water. They are distinguished from the other Molluscs by having no distinct head, and by having the body protected by a bivalve shell composed of two pieces. They are called *Lamellibranchiata* from the fact that the organs of respiration are in the form of leaf-like gills or branchiæ, two of which (or sometimes one only) are placed at each side of the body, constituting what is known in the oyster as the "beard." The body of the *Lamellibranchiata* is more or less completely enclosed in an expansion of the integument which constitutes the "mantle," and which is divided into two halves or "lobes," which are placed on the *sides* of the animal, and secrete the shell. The shell, therefore, of the true Bivalves is composed of two valves, which are "right" and "left," and not "dorsal" and "ventral" as in the *Brachiopoda*. Moreover, the valves of the shell are usually of the same size, so that the shell is "equivalve"; and, lastly, the shell is more developed on one side than the other, so as to become "inequilateral" (fig. 138). The lobes of the mantle are sometimes quite free along their ventral margin; but at other times they are more or less united to each other, and leave only two

openings. Through one of these openings (the anterior) the "foot" is protruded (fig. 137, *f*); and through the other pass the respiratory tubes or "siphons" (*s*). The foot in the Bivalves is a muscular organ developed upon the lower surface of the body, but not forming a creeping flattened disc as in the ordinary Univalves. In many cases it is quite rudimentary; and even when it is employed in locomotion it is usually small. Most generally it is hatchet-shaped or pointed (fig. 137, *f*), and serves to enable the animal to make short leaps. In many cases—as in the common Mussels—the foot is subsidiary to a special gland, which secretes a viscous fluid, that hardens rapidly on exposure to the air. This fluid is moulded by the foot into silky threads (the so-called "byssus"), by means of which the shell is firmly fixed to some solid object. Besides the muscular foot, other muscles are present as well in the *Lamellibranchiata*. Of these the most important are the muscles which close the shell, and are called the "adductor" muscles. In one group of the Bivalves (*e.g.*, Oyster, Scallop, &c.), there is only one adductor muscle, but ordinarily there are two (fig. 138). These muscles leave distinct scars or "muscular impressions" in the dead shell, so that it is easy to determine how many were present in any given shell. The margin of the mantle, too, is muscular, and leaves upon the shell a distinct line where it was attached, this

Fig. 137 —Anatomy of a Bivalve Mollusc. *Mya arenaria* (after Woodward). The left valve and mantle-lobe, and half the siphons, are removed. *s s* Respiratory siphons, the arrows indicating the direction of the currents; *a a'* Adductor muscles; *b* Gills; *h* Heart; *o* Mouth, surrounded by (*p*) labial palpi; *f* Foot; *v* Anus; *m* Cut edge of the mantle.

being known as the "pallial line" (Lat. *pallium*, a mantle), as shown in fig. 138.

As regards the shell of the Bivalves the following are the chief points to be noticed. Each valve of the shell (fig. 138) is to be regarded as essentially a hollow cone, the apex of which is turned more or less to one side. The apex of the valve is known as the "umbo" or "beak," and is turned towards the mouth of the animal. Consequently, the side of the shell towards which the beaks are turned is known as the "anterior" side, and it is usually much shorter than the opposite or "posterior" side. The side of the shell at which the beaks are situated is known as the "dorsal" margin; and here the valves are united to one another for a longer or shorter

Fig. 138.—Left valve of *Cytherea chione* (after Woodward). A, Anterior margin; B, Posterior margin; C, Ventral margin or base; *n* Umbo; *h* Ligament; *c* Cardinal tooth; *tt* Lateral teeth; *a* Anterior adductor; *a'* Posterior adductor; *p* Pallial line; *s* Pallial sinus caused by the retractor muscles of the siphons.

distance along a line which is known as the "hinge-line." The union between the valves is usually effected by means of interlocking parts or "teeth," and there is often a band of horny fibres passing between the two valves just behind the beaks. In many cases there is also a series of horny fibres placed perpendicularly between the beaks, so as to be compressed when the shell is shut. By the elasticity of these, and of the external ligament when present, the valves of the shell are opened, without any effort of the animal, simply by relaxing the adductor muscles. The valves are shut again by the contraction of the adductor muscle or muscles.

As already said, the margin of the mantle leaves on the shell a distinct impression—the "pallial line"—and by inspection of this,

important conclusions can be drawn in any given case as to the mode of life of the animal. In certain shells, namely—(e.g., the Scallop, the Fresh-water Mussel, &c.) the pallial line is unbroken or “entire,” and in these the mantle-lobes were either quite free, or if attached to one another and drawn out into respiratory tubes, these were not furnished with special muscles by which the tubes could be retracted within the shell. In other Bivalves, on the other hand (fig. 138) the pallial line is indented to a greater or less extent, showing that the mantle-lobes were more or less united to one another, and were drawn out into long respiratory tubes or siphons, which were furnished with special muscles by which they could be withdrawn within the shell. This difference expresses a real distinction amongst the Bivalves, due to their mode of life. In all alike, the respiratory organs are in the form of membranous leaf-like gills, of which there are usually two on each side of the body. The gills are composed generally of tubular rods (fig. 137, *b*) richly supplied with blood-vessels, and covered with vibrating cilia. For the proper maintenance of respiration, however, it is necessary that the gills should be constantly supplied with fresh water. In those Bivalves in which the animal is free and the mantle-lobes not attached to one another, this is effected without any special mechanism. In those forms, however, in which the animal lives buried in the mud and sand, and the mantle-lobes are more or less completely united, there are two orifices, one of which admits fresh water, while the effete water is got rid of through the other. These orifices, in the shells just spoken of, are extended into two long tubes which are known as the “respiratory siphons.” The water passes in by one siphon, is swept over the surface of the gills, and then reaches the mouth (fig. 137, *c*), when it is returned in the opposite direction to escape by the other siphon. The same current of water, therefore, both carries oxygen to the gills, and serves to convey food to the mouth. The two siphons may be quite distinct from one another, but they are very often united together so as to look like a single tube (fig. 137, *s s*). They are often very small, and then they leave no traces of their existence in the dead shell; but when they are very long, they are furnished with muscles to retract them within the shell, and it is the scar left by these muscles which causes the pallial line to be indented. This indentation, therefore, as seen in the dead shell, is an indication that the animal possessed long retractile respiratory siphons, and lived, therefore, most probably embedded in sand or mud.

There is always a distinct heart (fig. 139, *h*) composed of two or three chambers, and in all cases acting as a mere *arterial* heart. That is to say, the heart propels the aerated blood derived from the

gills through the body, and has nothing to do with the propulsion of the non-aerated or venous blood through the gills. There is never any distinct head in any of the Bivalves, and for this reason they are sometimes called the "headless" (*acephalous*) Molluscs. The mouth is simply placed at the anterior end of the body, and is never furnished with teeth, though usually provided with membranous processes or "palpi" (fig. 139, *lp*). The mouth opens into a gullet

Fig. 139.—*Lamellibranchiatu*. Diagrammatic representation of the anatomy of a siphonate Bivalve. The left valve and left mantle-lobe are removed, and the siphons are cut short. *u* Umbo; *ca* Cartilage pit; *o* Mouth; *lp* Labial palpi; *a* Stomach, surrounded by liver; *st* Sac containing the crystalline stylet; *i* Intestine, perforating the heart (*h*); *r* Rectum, terminating in the anus; *ad* Anterior adductor; *pd* Posterior adductor; *n* Supraesophageal or cerebral ganglion (the mouth is a little displaced upwards, so that the ganglion comes to lie below the gullet instead of above it); *n'* Parieto-splanchnic or branchial ganglion; *f* Foot; *x* Cut edge of the right mantle-lobe; *rs* Retractor muscle of the siphons; *br* Branchiae of the left side; *g* Renal organ ("Organ of Bojanus"); *s* Inhalant siphon; *s'* Exhalant siphon.

which conducts to a stomach. The intestine is convoluted, and usually perforates the ventricle of the heart, ultimately terminating in a distinct anus, which is always placed near the respiratory aperture (fig. 139, *r*). A large and well-developed liver is also present.

The nervous system has its normal form of three principal masses—the cerebral, the pedal, and the parieto-splanchnic ganglia.

The majority of the Bivalve Molluscs have the sexes distinct, but they are sometimes united in the same individual. The young are

hatched before they leave the parent, and, when first liberated, are ciliated and free-swimming.

The habits of the *Lamellibranchiata* are very various. Some, such as the Scallops (*Pecten*), habitually lie on one side, the lower valve being usually the deepest, and the foot rudimentary or wanting. Others are fixed to the bottom of the sea by the substance of one of the valves. Others, such as the common Mussel, are moored to some foreign object by a tuft of silky fibres, constituting a "byssus." Many, such as the Gapers (*Mya*) and Razor-shells (*Solen*), spend their existence sunk in the sand of the sea-shore or the mud of estuaries. Others, such as the *Pholades*, bore holes in rock or wood, in which they live. Finally, many are permanently free and locomotive.

CLASS II. GASTEROPODA.

This class includes an enormous number of Molluscs, such as the Land-snails, Sea-snails, Whelks, Limpets, Slugs, Sea-lemons, &c., which agree in many fundamental characters, but nevertheless present many striking differences. From the very common occurrence of a shell composed of a single piece, the *Gasteropoda* are often spoken of in a general way as the "Univalve" Molluscs. In many, however, there is either no shell at all, or one so small that it would not generally be recognised as such; and in a few (*Chiton*) the shell is composed of eight pieces ("multivalve"). In none, however, is the shell composed of two pieces or "bivalve." The large majority of the *Gasteropoda* are further distinguished by the great development of the foot, which constitutes a broad flattened disc upon which they creep about, as may readily be observed in the common Slugs or Snails (fig. 142). Some, however, have the foot much modified and adapted for swimming. In many cases, also, the foot carries behind a horny or shelly plate which is known as the "operculum" (fig. 140, *o*), and which serves to close the shell when the animal is withdrawn within it.

The head in most of the *Gasteropoda*, unlike the Bivalves, is very distinctly marked out, and carries two long feelers, and two eyes, often placed upon stalks (fig. 142). The mouth, also, differs from that of the Bivalves in being furnished with a singular apparatus of teeth, constituting what is known as the "odontophore" (fig. 141), or "lingual ribbon. This consists essentially of a number of chitinous teeth, of different shapes in different species, supported upon a kind of strap which can be made to work backwards and forwards over a cartilaginous cushion, thus acting like a chain-saw. In addition to the odontophore there are sometimes horny jaws as well. The mouth (see fig. 129) leads by a gullet into a distinct

stomach, which sometimes is provided with calcareous plates for grinding down the food. The intestine is long, and always terminates in a distinct anal aperture. Distinct salivary glands are usually present, and the liver is well developed.

A distinct heart (fig. 129) is almost always present, and consists of two chambers, an auricle and a ventricle. Respiration is very variously effected—one great division being constructed to breathe

Fig. 140.—A, Sketch of a Whelk (*Buccinum undatum*) in motion: *f* Foot; *h* Head, carrying the feelers (*l*) with the eyes (*e*) at their bases; *p* Proboscis; *s* Respiratory siphon or tube by which water is admitted to the gills; *o* Operculum. air by means of water, whilst in another section the respiration is aerial. In the former of these—often spoken of as the “branchiate” (Gasteropods—respiration may be carried on in three ways. Firstly, there may be no special breathing-organ, the blood being simply exposed to the action of the water, as it circulates through the thin walls of the mantle-cavity. Secondly, the breathing-organs may be in the form of outward processes of the skin, exposed to view on the back or sides of the animal (fig. 144). Thirdly, the breathing-

organs may be in the form of plume-like gills, contained in a more or less complete chamber, formed by a folding of the mantle (fig. 129). In many members of this group the water attains access to the gill-chamber by means of a tubular prolongation or folding of the mantle, forming a siphon (fig. 140, *s*), and often the effete water is expelled by another tube which is similarly constructed. In the second great section—often called the “pulmonate” Gasteropods—respiration is effected by a pulmonary chamber or lung, formed by a folding of the mantle, and having air admitted to it by a distinct aperture.

The sexes in the *Gasteropoda* are mostly distinct, but in some groups (*e.g.*, the Pulmonate forms and the Sea-slugs) they are united in the same individual. The young, when first hatched, are always provided with an embryonic shell, which may be entirely lost in the adult, or may simply become concealed by a fold of the mantle. In the water-breathing forms the young is protected by a small nautilus-shaped

Fig. 141.—Portion of the lingual ribbon of the common Whelk, magnified (after Woodward).

Fig. 142.—Gasteropoda. The Garden Snail (*Helix aspersa*).

shell, within which it can entirely withdraw. At this stage, it is enabled to swim about freely by means of two ciliated lobes springing from the sides of the head, but this ciliated “veil” is soon lost.

As regards the shell of the *Gasteropoda*, the following points may

be noticed. The shell is composed either of a single piece (univalve), or of a number of plates placed one behind the other (multivalve).

The univalve shell is to be looked upon as essentially a hollow cone, the apex of which is placed a little on one side. In the simplest forms, as in the Limpets, the conical shell is retained throughout life without any alteration. In the great majority of cases, however, the cone is considerably elongated, so as to form a tube, which may retain this shape (as in the "Tooth-shell"), but which is usually coiled up into a spiral. The "spiral univalve" may, in fact, be regarded as the typical form of the shell in the *Gasteropoda* (fig. 140, B). The coils of the spiral are termed the "whorls," and are usually more or less amalgamated on one side. In most cases, too, the whorls are wound obliquely round a central axis or pillar, increasing gradually in size to the mouth. The last whorl is the largest, and is termed the "body-whorl." The mouth of the shell in many forms is unbrokenly round or "entire" (fig. 143), and it is found that most of these forms subsist on vegetable food, as, for instance, the common Periwinkles. In others, again (fig. 140, B), the mouth of the shell is notched or is produced into a canal, as in the common Whelk, and it is found that these live upon animal food, or are "carnivorous." There may be more than one of these canals or tubes, but they do not necessarily indicate the nature of the food, as their function is to protect the respiratory siphons.

Fig. 143. — *Scalaria Greenlandica*, a Holostomatous Univalve.

The *Gasteropoda* are divided into a good many groups, of which the more important may be briefly noticed, the foregoing applying chiefly to the ordinary forms, which therefore need no further description. The remaining members of the water-breathing Gasteropods are divided into two sections, differing a good deal from the typical forms of the class in many respects.

Fig. 144. — Nudibranchiata. *Doris Johnstoni*, one of the Sea-lemons.

As examples of the first of these may be taken the Sea-slugs and Sea-lemons (*Nudibranchiata*), specimens of which may at any time be found creeping about on sea-weeds, or attached to the under surface of stones at low water. These slug-like animals (fig. 144) are wholly destitute of a shell when fully grown, but possess an embryonic shell when young. When there are any distinct respiratory

organs, these are in the form of gills, placed, without any protection, upon the back or sides of the body. The head is furnished with tentacles, which do not appear to be used as organs of touch, but are more probably connected with the sense of smell; and behind the tentacles are generally two eyes. Locomotion is effected, as in the true Slugs, by creeping about on the flattened foot.

The last remaining group of the "branchiate" Gasteropods is that of the *Heteropoda* (fig. 145), comprising a number of curious forms which are found swimming at the surface of the open sea, instead of creeping about at the bottom of the sea. In order to adapt them for this mode of life, the foot, instead of forming a creeping disc, is modified to form a compressed fin (*f*). The *Heteropoda* are to be regarded as the most highly organised of all the *Gasteropoda*, at the same time that they are not the most typical members of the class. Some of them can retire completely within their shells, but others

Fig. 145. — *Heteropoda*. . *Carinaria cymbium*. *p* Proboscis and mouth; *t* tentacles; *b* Gills; *s* Shell; *f* Foot; *d* Disc. (After Woodward.)

have large bodies, and the shell is either small or entirely absent. In *Carinaria*, which may be taken as a good example of the group, there is a little limpet-shaped shell protecting the gills (*b*) and heart. The animal swims, back downwards, by means of a vertically-flattened ventral fin (*f*), on one side of which is a little sucking-disc (*d*), by which the animal can adhere at pleasure to floating sea-weed. *Carinaria* is found in the Mediterranean and other warm seas, and is so transparent that the course of the intestine can be seen along its whole length.

The last group of the class is that of the "air-breathing" Gasteropods, so well-known as Land-snails, Pond-snails, and Slugs (fig. 146). All the members of this group are formed to breathe air directly, instead of through the medium of water, and they therefore never possess gills or branchiæ. In place of these they have a pulmonary chamber or lung, formed by a folding of the mantle, and having air admitted to it by a round hole on the right side of the

neck, which can be opened and closed at will. Though thus adapted for breathing air directly, many of the members of this group can only live in damp or moist places, while others habitually live in fresh water. The common Pond-snails are examples of these last. The condition of the shell varies very much. Some, such as the common Land-snails (fig. 142), have a well-developed shell within

Fig. 146.—*Lim x S verbi i*, one of the Slugs. (After Woodward.)

which the animal can completely withdraw itself for protection. Others, such as the common Slugs (fig. 146), have a rudimentary shell which is completely concealed within the mantle. Others are entirely destitute of a shell. They all agree with the typical Gastropods in creeping about on a broad, flattened foot.

CLASS III. PTEROPODA.

This class is a very small one, and includes a number of minute *oceanic* Molluscs, often called "Winged Snails," which are found swimming near the surface in the open ocean, far from land, and often in enormous numbers. The organs of locomotion are two wing-like fins (fig. 147) attached to the sides of the head, and formed by a modification of a portion of the foot. The body is usually protected by a symmetrical glassy shell (fig. 147, D), consisting of two plates united along their edges, or in other cases forming a spiral (fig. 147, A and C). In some, however, there is no shell, and the body is quite naked (fig. 147, B). The head is rudimentary, and bears the mouth, which is furnished with an odontophore. The heart consists of an auricle and ventricle, and the respiratory organs are extremely rudimentary. The sexes are united in the same individual in all the *Pteropoda*.

The Pteropoda occur, as already said, in the open ocean, and they are found in all seas from the tropics to within the arctic circle, sometimes in such numbers as to discolour the water for many miles. Minute as they are, they constitute in high latitudes one of the staple articles of diet of the whale, and they themselves in turn

are probably carnivorous, feeding upon small Crustaceans and other diminutive creatures. Though all the living forms are small, Geo-

Fig. 147.—Pteropoda. A, *Spirialis rostralis*. B, *Pneumodermon violaceum*. C, *Heterofusus buliminoides*. All enlarged. e Epipodia or fins; t Tentacles. logy leads us to believe that formerly there existed comparatively gigantic forms, which appear to be truly referable to this class.

CHAPTER XXI.

CEPHALOPODA.

CLASS IV. CEPHALOPODA.

THE last and highest class of the *Mollusca* is that of the *Cephalopoda*, comprising the Cuttle-fishes, Calamaries, Squids, and the Pearly Nautilus. They are all inhabitants of the sea, and are all

Fig. 148 —*Sepioida Atlantica*, one of the Cuttle-fishes. (After Woodward.)

carnivorous ; and they are possessed of considerable powers of locomotion. At the bottom of the sea they can walk about head downwards, by means of the arms (fig. 148) which surround the mouth, which are usually provided with numerous suckers, and which are really produced by a splitting up of the margins of the foot. It is from the presence of these arms that the class derives its name (Gr. *kephale*, head ; and *podes*, feet). The Cuttle-fishes can also swim rapidly, either by means of expansions of the skin constituting fins, or by the forcible expulsion of water from the cavity of the mantle, the reaction of which causes the animal to move in the opposite direction. The majority of the living Cephalopods are naked, possessing only an internal skeleton, and this often a rudimentary one ; but the Argonaut (Paper Nautilus) and the Pearly

Nautilus are protected by an external shell, though the nature of this is extremely different in the two forms.

The body in the *Cephalopoda* is symmetrical, and is enclosed in an

integument which may be regarded as a modification of the mantle of the other *Mollusca*. Ordinarily there is a tolerably distinct division of the body into an interior portion, carrying the head, and a posterior portion, in which the antenal organs are enclosed. The head (fig. 148) is very distinct, bearing a pair of large globular eyes, and having the mouth in its centre. The mouth is surrounded by a circle of eight, ten, or more, long muscular processes, or arms, which are generally provided with rows of suckers. Each sucker consists of a cup-shaped cavity, the muscular fibres of which converge to the centre, where there is a little muscular eminence or papilla. When the sucker is applied to any surface, the contraction of the radiating muscular fibres depresses the papilla so as to produce a vacuum below it, and in this way each sucker acts most efficiently as an adhesive organ. The whole of this complex mechanism of suckers is completely under the control of the animal, and the irritability of the suckers is retained even for days after death. In most of the Cuttle-fishes (*Octopoda*) there are only eight arms, and these are nearly similar to one another. In others, however (fig. 148), there are ten processes round the mouth, of which eight are like each other, and constitute the true arms, whilst two—called tentacles—are much longer than the others, and bear suckers only towards their extremities, which are enlarged and club-shaped. The Paper Nautilus (fig. 151) has two of the arms webbed at their extremities and secreting a shell; and the Pearly Nautilus, alone of all living *Cephalopoda*, has numerous arms, more than ten in number, and destitute of suckers.

The mouth leads into a cavity containing two powerful horny or partially calcareous jaws or mandibles, working vertically, very like

Fig. 149.—Diagram of a Cuttle-fish (altered from Huxley): *m* Mandibles; *n* Cerebral ganglia; *l* Liver; *p* Intestine; *o* Ovary; *g* Gill; *i* Ink-bag; *f* Funnel; *s* Internal skeleton, or "cuttle-bone."

the beak of a bird (fig. 149 *m*), together with an "odontophore" or "tongue," the hinder part of which is furnished with recurved spines. This cavity leads by a gullet, furnished with salivary glands, into a stomach, from which an intestine is continued to terminate by a distinct anus, which opens on the ventral surface at the base of the so-called "funnel." The funnel is a muscular tube placed on the under surface of the head, and communicating on the one hand with the external medium, and on the other with the cavity of the mantle. In the *Nautilus* alone it is simply formed of two muscular lobes, which are in apposition, but are not united together so as to form a tube. In many cases there is also a special gland, known as the "ink-bag" (fig. 149, *i*), for the secretion of an inky fluid, which the animal discharges into the water, so as to enable it to escape when menaced or pursued. The duct of the ink-bag opens at the base of the funnel near the anus; but the Pearly *Nautilus* and the allied fossil forms are without this means of defence, which the presence of an external shell renders unnecessary.

The respiratory organs are in the form of plume-like gills, placed on the sides of the body in a branchial chamber, which opens in front on the under surface of the body. In almost all the living *Cephalopoda* there are only two gills, one on each side, and hence this section is known as that of the "*Dibranchiata*." In the Pearly *Nautilus* alone there are four gills, two on each side, hence the name of "*Tetrabranchiata*" applied to the order of which this is the only living representative. In the Cuttle-fishes, at the base of each gill is a special contractile cavity, called a "branchial heart," by which the venous blood, returned from the body, is driven through the gills. In addition to these branchial hearts there is a true arterial heart, by which the aerated blood received from the gills is driven through the body. The admission of water to the branchiae is effected by the expansion of the mantle, which allows the entrance of the outer water into the mantle-cavity. The mantle then contracts, and the water is forcibly expelled through the funnel, which is often furnished with a valve, allowing the passage of water outwards, but preventing its entrance inwards. By a repetition of this process both respiration and locomotion are simultaneously effected, for the jets of water expelled from the funnel by their reaction drive the animal in the opposite direction. In this case, therefore, as in many others, the more active the animal is, the more perfectly is the respiratory process carried on.

The nervous system is formed upon essentially the same plan as in the other *Mollusca*, but the great nerve-centres are collected to form a ring round the gullet, and are protected by a cartilage, which is to be regarded as a rudimentary skull. This

structure, therefore, is a decided approach to the Vertebrate type of organisation.

The sexes in all the *Cephalopoda* are in different individuals, and the reproductive process in the Cuttle-fishes is attended with some singular phenomena. The most remarkable point in this connection is the modification of one of the arms of the male Cuttle-fishes, for the purpose of conveying the male element to the female. The details of the modification vary in different species of Cuttle-fish.

In some of the Cuttle-fishes the modified arm becomes the receptacle of the spermatozoa, but is not itself actually detached from the animal. In some cases, however, as in the Paper Nautilus (*Argonauta*), the process goes still further. The female of this species (fig. 151), attains a considerable size, and is protected by an external shell.

Fig. 150.—*a* Male of *Argonauta argo*, with the modified reproductive arm still contained in its enveloping cyst, four times enlarged (after H. Muller); *b* Detached reproductive arm or hectocotylus of *Tremoctopus violaceus* (after Kolliker).

The male (fig. 150, *a*) is not more than an inch in length, is devoid of a shell, and has its third left arm metamorphosed. This arm is developed in a cyst, and is ultimately detached from the body, and deposited by the male within the mantle-cavity of the female. When first discovered in this position, it was described as a worm living parasitically on the Argonaut, under the name of "Hectocotylus" (Gr. *hekaton*, a hundred; *kotulos*, a cup), from the suckers or cups with which it was furnished. Subsequently it was described as the entire male Argonaut; and it is only recently that it has been proved to be nothing more than one of the arms of the male, detached for

the purpose of conveying the sperm-cells to the female. For the above reason, the general name of "hectocotylus" is given to the detached reproductive arm of any of the Cuttle-fishes (fig. 150, *b*).

The *shell* of the *Cephalopoda* is sometimes external, sometimes internal. The internal skeleton is seen in most of the Cuttle-fishes, in which it is known as the "cuttle-bone" or "pen." It may be either horny or calcareous, and it is sometimes complicated by the addition of a chambered portion. The only living Cephalopods which are provided with an external shell are the Paper Nautilus (*Argonauta*) and the Pearly Nautilus (*Nautilus pompilius*); but not only is the structure of the animal different in each of these, but the nature of the shell itself is entirely different. The shell of the Argonaut (fig. 151) is coiled into a spiral, but it is not divided into chambers, and it is secreted by the webbed extremities of two of the dorsal arms of the female. These arms are bent backwards, so as to allow the animal to live in the shell; but there is no organic connection between the shell and the body of the animal. The shell of the Pearly Nautilus, on the other hand, is secreted by the mantle, and is organically connected to the animal. It is coiled into a spiral (fig. 155), but it differs from the shell of the Argonaut in being divided into a series of chambers by means of shelly partitions, which are connected together by a tube or "siphuncle," the animal itself living in the last and largest chamber only of the shell.

The *Cephalopoda* are divided into two extremely distinct and natural orders, termed respectively *Dibranchiata* and *Tetrabranchiata*, according as they have *two* or *four* gills or branchiæ.

The *Dibranchiata* comprise the Cuttle-fishes, Squids, Calamaries, and Paper Nautilus, and they are characterised by being almost invariably destitute of any external shell; by never having more than eight or ten arms, which are always furnished with suckers; by having only two gills, which are provided with "branchial hearts"; by the possession of an "ink-bag"; and by the fact that the "funnel" forms a complete tube. They are divided into two sections — *Octopoda* and *Decapoda* — according as they have only eight arms (fig. 150), or eight arms with two additional longer processes or "tentacles" (fig. 153). Amongst the *Octopoda* are the Paper Nautilus and the Poulpes (*Octopus*). The Paper Nautilus is found in the warmer seas of various parts of the world, generally floating at the surface. The two sexes differ, as already said, greatly in external appearance. The female (fig. 151) inhabits a beautiful one-chambered cell, which is secreted by the webbed extremities of two of the dorsal arms. The shell is not in any way attached to the body of the animal, but the webbed arms are turned backwards, and the animal sits in the shell with the funnel turned

towards the keel. It swims by the jets of water emitted from the funnel, and crawls upon the sea-bottom, head downwards, carrying its shell on its back. The male Argonaut (fig. 150) is only about an inch in length, has no shell, and has all its arms alike, except the one which is metamorphosed into the "hectocotylus." The Poulpes

Fig. 151.—*Argonauta argo*, the Paper Nautilus, female. The animal is represented in its shell, but the webbed dorsal arms are separated from the shell which they secrete, and which they ordinarily embrace.

(*Octopi*) are universally distributed in the seas of both temperate and tropical regions. They are the "polypi" of Homer and Aristotle, and are voracious animals inhabiting rocky shores.

The *Decapoda* are chiefly found in the open sea, often in enormous numbers, and the best known are the Calamaries and Squids. The body is elongated, and is always furnished with lateral fins, with which they swim actively. The shell is internal, hidden in the mantle, and differs considerably in different members of the group. In the common Calamaries it forms a horny pen, with a central shaft and two lateral expansions or wings (fig. 152, *b*). In the genus *Sepia*, the skeleton is calcareous, and is sometimes called the "cuttle-bone" (fig. 152, *a*). In the curious *Spirule* of recent seas, the shell is rolled up into an open spiral, and is divided by calcareous partitions into a succession of chambers (fig. 152, *c*), which are placed

in communication with one another by a small tube or "siphuncle." The shell thus constituted is buried in the mantle at the hinder end of the body (fig. 154). Lastly, in the curious extinct group of the *Belemnites*, which also belong here, the elongated body was supported by a long dart-like internal skeleton, the chief portion of which consisted of a cylindrical pointed fibrous body, called the "guard." In front, the guard was hollowed out into a conical cavity, in which was lodged a singular series of chambers, united by a tube or "siphuncle," and forming collectively what is called

Fig. 152.—*a* Internal skeleton of *Sepia orada*; *b* Pen of *Histiotentis Bonelliana*; *c* Shell ("phragmacone") of *Spirula fragilis*; *d* Animal of *Spirula Peronii*.

the "phragmacone." In front of that, again, the skeleton was prolonged forward into a more or less extensively developed horny expansion or "pen."

The second order of the *Cephalopoda*—that of the *Tetrabranchiata*—comprises forms characterised by being creeping animals, protected by an *external many-chambered shell*, the partitions between the chambers being perforated for the passage of a membranous or calcareous tube, termed the "siphuncle." The arms are more than ten in number, and are devoid of suckers; the gills are

four in number, two on each side of the body; the funnel does not form a complete tube; and there is no ink-bag.

Though abundantly represented by many and varied fossil forms, the only living member of the *Tetrabranchiata* with which we are acquainted is the Pearly Nautilus, which has long been known by its beautiful chambered shell. The shell of the Pearly Nautilus (fig. 155) is coiled into a spiral, and is many-chambered, the chambers being walled off from one another by curved shelly partitions or septa, perforated centrally by a foramen which transmits a mem-

Fig. 153.—Cephalopoda. *Sepia elegans*.

Fig. 154.—Anatomy of *Spirula australis* (after Owen), showing the position of the skeleton.

branous tube or siphuncle. The animal inhabits only the last and largest chamber of the shell, from which it can protrude its head at will. The function of the chambers of the shell is not very clearly understood; but it appears to be that of reducing the specific gravity of the shell to near that of the surrounding water; since they appear to be filled with some gas apparently secreted by the animal. Good authorities, however, believe that these chambers are filled with water. The siphuncle does not communicate in any way with the chambers of the shell, and its functions are also un-

known, except that it must certainly serve to maintain the vitality of the shell.

Of the fossil *Tetrabranchiata* the most important are the *Orthocerata* and the *Ammonites*. The *Orthocerata* played a very important part in the seas of the Paleozoic or Ancient-life period of the earth's history, in which they apparently filled the place now taken by the predaceous Cuttle-fishes. They agreed with the *Nautilus* in having a many-chambered shell, divided by curved partitions, perforated by a tube or siphuncle. The shell, however, differed from that of the *Nautilus* in not being curved or coiled up, but in being straight. In other nearly allied forms the shell was bent or even partially coiled up, but never so completely as in the true *Nautili*. Many of the

Fig. 155.—The Pearly Nautilus (*Nautilus pompilius*). *a* Mantle; *b* Its dorsal fold; *c* Hood; *o* Eye; *t* Tentacles; *f* Funnel.

Orthocerata were of small size, but some of them were colossal, shells having been found of six or seven feet in length, and as thick as the body of a man.

The *Ammonites* (fig. 156), with a number of allied forms of varied shapes and beautiful structure, appear to have taken the place of the *Nautilidae*, to a great extent, in the seas of the Secondary period; at which time, too, Dibranchiate Cephalopods first made their appearance. The true *Ammonites* resembled the *Nautilus* in having a many-chambered shell, which was coiled up into a spiral, but the position of the siphuncle was different, and the partitions or septa between the various chambers of the shell were wonderfully folded

and lobed instead of being simply curved. The numerous beautiful shells allied to the Ammonites cannot be even mentioned here; but it is to be remembered that they are principally characteristic of the

Secondary period in geology, and that they are hardly known as occurring in the older period (Palæozoic epoch)

VERTEBRATE ANIMALS.

CHAPTER XXII.

GENERAL CHARACTERS OF THE VERTEBRATA.

THE five sub-kingdoms which we have previously considered—viz. the *Protozoa*, *Cœlenterata*, *Echinodermata*, *Annulosa*, and *Mollusca*—were grouped together by Lamarck into one great division which he termed the *Invertebrata*. The remaining sub-kingdom, that of the *Vertebrata*, is so well-marked and compact a division, and its distinctive characters are so numerous and so important, that this mode of viewing the animal kingdom is, at any rate, a very convenient one.

The sub-kingdom *Vertebrata* includes the five great classes of the Fishes (*Pisces*), Amphibians, Reptiles, Birds (*Aves*), and Mammals; and the name of the sub-kingdom is derived from the very general, though not universal, presence of the bony axis known as the “vertebral column” or backbone. One of the most fundamental of the distinctive characters of Vertebrate animals is to be found in the fact that the main masses of the nervous system (that is to say, the brain and spinal cord) are completely shut off from the general cavity of the body. In all Invertebrate animals (fig. 157, A) the body may be regarded as a single tube, enclosing all the viscera; and consequently, when a distinct nervous system and alimentary canal are present, these are in no way shut off from one another. The transverse section, however, of any Vertebrate animal (fig. 157, B) shows *two* tubes, one of which contains the great nervous axis (*n'*), or brain and spinal cord, whilst the other contains the alimentary canal, the chief circulatory organs, and certain portions of the nervous system (*n*) which are known to anatomists as the “sympathetic” system.

Leaving the brain and spinal cord out of sight for a moment, we see that the lower or visceral tube of a Vertebrate animal contains the digestive canal (*b*), the hæmal or blood-vascular system (*c*), and a system of nervous ganglia (*n*). Now this is exactly what is contained within the visceral cavity of any Invertebrate animal; and it follows from this that the "cerebro-spinal" nerve-system of the *Vertebrata* is a structure for which no precise parallel exists among Invertebrates.

Another peculiarity which is present in all the *Vertebrata* is, that at an early period of life there is developed in the lower wall of the tube which contains the cerebro-spinal axis a singular structure known as the "notochord," or "chorda dorsalis" (fig. 157, B, *ch*). This is a semi-gelatinous rod, tapering at both ends, and extending along the floor of the cerebro-spinal tube. In some cases the notochord remains permanently in this condition, but in most cases it is replaced at maturity by the bony column or backbone, from which the *Vertebrata* derive their name. The general structure of the

Fig. 157.—Diagrams representing transverse sections of one of the higher Invertebrata, A—and one of the Vertebrata, B. *a* Wall of the body; *b* Alimentary canal; *c* Hæmal or blood-vascular system; *n* Nervous system; *n'* Cerebro-spinal axis or brain and spinal cord, enclosed in a separate tube; *ch* Notochord, or chorda dorsalis.

vertebral column will be described shortly, and it is sufficient to state here that it consists of a series of bony or cartilaginous segments or "vertebræ," arranged so as to form a longitudinal axis upon which the spinal cord is supported. It is to be remembered, however, that all Vertebrate animals do not possess a vertebral column. They all possess a notochord, but this may remain persistent throughout life, and in many cases the development of the spinal column is very imperfect.

The skeleton of all Vertebrate animals is *internal*, and the muscles are attached to its several parts. The value of this character is in no way affected by the fact that many Vertebrates, such as the Tortoises, Crocodiles, and others, possess an *external* skeleton as well. The *limbs* of Vertebrate animals are always articulated or

jointed to the body, and they are always turned away from that side of the body (the "neural" side) upon which the great masses of the nervous system are placed. The limbs may be altogether wanting, or partially undeveloped, but there are never *more than two pairs*, and they always have an internal skeleton for the attachment of the muscles of the limb.

A distinct blood-vascular or "hæmal" system is present in all Vertebrates, and in all except one—the Lancelet—there is a single contractile cavity or heart, furnished with valvular openings.

Lastly, the masticatory organs of all Vertebrates are modifications of parts of the walls of the head, and are never modified limbs or hard structures developed in the mucous membrane of the digestive tube, as they are in the Invertebrates.

The above are the leading characters which distinguish the *Vertebrata* as a whole; and before going on to consider the different classes, it may be as well to give a short and general sketch of the anatomy of the Vertebrates, commencing with their bony framework or skeleton.

The skeleton of the *Vertebrata* may be regarded as consisting of the bones which go to form the trunk and head on the one hand, and of those which form the supports for the limbs on the other hand. The bones of the trunk and head may be regarded as essentially composed of a series of bony rings or segments, arranged longitudinally. Anteriorly, these segments are much expanded and also much modified to form the bony case which encloses the brain and which is termed the *cranium* or skull. Behind the head, the segments enclose a much smaller cavity in which is contained the spinal cord, and they are arranged one behind the other, forming the "vertebral column." The segments which form the vertebral column are called "vertebræ," and they have the following general structure. Each vertebra (fig. 158, A) consists of a central portion known as the "body," or "centrum" (*c*), placed immediately below the spinal cord, and giving origin to certain "processes." The ends of the bodies of the vertebrae are all united together in different ways, so as to give the column great flexibility. From the back of the body of the vertebra proceed two bony arches which unite behind and thus form with the centrum a bony canal in which the spinal cord is contained. For this reason these arches (*n*) are called the "neural" arches. From the point where the neural arches unite—that is to say, from the back of the neural canal—proceeds a long process, sometimes cleft at its extremity, termed the "spinous process" (*s*). Springing also from each neural arch is a second shorter process (*a*) termed the "articular process," since by means of these, as well as by the bodies, the vertebrae are jointed or "ar-

ticulated" together. Also arising from the neural arches at their junction with the body of the vertebra, there may be two lateral processes (*d*) which are called "transverse processes." This is the

Fig. 158.—A, Vertebra (lumbar) of a Whale: *c* Centrum or body; *n* Neural arches; *s* Spinous process; *a* Articular process; *d* Transverse processes. B, Thoracic segment or vertebra: *c* Centrum of vertebra; *n* Neural arches, enclosing the canal for the spinal cord; *s* Spinous process; *r* Ribs; *p* Costal cartilages; *b* Breastbone or sternum. (After Owen.)

ordinary structure of the vertebra of a Mammal, and the names here used are those applied to the parts of the vertebra in human

Fig. 159.—Skeleton of an Armadillo, showing the regions of the vertebral column. *c* Cervical region; *d* Dorsal region; *l* Lumbar region; *s* Sacral region; *t* Caudal region or tail.

anatomy. In comparative anatomy, however, these parts have proper technical names which can be employed for them in all animals alike.

In the typical vertebra the segment is completed by a second arch, which is placed in front of or beneath the body of the vertebra, and which is known as the "haemal" arch, as it includes and protects the principal organs of the blood-circulation (fig. 158, B). This second arch is often only recognisable with great difficulty, as

its parts are generally much modified; but a good example may be obtained in the human thorax. Here, attached to the front of the vertebrae, we find a series of bony arches, known as the ribs (*r*), followed by a series of cartilaginous pieces of a similar shape, termed the "costal cartilages" (*p*), the whole united in front by a central bone, known as the breastbone or "sternum" (*b*).

As a general rule, amongst the higher Vertebrates, the following *regions* may be recognised in the vertebral column: Firstly, the *cervical region* (fig. 159, *c*), comprising a variable number of vertebrae, which constitute the neck, and immediately follow the head. Secondly, the cervical region is succeeded by a variable number of vertebrae which usually carry ribs, and are known as the *dorsal vertebrae* (*d*), or vertebrae of the back. Thirdly come certain vertebrae which constitute the *lumbar region* (*l*), or the region of the loins. Fourthly, there usually follows a series of vertebrae which are immovably united together to form a single bone, which is termed the *sacrum* (*s*). Lastly, there comes a variable series of vertebrae which are usually free and movable upon one another, and which constitute the *caudal region*, or the region of the tail (*t*).

The nature of the bones which enter into the composition of the limbs varies somewhat in different Vertebrates in accordance with their mode of life; but in all the higher

Fig. 160.—Fore-limb of the Chimpanzee. *c* Collar-bone, or clavicle; *s* Shoulder-blade, or scapula; *h* Bone of the upper arm, or humerus; *r* Radius; *u* Ulna; *d* Bones of the wrist, or carpus; *m* Bones of the root of the hand, or metacarpus; *p* Bones of the digits, or phalanges.

members of the sub-kingdom the limbs are built upon a general and easily recognisable type. The fore-limb consists generally of the following parts: 1. A series of bones uniting the limb to the trunk, the two most important being the shoulder-blade (*scapula*, fig. 160, *s*) and the *coracoid*, while a collar-bone (*clavicle*) may also be present.

2. The bone which forms the upper portion of the limb proper, and which is known as the *humerus* (*h*). 3. Two bones which form the middle portion of the limb (*e.g.*, the fore-arm in man), and which are known as the *radius* and *ulna* (*r* and *u*), of which the former is the bone mainly concerned in carrying the hand or fore-foot. 4. A number of small bones, which form the wrist, and are termed the *carpus* (*d*). 5. The cylindrical bones (usually five in number) which form the root of the hand, and are known as the *metacarpus* (*m*). 6. The bones which form the fingers proper, and which are known as the *phalanges* (*p*).

Essentially the same parts can be traced in the hind-limb of a typical Vertebrate animal, but they are known by different names. The bones which unite the limb to the trunk are usually more or less completely united together, constituting a single mass, known as the *innominate bone* (fig. 161, *i*). This is followed by a long cylindrical bone, which forms the upper portion of the hind-limb, and is known as the "thigh-bone," or *femur* (*f*). Following this are the two bones of the shank, corresponding to the *radius* and *ulna* of the fore-limb, and known as the *tibia* and *fibula* (*t* and *s*). Of these, the *tibia* (*t*) corresponds to the *radius*, and is mainly concerned in carrying the foot. Next comes a series of small bones, which form the ankle, and are known as the *tarsus* (*r*). This is succeeded by a series of cylindrical bones (usually five in number), which form the root of the foot, and which are termed the *metatarsus* (*m*). Finally, the metatarsus is succeeded by the bones of the toes, which in this case are again termed the *phalanges* (*p*). In both limbs the usual number of phalanges to each toe or "digit" is three.

The digestive system of the *Vertebrata* does not require a lengthened notice. The mouth is usually furnished with *teeth*, which have for their chief function the reduction of the food to a condition in which it can be digested. In some animals, however, such as the snakes, the teeth are only used to hold the prey, and not for mastication; and in others, such as the turtles and birds, the jaws are not furnished with any teeth at all. The food is also usually subjected

Fig. 161.—Hind-limb of the Chimpanzee. *i* Innominate bone; *f* Thigh-bone, or femur; *t* Tibia; *s* Fibula; *r* Bones of the ankle, or tarsus; *m* Metatarsus; *p* Phalanges.

in the mouth to the action of a special fluid—the saliva—which acts chemically as well as mechanically upon the food, and which is secreted by special glands, known as the “salivary glands.” From the mouth the food passes through a muscular tube—the gullet, or *œsophagus* (fig. 162, *g*)—to the proper digestive cavity, or stomach (*s*). Here it is subjected to the action of a special digestive fluid—the “gastric juice”—and is converted into a thick pasty fluid, which

is called *chyme*. From the stomach the chyme passes into a long convoluted muscular tube, which is called the “small intestine” (*sm*). Here it is subjected to the action of two other digestive fluids, called the “bile” and “pancreatic juice,” as well as to the fluids secreted by the intestine itself. The bile is secreted by a large gland, which is known as the “liver,” whilst the pancreatic juice is produced by another, termed the “pancreas,” both pouring their secretion into the upper part of the small intestine. By the combined action of these digestive fluids the chyme is ultimately converted into a milky fluid, which is called *chyle*, when it is fit to be taken up into the blood-vessels. The small intestine finally opens into a tube of larger diameter, which is called the “large intestine” (*lm*), and this opens on the surface of the body by an anal aperture. In the large intestine the last remaining portions of the food which can be rendered useful are absorbed into the blood, the indigestible portions being ultimately got rid of as useless. The fluid products of digestion (*chyle*) are chiefly absorbed from

Fig. 162.—Digestive system of a Mammal. *g* Gullet or *œsophagus*. *s* Stomach; *sm* Small intestine; *lm* Large intestine; *r* Large intestine terminating in its final portion, called the “rectum.”

the intestinal canal by a set of special vessels, which are present in all Vertebrates, and which are called the *lacteals*, from the milky fluid which they contain. These lacteals combine to form a large trunk, by which their contents are ultimately added to the circulating blood. Part of the products of digestion is absorbed by the veins which ramify on the intestinal canal, and which ultimately unite to form a great vessel, called the “vena portæ,” which goes to the liver.

The materials, however, which are taken up in this way also ultimately reach the circulating blood. In this way, therefore, fresh matter is being constantly added to the blood to replace the waste caused by the performance of the vital functions.

The blood is thus formed out of the materials which are taken into the alimentary canal as food ; and in almost all of the *Vertebrata* it is of a red colour, when viewed in mass. This is due to the presence in it of numerous microscopical particles, which are known as the "blood-corpuscles," the fluid itself being colourless. In fig. 163 are represented some of the forms of blood-corpuscles which are found in different divisions of the *Vertebrata*.

Fig. 163.—Blood-corpuscles, magnified. *a* Man ; *b* Goose ; *c* Crocodile ; *d* Frog ; *e* Skate.

The blood is always distributed through the body by means of a system of closed tubes, which constitute the "blood-vessels," and with the single exception of the Lancelet, it is always propelled by means of a contractile muscular cavity or "heart." The heart and other circulatory arrangements differ considerably in different classes of the *Vertebrata*, but these differences will be best considered at a later period. *Respiration* in all the *Vertebrata* is effected by means of distinct breathing-organs, assisted in many cases by the skin. In the water-breathing Vertebrates, such as fishes, the respiratory organs are in the form of *gills* or branchiæ, which are richly supplied with blood, and are exposed to the influence of water holding oxygen in solution. In the air-breathing Vertebrates, the breathing-organs are in the form of *lungs*. These essentially consist of cellular or spongy organs, placed in the cavity of the chest, richly furnished with blood-vessels, and receiving constant supplies of fresh air by means of a tube which opens in the throat and is known as the "windpipe," or *trachea*. In the higher Vertebrates the heart becomes a double organ, one side being concerned wholly with driving the impure (*venous*) blood to the lungs, whilst the other side propels the pure oxygenated (*arterial*) blood to all parts of the body.

The waste substances of the body—of which the most important are *water*, *carbonic acid*, and the peculiar substance called *urea*—are got rid of by the skin and lungs, but principally by two glands which are called the *kidneys*. The excretion of *urea* from the body, as a general rule, is wholly effected by means of the kidneys alone ; and this is

their most important function, as the retention of this substance within the body rapidly causes death. The secretion of the kidneys is sometimes got rid of by means of special canals appropriated to this alone; but in the lower *Vertebrata* it is discharged into the hinder extremity of the alimentary canal, and is evacuated along with the undigested portions of the food.

The *nervous system* varies greatly in its development in the *Vertebrata*. In the little fish called the Lancelet, the main mass of the nervous system consists of a cord of nervous matter, representing the spinal marrow, but not having in front any enlargement which represents the brain. In all the other *Vertebrata* the central masses of the nervous system (termed the *cerebro-spinal axis*) consist of a nervous cord (the spinal cord) contained in the canal formed by the *neural* arches of the vertebrae, and of an anterior mass of nervous matter, which is protected by the skull, and is termed the "encephalon," or *brain*. The size and development, however, of the brain vary enormously in different Vertebrates; and in the lower forms the brain is little more than an aggregation or collection of nervous masses or "ganglia," of which some are connected with the special senses, sight, hearing, taste, and smell, special organs for which are present in almost all the *Vertebrata*.

Reproduction in the *Vertebrata* is always truly sexual, the sexes are almost always in different individuals, and in no case are compound organisms produced by a process of budding or fission. Most are *oviparous*, producing eggs from which the young are developed. Some retain the eggs within the body till the young are hatched, but no direct connection is established between the young animal and the parent; and these are sometimes said to be *ovo-viviparous*. The higher Vertebrates, however, bring forth their young alive, and are said to be *viviparous* (Latin, *vivus*, living; and *pario*, I bring forth).

PRIMARY DIVISIONS OF THE VERTEBRATA.—The *Vertebrata* are variously divided into great primary sections by different writers, and all of these divisions have more or less merit. Here, however, the classification proposed by Professor Huxley will be followed, and it is not necessary to enter into any consideration of the others. It has also been thought advisable to give in this place a brief account of the leading characters which separate these divisions from one another, though it is not to be expected that the learner will be able to appreciate the full value of these characters till he has completed his study of the *Vertebrata* as a whole.

The *Vertebrata* are divided by Professor Huxley into the following great divisions:—

I. ICHTHYOPSIDA (Gr. *ichthus*, a fish; and *opsis*, appearance).—In

this section are included the Fishes (Class *Pisces*), and the Frogs, Newts, and their allies (Class *Amphibia*). They are all characterised by the fact that they possess gills or branchiæ, either throughout life or during the earlier stages of their existence; that they possess nucleated red blood-corpuscles (*i.e.*, blood-corpuscles with a central particle or *nucleus*, fig. 163, *d, e*), and by certain embryonic characters as well. From the temporary or permanent possession of gills they are often spoken of as the *Branchiate* Vertebrates.

II. SAUROPSIDA (Gr. *saura*, a lizard; and *opsis*, appearance).—In this division are the Birds (Class *Aves*), and the true Reptiles (Class *Reptilia*). They are characterised by the fact, that at no time of their life are they ever provided with gills; that the skull is jointed to the vertebral column by a single articulating surface (or *condyle*); that the lower jaw is composed of several pieces, and is united to the skull by means of a special bone (called the *os quadratum*); that they possess nucleated red blood-corpuscles (fig. 163, *b, c*), and by certain embryonic characters as well.

III. MAMMALIA (Lat. *mamma*, the breast).—In this division are all the ordinary Quadrupeds; characterised by the constant absence of gills; by the skull being jointed to the vertebral column by two articulating surfaces (or condyles); by the fact that the lower jaw is composed of only two pieces, and is not united to the skull by means of a special bone (the *quadrate* bone); by having non-nucleated red blood-corpuscles (fig. 163, *a*); and by having special glands—the mammary glands—which secrete a special fluid—the milk—by which the young are nourished for a longer or shorter period after birth.

These three primary divisions comprise the five great classes into which the *Vertebrata* are divided:—

1. *Pisces* (Fishes).
2. *Amphibia* (Frogs, Newts, &c.)
3. *Reptilia* (True Reptiles)
4. *Aves* (Birds).
5. *Mammalia* (Quadrupeds).

ICHTHYOPSIDA.

CHAPTER XXIII.

CLASS I. PISCES.

THE fishes form the lowest class of the *Vertebrata*, and they may be broadly defined as being Vertebrate animals *provided with gills*, whereby they are enabled to breathe air dissolved in water; *the heart*, when present, *consists of a single auricle and ventricle* (with the exception of the Mud-fishes); and the *limbs*, when present, are *in the form of fins, or expansions of the integument*.

In their external form, fishes are in most cases adapted for rapid locomotion in water, the shape of the body being such as to cause the least possible friction in swimming. To this end, as well as for purposes of defence, the body is generally enveloped in a species of chain-mail formed by overlapping scales, to which bony plates, tubercles, and spines are sometimes added. Valuable characters can sometimes be drawn from the nature of the scales; and with a view to this, the integumentary appendages of fishes have been divided by Agassiz as follows (fig. 164):—

Fig. 164.—Scales of different fishes.
a Cycloid scale (Pike); *b* Ctenoid scale (Perch); *c* Placoid scale (Thornback); *d* Placoid scale of *Rhina*; *e* Ganoid scales (*Palaeoniscus*.)

scales occur in most of our common fishes (*e.g.*, the Pike).

2. *Ctenoid* scales (*b*).—These resemble the cycloid scales in being thin, flexible, horny scales, but they are distinguished by having their hinder margins cut into comb-like projections, or fringed with

1. *Cycloid* scales (*a*), consisting of thin, flexible, horny scales, which are circular or elliptical in shape, and have a smooth outline. These

spines. The common Perch supplies a good example of these scales.

3. *Placoid scales* (*c, d*).—These are detached bony grains, tubercles, or plates, scattered through the skin, and sometimes armed with projecting spines, these latter being usually composed of a substance allied to dentine.

4. *Ganoid scales* (*e*), composed of a layer of true bone, covered by a layer of hard polished enamel.—These scales are usually much thicker and larger than the ordinary scales; they are often oblong or rhomboidal in shape; they are often connected together by little processes; and they generally are in contact by their edges, but rarely overlap one another.

In most fishes there is also to be observed a line of peculiar scales, forming what is called the “lateral line.” Each of the scales of this line is perforated by a minute tube, which leads into a longitudinal canal, supplied with special nerves; and the whole apparatus has apparently a sensory function.

As regards the true internal skeleton, fishes differ very widely from one another, but the skeleton is so complicated that only a few of the most important points can be mentioned here. In one fish—the Lancelet—there can hardly be said to be any true skeleton, the vertebral column being represented permanently by the semi-gelatinous notochord (fig. 171). In others, such as the Lampreys, Sturgeons, and Rays, the skeleton remains permanently in the condition of gristle (cartilage); in others, it is partially cartilaginous and partially ossified; and lastly, in most modern fishes it is completely converted into bone. The *vertebral column* in a Bony Fish consists of a number of vertebræ which are hollow or cup-shaped at both ends (biconcave or “amphicelous”), the cup-like margins being united together by ligaments. The cavities formed by the apposition of the vertebræ are filled with the gelatinous remains of the notochord. This gelatinous elastic substance acts as a ball-and-socket joint between the vertebræ, thus giving the whole spine the extreme flexibility which is essential to animals living in a watery medium. The entire spinal column is divisible into no more than two distinct regions, an *abdominal* and a *caudal*. The abdominal vertebræ possess a superior or *neural* arch, for the passage of the spinal cord, a superior spinous process, and two transverse processes to which the ribs are attached. The caudal vertebræ have no marked transverse processes; but, in addition to the other parts already mentioned, they give off an inferior or *hemal* arch, *below* the body of the vertebræ, and they carry *inferior spinous* processes (fig. 165, *h*). The *ribs* are attached to the transverse processes or to the bodies of the abdominal vertebræ (fig. 165, *r*); and they do not

enclose any thoracic cavity, or protect the organs which are usually contained in the chest—namely, the heart and breathing-organs. The anterior or lower ends of the ribs of fishes are free, or are rarely united to hard productions of the integument; but there is never any breastbone or *sternum* properly so called.

The only remaining bones of the trunk proper are the so-called “interspinous bones” (fig. 165, *i i*). These are a series of pointed dagger-like bones, embedded in the middle line of the body, between the great lateral muscles which form the greater part of the body of a fish. The inner ends or points of the interspinous bones are attached by ligament to the spinous processes of the vertebræ, and at their outer ends they support the framework (rays) of the so-called

Fig. 165.—Skeleton of the common Perch (*Perca fluviatilis*). *p* Pectoral fin; *v* One of the ventral fins; *a* Anal fin, supported upon interspinous bones (*i*); *c* Caudal fin; *d* First dorsal fin; *d'* Second dorsal fin, both supported upon interspinous bones; *i i* Interspinous bones; *r* Ribs; *s* Spinous processes of vertebrae; *h* Hamial processes of vertebrae.

“median” fins. As a rule there is only one interspinous bone to each vertebra, but in the Flat-fishes (Sole, Turbot, &c.) there are two. The limbs of fishes may be wholly wanting, or one pair may be absent, but in no case is the number greater than the regular Vertebrate type—namely, two pairs. When developed, however, the limbs of fishes are very different from those of other Vertebrates, consisting of expansions of the integument, furnished with bony or gristly supports or rays, and thus constituting what are called “fins” (fig. 166). The pair of limbs which correspond to the arms of man and to the fore-limbs of other Vertebrates are termed the *pectoral* fins, and they are attached to a bony arch which is attached either to the back of the the skull or to the spinal column (fig. 165, *p*, and 166, *p*). The hind-limbs in fishes are known as the *ventral*

fins (figs. 165, 166, *v*), and are not only often wanting altogether, but when present are less developed than the pectorals and less fixed in their position. They are united to an imperfect bony arch, which represents the innominate bones, or pelvic arch, of the higher Vertebrates, but which is never joined to the spinal column. In some fishes the ventral fins are placed far back, and in these the bony arch which supports them is freely suspended in the muscles. In others the ventral fins are altogether out of position, and are placed beneath or even in front of the pectoral fins; and in these cases the pelvic arch is attached to part of the pectoral arch. The pectoral and ventral fins represent, as just said, the fore and hind limbs, and consequently there are always *two* of each, when they are present at all. They are therefore spoken of as the "paired" fins. Besides

Fig. 166.—Outline of a Fish (*Perca granulata*), showing the "paired" and "median" fins. *p* Pectoral fin; *v* Ventral fin; *d* First dorsal fin; *d'* Second dorsal fin; *c* Caudal fin; *a* Anal fin.

these, however, or in the absence of one or both of these, there is also a series of what are called "median" fins; that is to say, fins which are placed in the middle line of the body, and which are *unpaired*, having no fellows. These median fins agree with the paired fins in being expansions of the integument, supported by bony or gristly supports or "rays," and they are carried by the heads of the "interspinous" bones, already described (fig. 165, *i i*). They are variable in number, and in some cases there is only a single fringe running round the hinder extremity of the body. Commonly, however, the median fins consist of one, two, or three expansions of the dorsal integument, called the "dorsal" fins (fig. 165, *d d'*); one or two on the ventral or lower surface near the vent, called the "anal" fins (*a*); and a broad fin at the extremity of the vertebral column, constituting the "caudal" fin or tail (*c*).

The tail in all fishes is placed vertically—that is to say, it strikes the water laterally or from side to side, and it is the chief organ of progression in the fish. Two very distinct types of tail are found amongst the fishes. In one of these, found in most living forms, the tail is composed of two nearly equal lobes which spring from the end of the spine (fig. 167, A). This form of tail is said to be “homocercal.” In the other type of tail, found in the Dog-fishes, Sharks, and other living fishes, as well as in many extinct forms, the tail is unequally lobed, and is said to be “heterocercal” (fig. 167, B). In these forms the vertebral column is prolonged into the upper lobe of the tail, and the greater portion of the tail is found below the spine.

In both the paired and the median fins the integument is supported by a series of spine-like bones, which are called “rays.”

Fig. 167 —A, Sword-fish, showing homocercal tail; B, Sturgeon, showing heterocercal tail.

These rays are sometimes simple undivided rays or spines, when they are called “spinous rays” (165, *d*) ; but in other cases they are both divided by transverse joints, and split up into numerous longitudinal branches towards their extremities, when they are spoken of as “soft rays” (165, *d'*). The soft rays occur in many fishes in different fins, but they are invariably present in the caudal fin or tail.

As regards the *digestive system* in fishes, the mouth is usually furnished with a complicated system of teeth, developed not only upon the jaws, but upon any or every bone which enters into the composition of the oral cavity. The gullet opens into a stomach, usually of large size, and its hinder aperture (the *pylorus*) is usually furnished with a valve. Immediately behind the pyloric opening of the stomach there is usually a variable number of blind tubes

(called the "pyloric cæca") which open into the intestine, and which are believed to represent the pancreas. In some fishes, however, there is a well-developed pancreas, and in others even these tubes are wanting. The intestinal canal is a longer or shorter, more or less convoluted tube, and its absorbing surface is sometimes largely increased by a spiral folding of the mucous membrane, which winds like a screw in close turns from near the pylorus to the anus. The liver is usually of large size, and saturated with oil, but in the Lancelet it is doubtfully represented by a hollow sac-like organ. The kidneys in fishes are of great comparative size, forming two elongated organs, situated beneath the spine, and extending along the whole length of the abdomen.

Respiration in all fishes is aquatic, and is effected by means of

Fig. 168.—Gills and heart of the Perch exposed by the removal of the gill cover on the left side. *a* First of the four bony arches which carry the gills (*b b'*); *b'* The lower edges of the gills on the right side; *h* Heart. (After Van der Hoeven.)

gills or *branchiæ*, in all except the Lancelet, in which respiration is effected by branchial filaments placed round the pharynx, and also by a greatly developed pharynx perforated by ciliated apertures (fig. 171). The arrangement and structure of the gills in fishes vary a good deal in different orders, and the leading modifications will be noticed hereafter. In the meanwhile it will be sufficient to give a short description of the branchial apparatus in one of the Bony Fishes. In such a fish the gills consist of a single or double series of flat cartilaginous leaflets, covered by mucous membrane, richly supplied with blood, and arranged on bony or cartilaginous arches which are connected with the tongue-bone (*hyoid bone*) below and with the under surface of the head above (fig. 168). The branchial arches and branchiæ are suspended in cavities placed on the side of the neck, and in the ordinary Bony Fishes there is only one such cavity

on each side. The water is taken in at the mouth by a process analogous to swallowing, and it gains admission to the branchial chambers by means of a series of clefts or slits which perforate the

Fig. 169.—Diagram of the circulatory system in a Fish, the vessels containing venous blood being longitudinally shaded, and those containing arterial blood being cross-shaded. *vc* Vena cava; *vp* Vena portæ; *au* Auricle; *v* Ventricle; *ab* Bulbus arteriosus; *b* Branchial artery; *ba* One of the divisions of the branchial artery going to the gills, from which proceeds one of the corresponding branchial veins, by the union of which the subvertebral aorta (*sa*) is formed; *i* Intestine; *k* Kidney.

sides of the pharynx. Having passed over the gills and lost its oxygen, the effete water makes its escape behind by an aperture called the "gill-slit," which is placed on the side of the neck. The opening of the gill-slit is closed in front by a chain of flat bones which constitute the "gill-cover," and by a membrane which is supported upon a variable number of slender bony spines. This is the general mechanism of respiration in one of the Bony Fishes, but different arrangements are found in other cases, which will be subsequently noticed.

The heart in fishes may be regarded as essentially a *branchial* or respiratory heart, being concerned chiefly with driving the venous and impure blood to the gills. It consists in almost all cases of two cavities, an auricle and a ventricle (fig. 169). The auricle (*au*) receives the venous blood which has passed through all the various parts of the body, and propels it into the ventricle (*v*). From the ventricle proceeds a single great vessel (the "branchial artery"), the base of which is usually developed into a mus-

cular cavity, the "bulbus arteriosus" (*ab*), which acts as a kind of additional ventricle. By the ventricle and *bulbus arteriosus* the venous blood is driven to the gills, where it is subjected to the action of the water. The aerated blood is not returned to the

heart, but is driven from the gills through all parts of the body, the propulsive force necessary for this being derived partly from the heart, and partly from the contractions of the muscles between which the blood-vessels pass. The essential peculiarity of the circulation of fishes consists in this, that the arterialised blood returned from the gills is propelled through the general vessels of the body (systemic vessels) without being sent back to the heart. In the Lancelet, alone of all fishes, there is no single heart, and the circulation is effected by means of contractile dilatations situated upon several of the vessels. In the Mud-fishes (*Lepidosiren* and *Ceratodus*) the heart consists of two auricles and a ventricle. In all cases the blood is cold, or, in other words, has a temperature very little, or not at all, higher than that of the surrounding medium. The red blood-corpuscles (fig. 163, *c*) are always nucleated, and are oval in shape.

Whilst the respiration of all fishes is truly aquatic, most are, nevertheless, furnished with an organ which apparently corresponds to (or is *homologous* with) the lungs of the higher *Vertebrata*. This is known as the "air-" or "swim-bladder," and is a sac filled with gas and situated between the alimentary canal and the kidneys. In most cases the sac contains only a single cavity, but in many instances it is variously divided by partitions. In most fresh-water fishes the gases in the swim-bladder are mainly composed of nitrogen, but in the sea-fishes it is chiefly filled with oxygen. The sac of the swim-bladder is often closed, but in other cases it opens into the gullet by means of a duct which corresponds to the windpipe. In the great majority of fishes the functions of the air-bladder are mainly hydrostatic—that is to say, it serves to maintain the necessary agreement between the specific gravity of the fish and that of the surrounding water. In the singular Mud-fishes (*Lepidosiren* and *Ceratodus*), the air-bladder is composed of two distinct sacs, divided into a number of cellular compartments, and opening into the gullet by a tube. In these fishes it acts as a respiratory organ, and is therefore, not only in structure, but also in function, the representative of the lungs of the other *Vertebrates*.

The nervous system of fishes is of an inferior type of organisation, the brain being of comparatively small size, and consisting of a collection of ganglia. As regards the organs of the senses, two peculiarities deserve notice. In the first place, though fishes possess the essential parts of the organ of hearing, they possess no external ears, and mostly no external auditory openings. In the second place, the organ of smell consists of a double cavity lined by a mucous membrane folded into numerous plaits, into which water is admitted, usually by two distinct apertures or nostrils. Behind,

however, the nasal sacs are closed, and they do not communicate by any aperture with the throat, as they do in all the higher Vertebrates. The only exceptions to this rule are the Hag-fishes and their allies (*Myrinoids*), and the Mud-fishes (*Lepidosiren* and *Ceratodus*). The Hag-fishes and Lampreys are further peculiar in possessing, alone of all Vertebrate animals, a single nasal sac, opening by a single external nostril.

As regards their reproductive system, most fishes are truly *oviparous*, and the ovaries are familiarly known as the "roe." Some fishes are *ovo-viviparous*, retaining their eggs within the body till the young are hatched. The male organs of reproduction are commonly spoken of as the "milt" or "soft roe."

CHAPTER XXIV.

ORDERS OF FISHES.

THE number of different kinds of fishes is so enormous that nothing further will be attempted than merely to give an outline of the leading peculiarities which distinguish the different orders. The classification here adopted is the one now most usually followed, by which the class *Pisces* is divided into the following six orders :—

1. *Pharyngobranchii*.
2. *Marsipobranchii*.
3. *Teleostei*.
4. *Ganoidei*.
5. *Elasmobranchii*.
6. *Dipnoi*.

ORDER I. PHARYNGOBRANCHII.

This order of fishes includes only a single animal, the anomalous *Amphioxus*, or Lancelet, the organisation of which differs in almost all its important points from that of all the other members of the class. In fact, the Lancelet presents us with the lowest type of organisation as yet known in the *Vertebrata*. The Lancelet (fig. 170)

Fig. 170.—Pharyngobranchii. The Lancelet (*Amphioxus lanceolatus*), enlarged.

is an extraordinary little fish, from one and a half to two inches long, which burrows in sand-banks in various seas, but is especially abundant in the Mediterranean. The body is lanceolate in shape, and is provided with a narrow membranous border, of the nature of a median fin, which runs along the whole of the dorsal and a portion of the ventral surface, and expands at the tail to form a lancet-shaped caudal fin. There are no true “paired” fins, repre-

senting the fore and hind limbs. The mouth is a longitudinal fissure, placed at the front of the head, and completely destitute of jaws, but surrounded by a number of cartilaginous filaments. The throat is provided with several leaf-like filaments which are richly supplied with blood, and are believed to discharge in part the function of gills. The mouth (fig. 171, *o*) opens into a dilated chamber, which is considered to represent the pharynx, and is termed the pharyngeal or "branchial" sac. The walls of this chamber (*b*) are strengthened by numerous cartilaginous filaments, between which is a series of transverse slits or clefts, and the whole is covered with a richly ciliated mucous membrane. The function of this sac is clearly respiratory, the water from without being admitted through the mouth, passing through the branchial clefts into the abdominal cavity, and finally escaping by means of an aperture placed on the ventral surface a little in front of the anus. From the hinder end of the branchial sac proceeds the alimentary canal, which has appended to

Fig. 171.—The Lancelet (*Amphioxus lanceolatus*), enlarged to twice its natural size.
o Mouth; *b* Branchial sac; *g* Stomach; *h* Diverticulum representing the liver;

it a sac-like organ believed to represent the liver, and which terminates behind in a distinct anal aperture. There is no heart, and the circulation is entirely effected by means of several contractile dilatations, developed upon the great blood-vessels. The blood itself is colourless. No kidneys have hitherto been discovered, and the reproductive elements are emitted into the abdominal cavity, from which they escape by the pore placed upon the lower surface.

There is no skeleton properly so called. The notochord (*n*) remains throughout life as a semi-gelatinous rod, enclosed in a membranous sheath, and supporting the spinal cord. There is no skull, and the spinal cord does not expand in front to form a distinct brain or *encephalon*. The brain, however, may be said to be represented, as the front portion of the nervous axis gives off nerves to a pair of eyes, and another branch to a ciliated pit, which is believed to be a rudimentary organ of smell.

ORDER II. MARSIPOBRANCHII.

This order includes the Hag-fishes (*Myxinidæ*) and the Lampreys (*Petromyzonidæ*), and it is defined by the following characters: The body is cylindrical and worm-like, and is destitute of limbs. The skull is cartilaginous, there is no lower jaw, and the notochord remains through life. The mouth is circular and cup-like. The heart is composed of an auricle and a ventricle, but there is no *bulbus arteriosus*. The gills are pouch-like, communicating with the throat on the one hand, and opening externally on the other by means of apertures placed on the sides of the neck, or on the ventral surface.

The Hag-fish (*Myxine*) is an eel-like fish (fig. 172, A), which agrees with the Lampreys in having neither pectoral nor ventral

Fig. 172.—Morphology of Marsipobranchii. A, *Myxine glutinosa*, the Hag fish, showing the sucker-like mouth, and the two ventral openings (*h*) by which the water escapes from the gills. B, The River Lamprey or Lampern (*Petromyzon fluviatilis*), showing the seven branchial apertures on the side of the neck.

fins, the representatives of the fore and hind limbs. The mouth is of a very remarkable character, and enables the Hag-fish to lead a very peculiar existence. It is generally found embedded in the interior of some large fish, into which it has penetrated by means of a single serrated and recurved fang attached to the centre of the palate. The mouth itself is destitute of jaws, and forms a sucking disc or cup. Another remarkable peculiarity of the Hag-fishes is found in the structure of the nose. In all fishes, namely, except these and the Mud-fishes (*Lepidosiren* and *Ceratodus*), the nasal chambers are closed behind, and do not communicate with the cavity of the mouth, as they do in the higher Vertebrates. In the

Myxinoids, however, such a communication does exist. The nasal sac is placed in communication with the throat (pharynx) by means of a canal which perforates the palate. A second canal leads from the nasal cavity in front to open by an external aperture (the nostril) on the top of the head behind the mouth.

Another peculiarity, which is best considered in the Lampreys, is to be found in the structure of the respiratory organs, from which the name of the order is derived. When viewed externally, instead of the single great "gill-slit," covered by a "gill-cover," as seen in the ordinary Bony Fishes, the side of the neck presents seven round holes placed far back in a line on each side. These holes are the external apertures of the gills (fig. 172, B), which in these fishes are in the form of sacs or pouches, the lining membrane of which is thrown into numerous folds or plaits, over which the branchial vessels ramify. Internally the sacs communicate with the cavity of the pharynx, by means of a common respiratory tube into which they all open. It follows from this arrangement that the gill-pouches on the two sides of the neck communicate freely with one another through the pharynx. The object of this arrangement is to obviate the necessity for admitting the water to the gills through the mouth, as ordinary fishes do. These fishes are in the habit of fixing themselves to foreign objects by means of the suctorial mouth; and when in this position, it is, of course, impossible that they can obtain the necessary water of respiration through the mouth. As the gill-sacs, however, on the two sides of the neck communicate freely with one another through the pharynx, water can readily pass in and out. The gills are not provided with cilia, but the circulation of water is assisted by a kind of elastic cartilaginous framework upon which the whole respiratory apparatus is supported, and which acts somewhat like the ribs of the higher Vertebrates.

In the Hag-fishes, the structure of the respiratory organs is essentially the same as in the Lampreys; but the gill-pouches on each side are connected with a common tube, each of which opens on the ventral surface of the body by a small aperture placed at a considerable distance behind the head (fig. 172, A).

The Lampreys are distinguished from the Hag-fishes, not only by having separate and laterally placed apertures to the gill-pouches, but also by the fact that the nasal sac does not open behind into the throat. Some of them are inhabitants of rivers; but others live in the sea, and, like the great Sea-lamprey (*Petromyzon marinus*), betake themselves to fresh waters for the purpose of spawning. The young live in rivers, and pass through a curious metamorphosis.

ORDER III. TELEOSTEI.

The fishes comprised in this order, as implied in their name, have a well-ossified or bony skeleton, and they are commonly known as the "Bony Fishes." In all the *Teleostei*, the skeleton is bony, the skull is composed of distinct bones, and there is a lower jaw. The vertebral column always consists of more or less completely ossified vertebræ; and the two pairs of limbs, when present, are in the form of fins, supported by rays. The gills are free, comb-like or tufted in shape, and always protected by a bony gill-cover. The *bulbus arteriosus* is not capable of regular contractions, and is separated from the ventricle by only a single pair of valves.

Fig. 173.—The common Perch (*Perca fluviatilis*). *o* Gill-cover, with the gill-slit behind it; *p* One of the pectoral fins, the left; *v* The left ventral fin; *d* The first dorsal fin; *d'* The second dorsal fin; *c* The caudal fin or tail; *a* The anal fin; *l* Lateral line.

The order *Teleostei* comprises almost all the most familiar fishes, and it will be unnecessary to dilate here upon their structure, as they were taken as the type of the class in describing the fishes generally. It may be as well, however, to recapitulate some of the leading points in the anatomy of the Bony Fishes. 1. The *skeleton* is always more or less completely ossified, and does not remain cartilaginous throughout life. The notochord is not permanent, and the vertebral column consists of a number of distinct vertebræ. The vertebræ, however, are "amphicelous," or hollow at both ends, so that there is left between each pair a doubly conical cavity, which is filled with the cartilaginous or semi-gelatinous remains of the notochord. In this way an extraordinary amount of flexibility is given to the entire vertebral column. In no fish (except the Bony Pike, which belongs

to another order, is the conversion of the bodies of the vertebrae into bone carried further than this.

2. The integument usually develops scales, and these in the great majority of cases are of the forms known as "cycloid" and "ctenoid," the former being circular or elliptical horny plates, with plain margins; whilst the latter have their hinder margins cut into comb-like projections or fringed with spines (fig. 164, *a*, *b*).

3. The *anterior and posterior limbs* (fig. 174) are usually, but not always, present, and when developed they are always in the form of fins. These fins may be supported by "spinous rays" or "soft rays," or by both. The spinous rays are simple undivided bony spines which taper to a point. The soft rays are doubly divided, splitting up towards their extremities into a number of secondary rays, and being also divided by transverse joints into numerous short pieces.

4. Besides the "paired" fins which represent the limbs, there is

Fig. 174.—The Cod (*Gadus morhua*).

also a series of *unpaired* or "median" fins, the rays of which are supported upon a series of dagger-shaped bones, deeply plunged in the flesh in the middle line of the body, and known as the "inter-spinous" bones (fig. 165). The median fins (fig. 174) are variable in number, but when fully developed they consist of one to three fins on the back (the dorsal fins), one or two on the ventral surface (the anal fins), and one clothing the posterior extremity of the body (the caudal fin, or tail). In all the *Teleostei*, the caudal fin has the shape called "homocercal"—that is to say, it consists of two equal lobes—and the vertebral column is not prolonged into the upper lobe (fig. 174).

5. The heart consists of two cavities, an auricle and a ventricle, but the *bulbus arteriosus* is not rhythmically contractile, and is separated from the ventricle by only a single pair of valves.

6. The respiratory organs are in the form of free, comb-like, or tufted gills, enclosed in two cavities placed on the sides of the neck.

Each of these branchial chambers opens externally by a single aperture, the "gill-slit," which is protected by a chain of bones, forming the "gill-cover," and by a membrane supported by bony rays. Internally the branchial chambers communicate with the throat by a series of clefts or fissures, and the water required in respiration is taken in at the mouth by a process analogous to swallowing.

7. The nasal sacs never communicate behind with the throat (pharynx).

TABULAR VIEW OF THE MAIN DIVISIONS OF THE TELEOSTEI.

SUB-ORDER I. MALACOPTERI.—Usually a complete series of fins, supported by rays, all of which are *soft*, or many-jointed (with the occasional exception of the first rays in the dorsal and pectoral fins). A swim-bladder is always present, and is always connected with the gullet by a duct. The skin is rarely naked, and is mostly furnished with cycloid scales, but sometimes ganoid scales are present.

Amongst the more important families in this sub-order are the Eels (*Muraenidae*), Herrings (*Clupeidae*), Pikes (*Esocidae*), Carp (*Cyprinidae*), Salmon and Trout (*Salmonidae*), and Sheat-fishes (*Siluridae*).

SUB-ORDER II. ANACANTHINI.—Fins entirely supported by soft rays, and never by spinous rays. Ventral fins either wanting or placed under the throat, beneath or in advance of the pectorals.

The two leading families in this sub-order are the Cod, Ling, and Haddock family (*Gadidae*), and the Flat-fishes (*Pleuronectidae*), comprising the Sole, Turbot, Flounder, and others.

SUB-ORDER III. ACANTHOPTERI.—Fins with one or more of the first rays in the form of undivided, inflexible, spinous rays. Scales mostly ctenoid. Swim-bladder without a duct.

The leading families in this order are the Wrasses (*Cyclolabridae*), the Perches (*Percidae*), the Mackerels (*Scomberidae*), the Mulletts (*Mugilidae*), and the Gobies (*Gobiidae*).

SUB-ORDER IV. PLECTOGNATHI.—Certain of the bones of the mouth (the maxillary and premaxillary bones) immovably connected on each side of the jaw. Integumentary skeleton in the form of ganoid plates, scales, or spines.

The chief families in this sub-order are the File-fishes (*Balistidae*), and the Trunk-fishes (*Ostraciontidae*).

SUB-ORDER V. LOPHOBRANCHII.—Gill arranged in little tufts on the branchial arches. Integumentary skeleton in the form of ganoid scales.

The two families contained in this division are the Sea-horses (*Hippocampidae*), and the Pipe fishes (*Syngnathidae*).

ORDER IV. GANOIDEI.

The fourth order of fishes is that of the *Ganoidei*, including few living forms, but having a great and varied development in past geological epochs. The Ganoids are distinguished by the generally imperfect development of the skeleton, which is mostly cartilaginous

throughout life, and by having an integumentary skeleton composed of *ganoid* scales, plates, or spines (fig. 164, *d*). The skull is composed of distinct bones, and there is always a lower jaw. There are usually two pairs of fins (pectoral and ventral), supported by many series of cartilages, and the ventral fins are placed very far back. The first rays in the fins are usually in the form of strong spines. The caudal fin or tail is mostly heterocercal or unsymmetrical (fig. 167, B). The swim-bladder is always present, is often cellular, and is provided with an air-duct. The gills and gill-covers are essentially the same as in the Bony fishes. The heart has one auricle and a ventricle; and the *bulbus arteriosus* is rhythmically contractile, is furnished with a distinct coat of muscular fibres, and is provided with several transverse rows of valves.

The best known of the living Ganoids are the Bony Pike or Gar-

Fig. 175. — A, *Lepidosteus osseus*, the "Gar-Pike" of the American Lakes; B, *Aspidorhynchus*, restored (after Agassiz), a Jurassic Ganoid allied to *Lepidosteus*, but having a homocercal tail.

fish (*Lepidosteus*), the Sturgeon (*Acipenser*), and the *Polypterus*. Of these, the Bony Pike (fig. 175, A), is found in the rivers and lakes of North America. It is a large fish, attaining a length of several feet, and it has the body entirely covered with an armour of ganoid scales arranged in obliquely transverse rows. The jaws form a long narrow snout, armed with a double series of teeth, and the tail is heterocercal. The vertebral column is more perfectly ossified than in any other fish, the bodies of the vertebrae being convex in front and concave behind ("opisthocelous"). The *Polypterus* inhabits the rivers Nile and Senegal, and is remarkable for the peculiar structure of the dorsal fin, which is broken up into a series of small detached portions, each composed of a single spine in front, with a soft fin attached to it behind. Some of the species of *Polypterus* possess

external gills when young, which they lose when grown up, thus making an approach to the *Amphibia*. Many of the fossil Ganoids are more or less closely allied to the living *Lepidosteus* and *Polypterus*.

Another great group of the Ganoid fishes is represented by the Sturgeons (*Acipenseridae*), in which the skeleton is alway very imperfectly ossified, and the head, with more or less of the body, is protected by large ganoid plates, which are often united together at their edges by sutures (fig. 167, B). The true Sturgeons are confined to the seas and rivers of the Northern hemisphere. They mostly inhabit rivers ; but some live in salt water, and ascend rivers for the purpose of spawning. They grow to a great size, and possess a toothless mouth on the under surface of the snout. A curious Ganoid found in the Mississippi is the Paddle-fish (*Spatularia*).

The living Ganoid fishes are essentially fresh-water types ; and they are merely scattered survivors of a very extensive series of forms, most of which are now extinct.

ORDER V. ELASMOBRANCHII.

This order includes the Sharks, Dog-fishes, Rays, &c., and is distinguished by the following characters : The skull and lower jaw

Fig. 176.—A, *Spinax acanthias*, one of the Dog-fishes ; B, *Chimaera monstrosa*.

are well developed, but the skull is not composed of distinct bones, and simply forms a kind of cartilaginous box. The vertebral column is cartilaginous, but usually composed of distinct vertebrae.

The integumentary skeleton is in the form of *placoid* scales (fig. 164, c)—that is to say, of detached grains, tubercles, or plates. There are two pairs of fins, corresponding to the fore and hind limbs, and the ventral fins are placed far back, close to the anus. The heart consists of an auricle and ventricle; and the *bulbus arteriosus* is rhythmically contractile, is provided with a distinct coat of muscular fibres, and is furnished with several transverse rows of valves. The gills are fixed, and form a number of pouches, which open internally into the pharynx, and mostly communicate with the outer world by a series of apertures placed on the side of the neck (fig. 176, A). The intestine is very short, but to compensate

for this, the mucous membrane is thrown into a fold, which winds round the intestine in close turns from near the pyloric orifice of the stomach to the anus, and which thus greatly increases its absorbing surface.

The most characteristic examples of the Elasmobranch Fishes are the Sharks, Dog-fishes, Skates, and Rays, usually called Plagiostomous Fishes, because the mouth is transverse, and is placed on the under side of the head. In all these types there are five branchial pouches on each side, which open by five distinct slits on the surface of the body. There are also two apertures ("spiracles") on the

Fig. 177. —Batoides. *Raia marginata*, one of the Skates. Reduced one-sixth. (After Gosse.)

top of the head, just behind the eyes, which lead by tubes into the pharynx, and which correspond with an anterior pair of branchial pouches.

The Sharks and Dog-fishes (*Selachii*) have pectoral fins of the ordinary size and shape (fig. 176, A), and have the gill-slits placed on the sides of the neck. They have sharp conical teeth, in several rows, and they are nearly all voracious and fierce animals. The Sharks in particular attain a great size.

The Port Jackson Sharks (*Cestracion*) of the Pacific Ocean, resemble the true Sharks in most points; but they have blunt teeth adapted for crushing shell-fish.

The Skates and Rays (*Batides*) have the branchial openings placed on the under side of the head, while the body is generally flattened out into a rhomboidal disc, the greater part of which is made up of the enormously developed pectoral fins (fig. 177). In the Skates, as in the Dog-fishes, the eggs are enclosed in leathery capsules, familiarly known as "Mermaid's Purses."

In another section of the Elasmobranchs, typified by the *Chimæra* (fig. 176, B), though the internal structure of the gills is the same as in the ordinary examples of the order, there is only a single external gill-aperture. The group is therefore spoken of by the name of *Holocephali*.

ORDER VI. DIPNOI.

The best-known, and until lately the only, forms included in this order, are the very singular Mud-fishes (*Lepidosiren*), which are of great interest from the many points of affinity which they exhibit

Fig. 178.—A, *Lepidosiren paradoxa*, one of the Mud-fishes; B, Front of the mouth of the same, showing the teeth; C, One of the overlapping scales, enlarged.

to the *Amphibia*. The body of the *Lepidosiren* (fig. 178) is completely fish-like, and is protected by a covering of small, horny, overlapping scales, which have the cycloid characters. There are

two pairs of limbs, but these are in the form of awl-shaped organs, each supported by a single, jointed cartilaginous rod. The pectoral limbs have a membranous fringe inferiorly, and the ventrals are placed very far back. There is also a median fin behind, forming a continuous fringe round the compressed tail, and supported by cartilaginous rays.

The skull is composed of distinct bones, and there is a lower jaw; but the notochord is persistent, and there are no bodies of vertebræ developed. The respiratory organs are *twofold*, consisting, *firstly*, of free filamentous branchiæ or gills, contained in a branchial chamber, which opens externally by a single vertical gill-slit; and, *secondly* of true lungs, in the form of a double cellular air-bladder communicating with the gullet by means of an air-duct or windpipe. Sometimes, if not always, there are rudimentary *external* gills as well, placed on the side of the neck. The heart consists of a ventricle, and of *two* auricles, divided from one another by an incomplete partition. Lastly, the nasal sacs open behind into the throat, and do not form closed chambers opening only by the nostrils, as they do in all other fishes except the Myxinoids. The two best-known species are the *Lepidosiren paradoxa* from the Amazon, and the *L. (Protopterus) annectens* from the Gambia; but the former is

Fig. 179.—*Ceratodus Forsteri*, one of the Australian Mud-fishes, reduced in size.

very rare and little known. They both inhabit marshy tracts, and both appear to be able in the dry season to bury themselves in the mud, and to form a kind of chamber, in which they remain dormant till the rains of the wet season set them free.

In the fresh waters of Queensland, Australia, are found two other remarkable Mud-fishes, belonging to the genus *Ceratodus*. The singular *Ceratodus Forsteri* (fig. 179), often called the "Barra-munda," grows to the length of six feet, and has the body covered with very large cycloid scales. The fins are not awl-like, but consist of a fringe of fin-rays surrounding a central lobe. The Barra-munda seems to feed upon leaves, which it masticates by means of curious undulated bony plates or "molars," of which each jaw carries two. It appears occasionally to come to land, at which times it doubtless breathes by means of its lungs; but it has well-developed gills also, and is essentially an aquatic animal.

ICHTHYOPSIDA.

CHAPTER XXV.

CLASS II. AMPHIBIA.

THIS class of *Vertebrata* comprises the Frogs and Toads, the Newts and Land-salamanders, the *Ceciliæ*, and some extinct forms, and it may be briefly defined as follows : In all cases gills or branchiæ adapted for aquatic respiration are present during a part or the whole of life ; but in all cases true lungs adapted for breathing air are ultimately developed, even when the gills are retained through life. All pass through some sort of a metamorphosis after being set free from the egg. The limbs may be absent, or there may be only one pair, but in no case are they ever converted into fins. When median fins are present, as is sometimes the case, these are never furnished with fin-rays or interspinous bones, as in the fishes. The skull always articulates with, or is jointed to, the spinal column by *two* articular surfaces or *condyles*. The heart consists of two auricles and a single ventricle. The nasal sacs always open behind into the mouth ; and there is a common cavity or "cloaca" which receives not only the termination of the intestine (*rectum*), but also the ducts of the kidneys and of the reproductive organs. The skin is soft and glandular, and, as a rule, neither horny nor bony structures are developed in it.

The great and distinguishing character of the *Amphibia* is that they invariably undergo some kind of metamorphosis after birth ; though in some rare cases the eggs are retained so long within the body of the parent that there is little or no obvious change. In the great majority of cases, however, the Amphibians commence life as water-breathing larvæ, provided with gills ; but in their adult state they possess two air-breathing lungs, the gills sometimes disappearing when the lungs are developed, but being sometimes retained throughout life. In most cases, and always if retained, the gills are *external*, placed on the sides of the neck, and not contained in a special cavity, thus differing from the gills of fishes. In the Frogs and

Toads, and in some others, there are two sets of gills, one external and the other internal, of which the former is soonest lost. The lungs of the Amphibians never attain a very high state of development; and in those forms in which the gills are retained throughout life, the chief business of respiration appears to be carried on by the gills. In accordance with the changes in the respiratory process, corresponding alterations take place in the blood-vessels. With the development of the lungs the vessels which carry blood to them (the pulmonary arteries) increase in size, whilst the branchial vessels, which carry the blood to the gills, undergo a proportionate diminution. At first the condition of the circulation is very much the same as it is in fishes, but ultimately it becomes nearly the same as in the true Reptiles.

The *Amphibia* are divided into three living and one extinct order as follows:—

ORDER I. OPHIOMORPHA.

This order is an extremely small one, and, as its name implies, it comprises certain snake-like Amphibians. The order includes only the curious animals known as *Ceciliæ* (fig. 180), which are found in

Fig. 180. *a* *Siphonops annulatus*, one of the Cecilians, much reduced; *b* Head of the same; *c* Mouth, showing the tongue, teeth, and internal openings of the nostrils; *d* Tail of the same. (After Dumeril and Bibron.)

Southern Asia, Africa, and South America. The body is entirely destitute of limbs, and is enclosed in an integument which is thrown into numerous transverse wrinkles, and sometimes has numerous

horny scales embedded in it. The eyes are concealed by the skin, and are rudimentary. There is no tail, and the anal aperture is placed almost at the extreme end of the body. When adult, respiration is carried on by means of lungs, but gills are present in the young, and there can therefore be no doubt as to their being genuine Amphibians.

The *Cæciliæ* are found burrowing in marshy ground, and they are not unlike large earth-worms in appearance, but they sometimes attain a length of several feet.

ORDER II. URODELA.

In this order are a number of fish-like Amphibians, of which the Newts and Land-salamanders are the most familiar examples. In all the members of this section the skin is naked, and never develops any hard structures, and in all there is a well-developed fish-like tail, which is retained throughout life. The vertebrae are sometimes hollow at both ends (*amphicæalous*), sometimes hollow behind and convex or rounded in front (*opisthocæalous*). The ribs are rudimentary, and the bones of the fore-arm (*radius* and *ulna*), and of the shank (*tibia* and *fibula*), are separate, and are not combined so as to form single bones.

The *Urodela* are not unfrequently spoken of as the "Tailed" Amphibians, and they fall into two natural sections, according as the gills are permanently retained throughout life, or are cast off before maturity is attained. The animals belonging to the first section are often called "perennibranchiate," whilst those belonging to the second are said to be "caducibranchiate."

Among the Perennibranchiate forms, in which the gills are permanently retained after the lungs make their appearance, the best-known examples are the Axolotl, the curious *Proteus anguinus*, the *Menobranchus*, and the Mud-eel (*Siren*). Axolotls inhabit various of the lakes of the American continent, the best-known species being the *Siredon pisciforme* of the Mexican lakes. It attains the length of a foot or more, and possesses both pairs of limbs, the fore-feet having four toes, the hind-feet five toes. The branchiae are in the form of three long ramified processes on each side of the head; and the tail is compressed, and fringed by a fin which is prolonged on the back between the shoulders. In a state of nature, the Mexican Axolotl is certainly perennibranchiate, and it breeds freely in this condition. It has been shown, however, by Prof. Marsh, of New Haven, and others, that some species, when kept in confinement, lose their gills, and undergo certain other changes, becoming ultimately converted into Salamandroids, belonging to the genus *Ambly-*

stoma. Moreover, in one species (viz., *Amblystoma mavortium*), this change is known to occur in a state of nature; the larva being an Axolotl, with gills, and capable of breeding, but ultimately changing to a gill-less Salamander.

The *Proteus* is an extraordinary Amphibian which is found inhabiting the waters of caves in Illyria and Dalmatia. It attains a length of about a foot, and is of a pale flesh-colour or nearly white. The gills, which are retained throughout life, are of a bright scarlet. Both pairs of limbs are developed, but they are only short and weak, the fore-limbs having three toes each, and the hind-limbs only two. The eyes are rudimentary, the animal spending its existence in darkness; and swimming is effected mainly by means of the tail. Allied to *Proteus* is the Mud-puppy (*Menobranhus*, fig. 181, C) of

Fig. 181.—Tailed Amphibians. A, *Siren lucertina*; B, *Amphiuma*, showing the four minute limbs; C, *Menobranhus maculatus*. (After Mivart.)

North America, which is from six inches to a foot in length. The *Siren* or Mud-eel (fig. 181, A) is a large lizard-like Amphibian, which is found abundantly in the swamps of South Carolina, and attains the great length of three feet. The external branchiæ are retained throughout life, and they are the main organs of respiration. The fore-limbs are present, but the hinder pair of limbs is never developed. Another form, which occurs in the Southern United States, is the Congo-snake (*Amphiuma*). This has a snake-like body, with rudimentary two-toed limbs (fig. 181, B), and though the gill-slits remain on the side of the neck, it has no gills.

The “caducibranchiate” section of this order is characterised by the fact that both pairs of limbs are always developed, and the branchiæ are never retained throughout life. The most familiar examples are the Water-salamanders or Newts (*Triton*). The Newts (fig. 182), are well known as inhabiting pools in many regions, and the young lead a strictly aquatic life. When the lungs are developed the external gills wholly disappear; and the respiration becomes strictly aerial, though the animals still spend a great part of their time in the water. The larva or young form is at first destitute of limbs, and the fore-limbs are the first to be developed, the reverse of this taking place in the Frogs. In accordance with their mode of life, the tail is compressed and flattened, so as to form an efficient

Fig 182.—The Great Water-Newt (*Triton cristatus*), male. (After Bell.)

swimming apparatus. The Water-salamanders are all oviparous, and the young are like the tadpoles of the common Frog.

The so-called Land-salamanders (*Salamandra*), in the strict sense of the term, are essentially terrestrial animals, though commonly frequenting water; and they retain the larvæ within the oviducts for a longer or a shorter time after the emergence of the embryo from the egg. They are, therefore, ovo-viviparous or even viviparous. The tail is rounded and cylindrical. A common form is the Spotted Salamander of Europe, in which the larvæ have at first external gills; but in the Alpine Salamander of Southern Europe, the larvæ are not brought forth until the gills are shed.

ORDER III. ANOURA.

This order is the highest of the *Amphibia*, and comprises the Frogs and Toads. It is sometimes known by the name of *Batrachia* (Gr. *batrachos*, a frog), or *Anoura* (Gr. *a*, without; *oura*, a tail), the latter name being derived from the fact that the adults are “tailless.”

The tailless *Amphibia* are characterised by the fact that whilst the larva possesses a tail, and is furnished with gills, the adult has no

tail, and breathes wholly by lungs, and through the skin. Both pairs of limbs are always developed in the full-grown animal, and the hind-limbs are usually considerably longer than the fore-limbs, and generally have the toes webbed, whilst those of the fore-limbs are free. The skin is soft, and there are rarely any traces of any integumentary skeleton. The spinal column is short; the dorsal vertebræ are very long; and the ribs are quite rudimentary, their place being taken by greatly-developed transverse processes. The bodies of the vertebræ are hollow in front and convex behind (*pro-cævous*). The bones of the fore-arm (*radius* and *ulna*), and those of the shank (*tibia* and *fibula*), are united together to form single bones. The upper jaw is usually furnished with teeth, and the lower jaw sometimes, but there are no teeth in the Toads. The lungs are well developed, comparatively speaking; and as there are no ribs by

Fig. 183.—The common Frog (*Rana temporaria*).

which the cavity of the chest can be expanded, the air is taken into the lungs by a process nearly akin to that of swallowing. There can be no doubt, also, that the skin plays a very important part in the aeration of the blood, and that the frogs especially can carry on their respiration by means of the skin without the assistance of the lungs for a very lengthened period. This, however, should not lead to any credence being given to the often-repeated stories of frogs and toads being found in closed cavities in solid rock, no authenticated instance of such an occurrence being known to science. The ova of the frogs and toads are deposited, in masses or strings, in water, and the young or larvæ are familiar to every one as tadpoles. Upon its escape from the egg, the young frog (fig. 184) presents itself as a little fish-like creature with a broad head, a sac-like belly, and a

long compressed tail with which it swims actively. It breathes by means of gills or branchiæ, of which there are two sets, one external and the other internal. At first there are no limbs; but, as development proceeds, the limbs make their appearance the hind-legs first, and then the fore-legs. The tail, however (fig. 184), is still retained as an instrument of progression. Ultimately, when the limbs are fully developed, and the gills have given place to lungs, the tail is absorbed, and the animal now takes to the land as a perfect frog.

The development of the Frog is a good illustration of the general zoological law, that the transitory embryonic stages of the higher members of any division of the animal kingdom are often represented by the permanent condition of the lower members of the

Fig. 184.—Development of the common Frog. *a* Tadpole, viewed from above, showing the external branchiæ (*g*); *b* Side view of a somewhat older specimen, showing the fish-like tail; *c* Older specimen, in which the hind-legs have made their appearance; *d* Specimen in which all the limbs are present, but the tail has not been wholly absorbed. (After Bell.)

same division. Thus the transitory condition of the young Frog, in which it breathes by external branchiæ, is to a certain extent permanently represented by the permanent condition of a perenni-branchiate Amphibian, such as the *Proteus*. The stage at which the external branchiæ have disappeared, but the tail is still present, and the limbs are developed, is permanently represented in the common tailed Amphibians, such as the Newts.

The order *Anoura* comprises the three families of the Frogs, Toads, and Surinam Toads. The Frogs (*Ranidae*) are distinguished by having a tongue which is fixed to the front of the mouth, and can be protruded at will, while the upper jaw is always armed with

teeth. The typical Frogs have enormously developed hind-legs, the toes of which are united by membrane, or are "webbed." They swim very powerfully, and can take extensive leaps. Excellent examples are the Grass Frog (*Rana temporaria*) and Edible Frog (*Rana esculenta*) of Europe, and the Bull-frog (*Rana pipiens*) of North America. The Tree-frogs, on the other hand, are adapted for a wholly different life, inhabiting trees, among which they climb with great ease by the help of suckers developed upon the ends of the toes. They are mostly found in warm countries, especially in America, but one species is European.

In the equally familiar Toads (*Bufonidæ*), the structure of the tongue is the same as in the Frogs, but the jaws are not furnished with teeth. In the Surinam Toads (*Pipidæ*) there is no tongue at all, and usually no teeth.

ORDER IV. LABYRINTHODONTIA.

This, the last order of the *Amphibia*, is not represented by any living forms, and requires to be little more than mentioned. The Labyrinthodonts were Amphibia which were all of large size, and of which some must have attained absolutely gigantic dimensions, the skull of one species being three feet in length and two in breadth. They were first known to science simply by their footprints, which were found in certain Secondary sandstones (*Trias*). These footprints consisted of a series of alternately placed pairs of hand-shaped impressions, the hinder print of each pair being much larger than the fore one. So like were these prints to the shape of the human hand that the unknown animal which had produced them was christened the "*Cheirotherium*" (Gr. *cheir*, hand; *thēr*, beast). Further researches, however, showed that these footprints were produced by various species of large Amphibians, to which the name of *Labyrinthodontia* was applied, in consequence of the complicated microscopic structure of the teeth. These extinct Amphibians are known to have existed at the time of the Coal, but they are most characteristic of the period known to geologists as the *Trias*.

SAUROPSIDA.

CHAPTER XXVI.

CLASS III. REPTILIA.

WE commence now the second great primary division of the *Vertebrata*—namely, that of the *Sauropsida*, comprising the Reptiles and the Birds. These two classes, though very unlike in external appearance, are united by the following characters: There are never at any period of life gills or branchiæ adapted for aquatic respiration; the red corpuscles of the blood are nucleated (fig. 163, *b*, *c*); the skull articulates with the vertebral column by means of a single articulating surface or condyle; each half of the lower jaw is composed of several pieces, and is jointed to the skull, not directly, but by the intervention of a special bone (the so-called “quadrate bone”).

These being the characters by which, amongst others, Reptiles and Birds are collectively distinguished from other Vertebrates, it remains to see what are the characters by which the Reptiles are distinguished, as a class, from Birds. In all Reptiles the blood is cold—that is to say, very slightly warmer than the temperature of the external medium in which they live. The integument generally secretes scales, with or without bony plates, but in no case do the integumentary appendages take the form of feathers. The heart consists of two auricles and a ventricle, which in most is partially divided into two chambers by an incomplete partition, and in a few is completely divided. In any case, however, more or less of the impure venous blood is mixed with the pure arterial blood which circulates over the body. There is no division between the cavities of the thorax and abdomen, and the lungs are not connected with air-sacs placed in various parts of the body. The limbs may be wanting, or rudimentary, but in no case are the fore-limbs constructed upon the type of the “wing” of birds, and in no living Reptile is there the bone which is known in Birds as the “tarsometatarsus.”

The class *Reptilia* includes, among living forms, the Tortoises and Turtles (*Chelonia*), the Snakes (*Ophidia*), the Lizards (*Lacertilia*), and the Crocodiles (*Crocodylia*). With the exception of the Tortoises and Turtles, they are mostly of an elongated cylindrical form, furnished behind with a long tail. The limbs may be altogether absent or quite rudimentary, as in the Snakes, but in almost all the higher members of the class there are two pairs of limbs, which may be either adapted for walking or swimming, and which in some extinct forms support a flying membrane. The internal skéleton is always bony, never cartilaginous or semi-cartilaginous as in many of the fishes. The skull is jointed to the spine by a single articulating surface (or *condyle*). The lower jaw is complex, each half being composed of several pieces united by sutures. In Tortoises and Turtles, however, these separate pieces are amalgamated together, and the two halves are also united, so that the whole lower jaw appears to form a single piece. In most reptiles, on the other hand, the two halves of the lower jaw (fig. 185), are only loosely united ; in the Snakes by ligaments and muscles, in the Lizards by gristle, and in the Crocodiles by suture. In all, the lower jaw is jointed

Fig. 185. —Skull of a Serpent (Python). *a* Quadrate bone ; *b* Lower jaw, articulating with the movable quadrate bone (*a*).

to the skull by means of a special bone, called the “quadrate bone”; and as this often projects backwards, the opening of the mouth is often very extensive, and may even extend backwards beyond the base of the skull (fig. 185, *a*). Teeth are generally present, but these are used chiefly to hold the prey, and not in biting or chewing the food. Except in the Crocodiles, the teeth are not sunk into distinct sockets, and they are usually replaced as fast as shed. They likewise do not differ from one another sufficiently in form or function as to allow of their being divided into different sets, as they can be in the Mammals. Usually the teeth are confined to the jaws

proper, but in some cases they are carried by other bones of the mouth. In the Tortoises and Turtles there are no teeth, and the jaws are simply sheathed in horn, so as to constitute a kind of beak, like that of a bird. The integumentary skeleton is in the form of scales, sometimes combined with bony plates. In the Tortoises and Turtles the integumentary skeleton is so united with the true skeleton as to form a kind of bony case or box, in which the body is enclosed.

The digestive system presents little worthy of special notice, except that the termination of the intestine (*rectum*) opens into a cavity called the "cloaca," which receives also the ducts of the urinary and generative organs.

It is, however, in the structure of the circulatory and respiratory organs that the most important characters of the Reptiles are to be looked for. The heart in all Reptiles may be regarded as being, *in function*, three-chambered, being composed of two auricles and a single ventricle, imperfectly divided by an incomplete partition. In the Crocodiles alone the heart is, *structurally*, four-chambered, the ventricle being divided into two by a complete partition. Here, however, the same results are brought about as in the other Reptiles, by means of a communication which subsists between the great vessels which spring from the ventricles thus formed. In the ordinary Reptiles the course of the circulation is, roughly speaking, as follows (fig. 186): The impure or venous blood that has circulated through the body is poured by the great veins into the right auricle (*a*). The pure or arterial blood that has been submitted to the action of the lungs is poured by the pulmonary veins into the left auricle (*a'*). Both auricles empty their contents into the ventricle, and as the partition which divides the ventricle is an incomplete

Fig. 186.—Sketch-diagram of the circulation of a Reptile. *a* Right auricle, receiving venous blood from the body; *a'* Left auricle, receiving arterial blood from the lungs; *v* Arterio-venous ventricle, containing mixed blood, which is driven by (*p*) the pulmonary artery to the lungs, and by (*o*) the aorta to the body. (The venous system is left light, the arterial system is black, and the vessels containing mixed blood are cross-shaded.)

one, it follows that the venous and arterial streams must mix to some extent in the ventricle. From the ventricle arise the great vessels which carry the blood to the lungs and to all parts of the body, and it follows that to some extent all these parts are supplied with a mixed fluid, consisting partly of impure or venous blood, and partly of pure or arterial blood. In the Crocodiles, in which there are two ventricles completely separated from each other, the same result is brought about by means of a communication which takes place between the great vessels which spring from the ventricles, in the immediate neighbourhood of the heart.

As a matter of fact, the heart of the Reptiles is so constructed that this theoretical mixture of the arterial and venous currents in the common ventricle only takes place in practice to a limited extent. What actually occurs is that the lungs are supplied mainly with venous blood, and the head and fore-limbs are supplied mostly with pure arterial blood, while the body and hind-limbs are supplied with mixed blood; but the arrangements whereby this is brought about are too complicated for description here.

As regards the structure of the lungs, it is merely to be noted that there is no partition (*diaphragm* or midriff) separating the two cavities of the thorax and abdomen, and that the lungs, therefore, often attain a great proportionate size, sometimes extending through almost the whole length of the cavity of the trunk. There are also no air-sacs communicating with the lungs, as in the Birds.

Lastly, all Reptiles are essentially oviparous, some being ovoviviparous. The egg-shell is usually parchment-like, but in other cases contains more or less calcareous matter.

The class *Reptilia* is divided into four living and six extinct orders, as follows, but the latter require no extended notice here:—

1. *Chelonia* (Tortoises and Turtles).
2. *Ophidia* (Snakes).
3. *Lacertilia* (Lizards).
4. *Crocodylia* (Crocodiles).
5. *Ichthyopterygia*
6. *Sauropterygia*
7. *Pterosauria*
8. *Anomodontia*
9. *Deinosauria*
10. *Theriodontia*

} Extinct.

CHAPTER XXVII.

DIVISIONS OF REPTILIA.

ORDER I. CHELONIA.

IN this order are included the various Tortoises and Turtles, characterised by having the body enclosed in a bony case or box, and by the fact that the jaws are not provided with teeth, but are encased in horn, so as to form a kind of beak. The case in which the body of a Chelonian is protected is composed partly of integumentary plates and partly of flattened bones belonging to the true skeleton, and it is composed essentially of two pieces, one placed on the back and the other on the lower surface of the body, firmly united together at their edges. The dorsal shield is more or less convex and rounded, and is called the *carapace*; whilst the ventral shield is more or less completely flat or concave, and is called the *plastron*. The carapace and plastron, as just said, are united by their edges, but they leave two openings, one in front for the head and forelimbs, and one behind for the tail and hind-limbs. The carapace is essentially composed of the flattened and expanded spinous processes of the vertebræ, and the greatly developed ribs, covered by a series of horny plates. These are growths of the integument, and in some cases (fig. 188) they constitute the "tortoise-shell" of commerce. The plastron is also composed partly of bony and partly of horny plates, but opinions differ as to whether the bony plates are to be looked upon as formed by an expanded breastbone, or whether they are merely integumentary, the probabilities being in favour of the latter view.

The remaining peculiarities with regard to the skeleton which deserve special mention are: Firstly, that the dorsal vertebræ are immovably connected together, so that this region of the spine is quite inflexible; secondly, that the heads of the ribs are articulated directly to the bodies of the vertebræ; and, thirdly, that the scapular and pelvic arches, supporting respectively the fore and hind limbs, are situated *within* the carapace (fig. 187), so that the

shoulder-blade is placed *inside* the ribs instead of outside, as is usually the case.

The *Chelonia* are conveniently divided into groups, according as the limbs are adapted for swimming (natatory), or for progression on land (terrestrial); or, again, enable the animal to lead an amphibious life, sometimes on land and sometimes in the water. Of the

FIG. 187.—Skeleton and carapace of the Logger-headed Turtle (*Chelone caouanna*), viewed from below, the plastron being removed.

strictly aquatic forms the best known are the edible Green Turtle (*Chelone mydas*) and the Hawk's-bill Turtle (*Chelone imbricata*). The former is found abundantly in many of the seas of warm climates, and is largely imported into Europe as a delicacy. The latter (fig. 187) is truly a native of warm seas, though an occasional straggler has reached Britain. It is of comparatively small size—not more than about three feet in length—but is of considerable

commercial importance, as it furnishes the "tortoise-shell" of trade, so largely used in various kinds of ornamental work.

Fig. 188.—The Hawk's-bill Turtle (*Chelone imbricata*). (After Bell.)

The Sea-tortoises or Turtles have the carapace much flattened, the legs of unequal length, in the form of solid fins or oars, the toes being conjoined, and hardly distinct from one another.

The Marsh, Pond, and River Tortoises are generally furnished with webbed feet, and lead an amphibious, semi-aquatic existence. The so-called "Soft Tortoises" (*Trionycidae*) belong here, and are distinguished by the imperfect condition of the carapace, which is simply covered with a leathery skin. A good example is the Soft-shelled Turtle (*T. ferox*) of the Southern States. Here also belong the Snapping-turtles, so well known in the person of the common American species (*Chelydra serpentina*), and the Terrapins (*Emydidæ*), of which many forms are found in all parts of the United States. In the curious little Box-tortoise (*Cistudo Virginea*) the plastron is composed of two movable portions which can be brought into accurate apposition with the carapace, thus completely protecting the animal within.

The Land-tortoises have short legs of nearly equal length, the toes little distinct, and united into a sort of stump, with indistinct, horny claws. Good examples of this group are the common European Tortoise (*Testudo Græca*) and the Indian Tortoise (*T. Indica*), the last attaining a length of over three feet.

ORDER II. OPHIDIA.

This order includes most of the animals which would commonly be called snakes or serpents, and is characterised by the following peculiarities: The body is always more or less elongated, worm-like, or cylindrical, and the skin develops horny scales, but never bony plates. There is never any breast-bone (*sternum*), nor pectoral arch, nor fore-limbs; nor, as a rule, are there any traces of hind-limbs. In a few cases, however, rudimentary hind-limbs can be detected. The ribs are always very numerous. The two halves of the lower jaw are composed of several pieces each, and they are united to one

Fig. 189. — The *Naja haje*, a poisonous Snake of Egypt.

another in front only by ligaments and muscles (fig. 185). Hooked, conical teeth are always present, but they are never lodged in distinct sockets, and are only used to hold the prey, and not in mastication. The lungs and other paired organs are often not symmetrical, one of each pair being usually smaller than the other, or altogether absent.

The most striking of these characters of the snakes (fig. 189) is to be found in the nature of the organs of locomotion. The fore-limbs are invariably altogether wanting, and there is no pectoral arch nor

breast-bone ; nor, as a rule, are there any traces of hind-limbs. In a few forms, however, the hind-limbs are present in an extremely rudimentary form, never exhibiting any outward evidence of their existence, beyond the occasional presence of short horny claws or spurs. In the entire absence, then, or rudimentary condition of the limbs, the snakes progress by means of the ribs, which are always excessively numerous, and, in the absence of a breast-bone, are also extremely movable. Their free ends, in fact, are simply attached by muscular fibres to the scales or "scutes," which cover the lower or abdominal surface of the animal. The number of ribs varies greatly, and by means of the above arrangement the snakes are able to progress rapidly, walking, as it were, upon the ends of the ribs.

Fig. 190.—A, Diagrammatic section of the eye of a Viper (after Cloquet): *a* Eyeball; *b* Optic nerve; *c* Chamber into which the tears are poured; *d* Epidermic layer covering the eye. B, Head of the common Viper (after Bell), showing the poison-fangs.

Their movements are also much assisted by the extreme flexibility of the whole spine, caused by the cup-and-ball articulation of the bodies of the vertebræ, each of which is concave in front, and convex behind (*procœlous*).

Of the other characters of the snakes, a few words may be said as to the tongue, the eye, and the teeth—all important structures in this order. The *tongue*, in serpents, is probably more an organ of touch than of taste, and consists of two muscular cylinders, which are united towards their bases. The forked organ thus formed can be protruded and retracted at will, being in constant vibration when protruded, and being in great part concealed by a sheath when retracted. The *eye* of serpents (fig. 190, A) is not protected by any eyelids, and hence the peculiar stony and unwinking stare for which these reptiles are celebrated. In place of eyelids, the outer layer of the skin is prolonged over the eye as a continuous and transparent film, behind which is a chamber formed by the mucous covering of the eye, into which the tears are discharged. The outer membrane is

periodically shed along with the rest of the external or epidermic layer of the integument, and is again renewed. The pupil is round in most serpents, but it forms a vertical slit or fissure in many venomous Snakes and in the Boas.

As regards the teeth, it is to be noticed that the snakes are not in the habit of chewing their prey, but of swallowing it whole, and the construction of their dental apparatus is in accordance with this peculiarity. The lower jaw, as before said, articulates with the skull by means of a quadrate bone (fig. 185), and this in turn is movably jointed to the cranium. The two halves of the lower jaw are also merely united loosely in front by ligaments and muscles. In consequence of this peculiar arrangement of parts, the serpents have the power of opening the mouth to an extraordinary width, and they can perform the most astonishing feats in the way of swallow-

Fig. 191.—Skull of the Rattlesnake (after Dumeril and Bibron). *l* One half of the lower jaw united to the skull by the quadrate bone (*q*); *m* Upper jaw carrying the poison-fang; *p* Series of teeth upon the palate.

ing. The teeth are simply fitted for seizing and holding the prey, but not in any way for chewing or dividing it. In the harmless snakes the teeth are in the form of solid cones, which are arranged in rows round the whole of the upper and lower jaws, a double row existing on the palate as well. In the venomous snakes, on the other hand, the ordinary teeth are usually wanting upon the upper jaws, or are few in number; and these bones are themselves much reduced in size. In place of the ordinary teeth, however, or in addition to these, the upper jaws carry the so-called "poison-fangs" (fig. 191). In the Viperine Snakes these are a pair of long curved fangs, one on each maxilla or upper jawbone, which, when not in use, are pointed backwards, but can be raised at will by special muscles, by the elevation of the movable maxillæ. Each tooth is perforated by a fine canal or tube, which opens by a distinct aperture at the point

of the fang, and is connected with the duct of the "poison-gland." This is a gland (fig. 192, *a*), situated under and behind the eye, secreting the poisonous fluid which renders the bites of these snakes

Fig. 192.—The head of the Rattlesnake, dissected to show the poison-gland (*a*) and poison-fangs (*f*). (After Duvernoy.)

dangerous or fatal. When the serpent strikes at any animal, the poison is forced through the poison-fang into the wound, partly by the contractions of the muscular walls of the gland, and partly by the compressive action of the muscles of the jaws and cheeks.

The *Ophidia* are usually classified in accordance with the characters of their dental apparatus, and may be divided as follows, some minor groups being omitted: (1.) The *Viperina* comprise the most typical of the venomous Snakes (*Venenosa*), and include the common Vipers (*Viperida*) and the Rattlesnakes (*Crotalidae*), the former being confined to the Old World, whilst the latter are mainly American. The common Viper (*Pelias berus*) occurs abundantly in Europe and Northern Asia, and is capable of inflicting a severe and even dangerous bite. The rest of the true Vipers are African and Asiatic, well-known examples being the Puff-adder of the Cape of Good Hope (*Croto*), the Horned Viper (*Cerastes*) of North Africa, and the "Tie-polonga" (*Daboia Russellii*) of India.

The true Rattlesnakes (*Crotalus*) are exclusively natives of America, and they are highly poisonous. The extremity of the tail in the common Rattlesnake (*Crotalus durissus*) is furnished with a series of horny epidermic cells of an undulated pyramidal shape, articulated one within the other, constituting an appendage which is known as the "rattle." Before striking its prey, the Rattlesnake throws itself into a coil, and shakes its rattle, as it does also when alarmed. A nearly allied form (*C. horridus*) is found in South America. Other American examples of the *Crotalidae* are the Fer-de-lance (*Trigonocephalus*) of the West Indies, the Copper-head (*Ancistrodon contortrix*), and the Water-moccasin (*A. piscivorus*), in which there is no rattle. In India and Southern Asia there are also various Snakes belonging to the *Crotalidae*.

Taken as a whole, the Viperine Snakes are distinguished by having only a single poison-fang on each maxilla; while this bone is short and movable, and carries no other teeth. There are, however, one or more reserve-fangs behind

the poison-fang. The head is broad, somewhat triangular in shape, broadest in its middle, and showing a very distinct line of demarcation between the head and neck. The head, also, is usually covered with small scales (fig. 193, C), and rarely exhibits large plates or "scuta." The Crotalids have a deep pit between the eye and the nostril, by which they are distinguished from the true Vipers, and from which they have acquired the common name of "Pit-vipers."

(2.) The *Elapina* are poisonous Snakes, in which the poison-fangs are permanently fixed and erect, and have smaller solid teeth behind them. The head (fig. 193, A) is shield-shaped, and not much wider than the body, its upper surface being covered with large shields or scuta. This group comprises some of the most deadly of all the Serpents, one of the best known being the Hooded Snake or *Cobra di Capello* (*Naja tripudians*), which is commonly found in

Fig. 193.—Ophidia. A, Head of an Elapine Snake (*Bungarus fasciatus*), viewed from above. B, Head of a Colubine Snake (*Tropidonotus natrix*). C, Head of a Viperine Snake (*Daboia Russellii*). (A and C are after Sir Joseph Fayrer; B is after Bell.)

Hindustan, and is the snake usually carried about by the Indian snake-charmers. It varies from two to six feet in length, and the neck can be extensively dilated, covering the head like a hood. A nearly allied species is the *Naja haje* (fig. 189) of Egypt. The genus *Bungarus*, including the deadly "Krait" (*B. caeruleus*) of India, is nearly allied to *Naja*, but the neck is not dilatable. America has representatives of this family in the beautifully marked Coral-snakes and Harlequin-snakes (*Elaps*); and they abound in the Australian region, a well known type being the Death-adder (*Acanthophis*).

(3.) The *Hydrophida* comprise aquatic Ophidians which have the tail vertically compressed and broadened out. They are found principally in the Indian and Chinese seas, often frequenting the mouths of rivers, though sometimes ranging far from land. They are extremely poisonous, and swim with great ease and rapidity.

(4.) The *Colubrina* comprise a great number of altogether innocuous Snakes, in which the superior maxillæ are provided with solid teeth only, and there are no fangs. The head in the Colubrine Snakes is not much wider than the neck, and is covered with large shields (fig. 193, B). The Colubrine Snakes are cosmopolitan in their distribution, and an excellent example is the common Ringed Snake (*Coluber* or *Tropidonotus natrix*) of Britain, a perfectly harmless animal, which is commonly found in damp situations, and which lives mainly upon frogs. Closely allied to this is the Black Snake (*Dascanion constrictor*) of North America, which attains a length of from three to five feet, but is perfectly harmless, so far as man is concerned.

(5.) The *Pythonina* comprise the well-known serpents termed the Boas, Pythons, Anacondas, and Rock-snakes. The members of this group are the largest of all living Snakes, attaining a length of certainly over twenty feet. Their bite is not venomous, but they are nevertheless highly dangerous and destructive animals, owing to their great size and enormous muscular power. They seize their prey and coil themselves round it in numerous folds, by tightening which they gradually reduce their victim to the condition of a shapeless bolus, fit to be swallowed. The dental apparatus is extremely powerful giving a firm hold for the constriction of the prey. They possess rudimentary hind-limbs, terminating in horny anal spurs, which co-operate with the prehensile tail in enabling the animal to suspend itself from trees. The true Boas and Anacondas are South American, but the Pythons are inhabitants of Southern Asia and Africa.

ORDER III. LACERTILIA.

The third order of Reptiles is that of the *Lacertilia*, comprising all the animals which are properly known as Lizards, together with some snake-like creatures, such as the Blind-worm. They are distinguished by the following characters: Usually there are two

Fig. 194.—Iguana.

pairs of well-developed limbs, but there may be only one pair, or all the limbs may be rudimentary. In all cases, however, a scapular arch is present. The vertebræ are usually hollow in front (*procelous*), rarely hollow at both ends (*amphicelous*). In no living Lacer-

tilian are the teeth lodged in distinct sockets. The eyes are mostly furnished with movable eyelids. The integument is usually furnished with horny overlapping scales, like those of the Snakes (fig. 195).

As a general rule the animals included under this head have four well-developed legs, and would therefore be popularly called "Lizards." Some of them, however, such as the common Blind-worm (*Anguis fragilis*) of our own country, exhibit no external indications of limbs, and would therefore be generally regarded as Snakes. These snake-like Lizards, however, can be distinguished from the true Ophidians by the consolidation of the bones of the

Fig. 195.—Blind-worm (*Anguis fragilis*) (After Bell.)

head and jaws, and by the fact that the eyes are generally provided with movable eyelids. Dissection also shows that the shoulder-girdle (or scapular arch) is always present in a rudimentary condition.

Few Lizards are natives of Britain; the only forms which can be said to be at all abundant being the Blind-worm or Slow-worm and the Sand-lizard (*Lacerta agilis*). Of the snake-like Lizards, a good example is to be found in the common Blind-worm or Slow-worm of Europe. It is completely serpentiform, without any external indications of limbs (fig. 195), and it is quite harmless. It is remarkable for the fact that, when alarmed, it stiffens its muscles to such an extent that the tail can readily be broken off, as if it were brittle.

This same brittleness exists in the Glass-snake (*Ophisaurus ventralis*) of the Southern United states, in which also there are no limbs. In other allied genera, there may be fore-feet alone, or hind-feet may be present, or all four limbs exist in a more or less rudimentary condition. In the true Lizards (*Lacerta*), all four limbs are present in a well-developed form ; as is seen in the common Green Lizard (*L. viridis*) of Europe. The genus *Lacerta* is represented in America by the *Ameiva*, of which the Striped Lizard (*Ameiva sex-lineata*) of the Southern States may be taken as a good example. Of all living Lizards the largest are the Monitors (*Varanide*), which are exclusively confined to the Old World, and attain sometimes a length of from six to eight feet. Very large, too, are some of the Iguanas

Fig. 196.—Head of *Gecko stentor*. (After Günther.)

(fig. 194), which occur in warm regions in various parts of the world, but especially in South America, where they are often eaten. Related to the Iguanas are the singular Lizards known as the Flying Dragons (*Draco*), various species of which inhabit the Indian Archipelago and the East Indies. They are all of small size, living in trees and feeding on insects ; and their great peculiarity consists in the fact that certain of the ribs are straightened out and support a wing-like fold of the skin on each side of the body, by means of which the animal can take very extensive leaps from tree to tree.

The Scincoid Lizards form a very large family, represented by numerous species in all parts of the world. One species is a common form in Egypt and Arabia, and was formerly used as a remedy in

various diseases. A nearly allied species is the blue-tailed Lizard (*Scincus fasciatus*) of the United States.

The Geckos (*Gekkotidae*) form a large group of night-loving Lizards, which are found in most parts of the world, and chiefly deserve notice from the fact that their eyes are not provided with movable eyelids (fig. 196). The Chamaelons, also, cannot be said to possess movable eyelids, for the eye is covered with a single lid, leaving only a central aperture for the pupil. The common species (*Chamaeleo Africanus*) occurs abundantly in the north of Africa, and has long been known for the changes of colour which it has the power of exhibiting. It is a sluggish animal, and catches insects by darting out its long and worm-like tongue with extreme rapidity.

ORDER IV. CROCODYLIA.

The last and highest order of the living Reptiles is that of the *Crocodylia*, comprising the Crocodiles, Alligators, and Gavials, and characterised by the following peculiarities: The outer or integu-

Fig. 197.—A, Head and anterior portion of the body of *Crocodilus pondicerianus*;
B, Hind-foot of the same. (After Gunther.)

mentary skeleton consists partly of horny scales developed by the outer layer of the skin, and partly of large bony plates produced by the inner layer of the skin (fig. 197). The bones of the skull and

face are firmly united, and the two halves of the lower jaw are joined by a distinct suture. The teeth form a single row in both jaws, and are implanted in distinct and separate sockets. The front ribs of the trunk are double-headed, and there are no collar-bones. The heart consists of four distinct chambers, two auricles and two ventricles, all completely separated from one another. The mixture of arterial and venous blood, however, which is so characteristic of Reptiles, is provided for by a communication between the great vessels which spring from the two ventricles in the immediate neighbourhood of the heart. The eyes are protected by movable eyelids, and the ear by a movable ear-lid. The tongue is large and fleshy, and is immovably attached to the bottom of the mouth (hence the belief of the ancients that the Crocodile had no tongue). Lastly, the *Crocodylia* agree with the typical Lizards, and differ from the Snakes in having four well-developed limbs.

The *Crocodylia* abound in the fresh waters of hot climates, and are the largest of all living Reptiles, not uncommonly attaining a length of sixteen feet or upwards.

The true Crocodiles have the feet more or less webbed, the hind-legs bordered by a fringe, and the fourth tooth in the lower jaw received in a notch on the side of the upper jaw. They belong mainly to Africa and Asia, but they are also represented in Australia, in the West Indies, and in South America.

The Alligators have the hind-legs simply rounded, and the toes not completely webbed; while the fourth tooth in the lower jaw fits into a cavity in the palate, and is concealed from view when the mouth is shut. Like the Crocodiles, they are essentially aquatic in their habits, and lie dormant during the winter in cold climates, and the hot season in warm countries. They are extremely voracious, and live upon fish and small Mammals. The best-known species are the common Alligator (*A. Mississippiensis*) of the Southern States, the Caiman (*A. palpebrosus*) of Surinam and Guiana, and the "Jacaré" (*A. sclerops*) of South America.

The Gavial or Gangetic Crocodile occurs in India, and is distinguished by its narrow, elongated jaws, forming a kind of beak. It attains a length of more than twenty feet. Closely allied types occur in the rivers of North Australia and in Borneo.

EXTINCT ORDERS OF REPTILES.

ORDER V. ICHTHYOPTERYGIA.

In this order are included a number of gigantic fish-like Reptiles, which are all extinct, and are characteristic of the Secondary period of geology, and especially of the formation known as the Lias. The chief characters by which they are distinguished have reference to their purely aquatic life, for there can be no doubt that they were inhabitants of the sea. Thus the body was fish-like, without any distinct neck. The vertebræ were hollow at both ends (*amphicelous*), and the spine thus possessed the flexibility and power of motion so characteristic of the true Fishes. The limbs also constituted powerful swimming-paddles, and it is probable that there was a vertical tail-fin.

Much has been gathered from various sources as to the habits of the *Ichthyosauri*, and their history is one of the most interesting chapters in the geological record. That they chiefly kept to open seas may be inferred from their

Fig. 198.—Skull of *Ichthyosaurus*, showing the sclerotic plates.

strong and well-developed swimming apparatus; but the presence of a powerful bony arch supporting the fore-limbs proves that they must occasionally have betaken themselves to the land. That they were tenants of stormy waters, or were in the habit of diving in search of prey, has been inferred from the fact that the eyeball is protected from pressure by a ring of bony plates. That they possessed great powers of vision, especially in the dusk, seems to be rendered certain from the size of the pupil and the enormous width of the bony cavities (orbits) which contained the eyes. Lastly, that they were carnivorous and predaceous in the highest degree is shown by their wide mouths, long jaws, and numerous powerful and pointed teeth. This is also proved by an examination of their petrified droppings, which are known as “coprolites,” and which contain in abundance undigested fragments of fishes and other marine animals.

ORDER VI. SAUROPTERYGIA.

The Reptiles belonging to this order agree with the last in being all extinct, and in being confined to the Secondary period of geology. The best known are the *Plesiosaurs*, which resembled the *Ichthyosaurs* in having all the limbs converted into swimming-paddles, but differed in several respects, of which the most obvious is the great elongation of the neck (fig. 199). The *Plesiosaur*

were gigantic marine Reptiles, chiefly characteristic of the formations known as the Lias and Oolites. As regards the habits of the *Plesiosaurus*, Dr Couv beare concludes: "That it was aquatic is evident from the form of its paddles; that it was marine is almost equally so from the remains with which it is universally associated; that it may have occasionally visited the shore, the resemblance of its extremities to those of the Turtle may lead us to conjecture; its movements, however, must have been very awkward on land; and its long neck must have impeded its progress through the water, presenting a striking contrast to the organisation which so admirably fits the *Ichthyosaurus* to cut

Fig. 199.—*Plesiosaurus dolichodeirus*. Lias.

through the waves." As its breathing-organs are such that it must of necessity have required to obtain air frequently, it may be inferred "that it swam upon or near the surface, arching back its long neck like a swan, and occasionally darting it down at the fish which happened to float within its reach. It may perhaps have lurked in shoal-water along the coast, concealed amongst the sea-weed, and, raising its nostrils to a level with the surface from a considerable depth, may have found a secure retreat from the assaults of powerful enemies; whilst the length and flexibility of its neck may have compensated for the want of strength in its jaws and its incapacity for swift motion through the water."

ORDER VII. PTEROSAURIA.

The Reptiles of this order are all extinct, and, like those of the preceding orders, are exclusively confined to the Secondary period of geology. The most familiar examples are the so-called *Pterodactyles*, and the distinguishing characters of the order have reference to the fact that they were all adapted for an aerial life. They present, in fact, an extraordinary combination of the characters of Birds and Reptiles, and they make also some approach to the Mammalian order of the Bats. In the presence of teeth in distinct sockets, and, as we shall see hereafter, in the structure of the fore-limbs, the *Pterodactyles* differ altogether from all living birds; and there can be little doubt as to their being

genuine reptiles. The only living Reptile which has any power of sustaining itself in the air is the Flying Dragon (*Draco*), which has been previously mentioned. In this case, however, the animal has no power of true flight, but is simply enabled to take extensive leaps by means of a membranous expansion on each side of the body. In the Bats, again, the power of genuine flight is present; and this given by means of a leathery membrane which is supported chiefly by certain of the fingers—which are greatly lengthened—and is attached to the sides of the body and hind-limbs.

In the Pterodactyles the power of true flight was present; and this was also conditioned by means of a leathery expanded membrane, attached to the hind-limbs, the sides of the body, and the fore-limbs. In this case, however, the chief support of the flying membrane was derived from the outermost finger of the fore-limb, which was enormously elongated (fig. 200). That the Ptero-

Fig. 200.—*Pterodactylus crassirostris*. From the Lithographic Slates of Solenhofen (Upper Oolite). In accordance with the view originally entertained, the digits of the hand are here erroneously represented as five instead of four in number.

dactyles passed their existence chiefly in the air, and did not simply leap from tree to tree, is shown by two characters in which they agree with the flying birds. Many of the bones, namely, were “pneumatic”—that is to say, were hollow, and were filled with air. Secondly, whilst the shoulder-girdle has many of the characters of that of birds, the breast-bone (*sternum*) is furnished with a prominent ridge or keel, serving for the attachment of the great muscles which work the wings. There can be no doubt, therefore, as to the Pterodactyles having enjoyed the power of genuine flight. Many of them attained no great size, but some of them must have been gigantic, the expanse of wing in one species having been calculated at probably about twenty-seven feet from tip to tip.

ORDER VIII. ANOMODONTIA.

This order has been founded for the reception of a number of fossil Reptiles belonging to the period of the New Red Sandstone, all of which seem to have been adapted for walking upon the dry land. They were either destitute of teeth—in which case the jaws seem to have constituted a beak, like that of a Turtle—or they possessed two great tusk-like teeth in the upper jaw (as is the case in *Dicynodon*).

ORDER IX. DEINOSAURIA.

The Reptiles of this order resemble the preceding in being adapted for walking upon the dry land; and they are confined to the Secondary period of geologists. They were mostly of large size, and the structure of the hind-limb is in some respects singularly similar to the conformation of the same part in the great wingless birds, such as the Ostrich (*Cursores*). The fore-limbs are in many instances so small, that these extinct Reptiles must have walked upon their hind-legs alone. The teeth are mostly adapted for an animal diet; but in some cases the animal must have lived upon vegetable food. The most important groups comprised in this order are *Iguanodon*, *Megalosaurus*, and *Hadrosaurus*.

ORDER X. THERIODONTIA.

This order has been recently established by Professor Owen for the reception of a number of extinct Reptiles from the New Red Sandstone. They present some singular resemblances to the ordinary Beasts of Prey (*Carnivora*), this resemblance being especially seen in the fact that their teeth were arranged in three distinct sets—incisors, canines, and molars; and the canine teeth were of large size and pointed, adapting their possessors for a predaceous and carnivorous mode of life.

CHAPTER XXVIII.

CLASS IV. AVES.

THE fourth class of the Vertebrates is that of the Birds or *Aves*, which may be shortly defined as being "oviparous Vertebrates, with warm blood, a double circulation, and a covering of feathers" (Owen). The other leading characters which separate the Birds from the other *Vertebrata* are, that the red blood-corpuscles are nucleated; the skull articulates with the spine by a single articulating surface (or condyle); the breathing-organs are in the form of lungs, which communicate with a variable number of air-sacs scattered through the body; and the fore-limbs are never terminated (in existing birds) by more than two fingers, ending in claws, and are generally modified so as to form "wings" or organs of flight.

The feathers, which form such a distinctive character of birds, are formed by a modification of the outer layer of the skin (epidermis), and from their non-conducting nature they serve to maintain the high temperature of the body which is so characteristic of the class. A typical feather (fig. 201), such as one of the long feathers of the tail or wing, consists of the following parts: 1. A horny cylindrical tube, which forms the lowest portion of the feather, and is termed the "quill." 2. The "shaft," which forms the central axis of the feather, and which is simply the continuation of the "quill." The under surface of the shaft is always marked by a strong longitudinal groove, and it consists of a horny sheath, filled with a white spongy material, not unlike the pith of a plant. 3. The "webs," which form the lateral expansions of the feather, and are attached to the sides of the shaft. Each web is composed of a number of small branches, called the "barbs"; and each barb, in turn, is furnished with a series of smaller fibres called the "barbules." As a rule, the barbs are all kept in connection with one another by means of the barbules, the ends of which are hooked. Towards the base of the shaft, however, the barbs are usually more or less separate and placed at a distance from one another, con-

stituting what is known as the "down." In the Ostriches and the birds allied to them, all the barbs are disunited and placed at a distance, and they are often not at all unlike hairs in appearance. The feathers of Birds not only greatly conduce to the high temperature of the body, but also serve to keep out moisture, to which end there is a peculiar oil-gland at the base of the tail, with the secretion of which the bird anoints its plumage.

The skeleton of Birds exhibits many points of peculiar interest, mostly in adaptation to an aerial mode of life ; but only some of the more important of these can be noticed here. The entire skeleton is at the same time peculiarly compact and singularly light, the compactness being due to the presence of an unusual quantity of phosphate of lime, and the lightness to the fact that many of the bones are filled with air in place of marrow. The cervical region (neck) of the vertebral column is unusually long and flexible, since the fore-limbs are useless as organs of prehension, and all these functions have to be performed by the beak. In all Birds the neck is, at any rate, sufficiently long to allow of the application of the beak to the tail, so as to permit of the cleaning and oiling of the whole plumage. The vertebræ which form the back or dorsal region of the spine are generally more or less immovably connected together, so as to give a base of resistance to the wings. In the Ostrich, however, and in other birds, in which the power of flight is either very limited or is absent, the dorsal vertebræ are more or less movable one upon the other. The vertebræ which follow the dorsal region of the spine are all amalgamated together to form a single bony mass, which is termed the

Fig. 201.—Quill-feather (*Stenopsis*): *a* Quill or barrel; *b* Shaft; *c c* Webs, composed of the barbs, and together forming the "vane."

"sacrum"; and this, in turn, is united on both sides with the bones which form the pelvic arch, which carries the hind-limbs. The vertebræ of the tail are more or less movable upon one another; and in almost all living birds, when fully grown, the last joint of the tail (fig. 204, B, s) is a long, slender, ploughshare-shaped bone, which is really composed of several vertebræ united together. It is usually set on at an angle nearly perpendicular to the axis of the body, and it serves to support the great tail-feathers, which act as a rudder during flight. It also serves to support the oil-gland, which supplies the secretion with which the feathers are lubricated. The skull in Birds has its several bones generally so amalgamated in the adult, that it forms a bony case in which the sutures can no longer be recognised. The head is jointed to the spine by no more than a single articulating surface or condyle. The beak, which forms such a conspicuous feature in Birds, is composed of two halves, an upper half or "upper mandible," and a "lower mandible." The lower mandible, like the lower jaw of all the *Sauropsida*, is at first composed of several pieces, but these are all undistinguishably united in the adult, and the two halves of the jaw are also amalgamated together. In no *living* Bird are *teeth* ever developed in either mandible; but both mandibles are sheathed in horn, constituting the "beak," and the margins of this sheath are sometimes serrated. In some curious fossil Birds, however, there are teeth in the jaws. The lower jaw is articulated to the skull by the intervention of a movable "quadrate bone." In many Birds, also, the upper mandible of the beak is so joined to the skull as to be capable of movement.

The most characteristic points, however, in the skeleton of the Birds, are to be found in the structure of the limbs. The cavity of the chest or thorax is bounded behind by the dorsal vertebræ, on the sides by the ribs, and in front by the breast-bone or sternum. The ribs vary in number from seven to eleven pairs, and in most Birds most of the ribs give off a peculiar process ("uncinate process," fig. 202, B), which passes over the rib next in succession behind. In front the ribs are jointed to a series of straight bones, which are called the "sternal ribs," and these, in turn, are movably articulated to the breast-bone in front. According to Owen, these sternal ribs are "the centres upon which the respiratory movements hinge." In front the cavity of the chest is completed by an enormously expanded breast-bone or *sternum* (fig. 202, A), which, in most birds of any powers of flight, extends more or less over the abdominal cavity as well. The sternum of all Birds which possess the power of flight is characterised by the presence of a prominent ridge or "keel" (fig. 202, A, b), to which are attached the great

muscles (pectoral muscles) which move the wings. As a general rule, the size of this crest or keel gives a tolerably just estimate of the flying powers of the bird to which it belonged. The keel is, of course, most largely developed in those birds which possess the power of flight in its greatest perfection; and in certain birds which do not fly, such as the Ostrich, there is no sternal keel at all. The pectoral arch or shoulder-girdle of birds, consists of the shoulder-blades (*scapulae*), the clavicles or collar-bones, and of two bones,

Fig. 252.—A, Breast-bone, shoulder-girdle, and fore-limb of Penguin (after Owen): *b* Breast-bone (*sternum*), with its prominent ridge or keel; *s s* Shoulder-blades (*scapulae*); *k k* Coracoid bones; *c* Furculum or merry-thought, composed of the united collar-bones (*clavicles*); *h* Bone of the upper arm or *humerus*, *r* Radius, and *u* Ulna, forming together the fore-arm; *g* Bones of the wrist or *carpus*; *t* Thumb; *m* Metacarpus; *p* Phalanges of the fingers. B, Ribs of the Golden Eagle: *a a* Ribs giving off processes (*b b*); *c c* Sternal Ribs.

which are distinct in Birds, and are called the “coracoid bones.” The shoulder-blades (*s s*) are usually long and narrow bones. The coracoid bones (*k k*) correspond with the part of the shoulder-blade which is known in most of the Mammals as the “coracoid process”; and in Birds they are not only separate bones, but they are the strongest bones of the pectoral arch. They are more or less nearly vertical, and they form fixed points for the downward stroke of the wing. The collar-bones or clavicles (*c*) in the great majority of Birds are united together in front, so as to form a somewhat V-

shaped bone, which is technically called the "furculum," but is familiarly called the "mercy thought." The function of this clavicular arch is to keep the wings asunder during their downward stroke, and the strength of the furculum varies, therefore, with the powers of flight enjoyed by each bird. The bones which form the limb proper, or "wing," are considerably modified to suit the special function of flight, but essentially the same parts are present as in the fore-limb of the Mammals. The upper arm (fig. 203) is constituted by a single bone, the *humerus* (*h*), which is generally

Fig. 203.—Fore-limb of the Jer-falcon. *h* Humerus; *r* Radius; *u* Ulna; *t* "Thumb"; *m* Metacarpals, ankylosed at their extremities; *p p* Phalanges of fingers.

short and stout. The fore-arm is composed of two bones, the *radius* (*r*) and the *ulna* (*u*), of which the ulna is the bigger. These are followed by the small bones, which form the wrist or *carpus* (*q*), but these are reduced to *two* in number. The carpus is followed by the bones which constitute the root of the hand or *metacarpus* (*m*), but these are also reduced to *two*, instead of being five in number, as they are in most Mammals. The two metacarpal bones are also amalgamated together at both ends, so as to form a single piece, at the base of which, on its outer side, is a rudimentary digit, the "thumb" (*t*), which carries a tuft of feathers, known as the "bastard wing." The metacarpal bones, finally, support each a single finger (*p*), of which one is never composed

of more than one bone or *phalanx*, whilst the other is composed of two or three phalanges. (To understand thoroughly the leading modifications of the limbs of Birds, the student will do well to refer to the general description of the limbs of Vertebrates, pp. 222, 223, figs. 160, 161.)

As regards the composition of the hind-limb in Birds, the two halves of the pelvic arch (*i.e.*, the *innominate bones*) always form a single piece each, and they are always firmly united with the sacral region of the spine. With the single exception, however, of the

Ostrich, they do not unite below, but remain separate. As in the higher Vertebrates, the lower limb consists of a thigh-bone (*femur*), a shank, composed of two bones (*tibia* and *fibula*), a tarsus, a metatarsus, and phalanges, but some of these parts are obscured by coalescence. The thigh-bone or femur (fig. 204, *f*), is generally very short, comparatively speaking; and the chief bone of the leg is the *tibia* (*t*), to which a thin and tapering *fibula* (*r*) is attached.

Fig. 204.—A, Pelvis and bones of the leg of the Loon or Diver (after Owen): *i* Innominate bone; *f* Thigh-bone (*femur*); *t* Tibia; *r* Fibula, together forming the shank; *m* Tarso-metatarsus; *p* Phalanges of the toes. B, Tail of the Golden Eagle: *s* Ploughshare-shaped bone, carrying the great tail-feathers.

In the regular typical limb of a Vertebrate animal the tibia and fibula would be followed by a series of small bones, called the *tarsus*, constituting the ankle-joint (fig. 161); and the tarsus would in turn be followed by a series of bones constituting the root of the foot, or *metatarsus*. In Birds, however, the tibia and fibula are followed by a single cylindrical bone, which is called the “tarso-metatarsus” (*m*), and which is formed by the amalgamation of the three principal metatarsal bones with the lower row of tarsal bones,

the metatarsal bone of the great toe being, when present, distinct and rudimentary. The upper portion of the tarsus is amalgamated with the lower end of the tibia, to which, therefore, the name of "tibio-tarsus" is often applied. The ankle-joint is thus placed in the middle of the tarsus. In most of the long-legged birds it is by the great elongation of the tarso-metatarsus that the enormous length of the legs is produced. The tarso-metatarsus is followed below by the foot, which consists in most birds of four toes, of which three are directed forwards and one backwards. In no wild Birds are there more than four toes; but some domesticated varieties possess a fifth. In all birds with four toes, the toe which is directed backwards (the great toe or "hallux") consists of two phalanges; the innermost of the three forward toes has usually three phalanges, the next has four, and the outermost toe is composed of five. In many Birds, such as the Parrots, the outer toe is turned backwards, so that there are two toes in front and two behind. In the Swifts, again, all the four toes are turned forwards. In many of the Swimming Birds (*Natatores*) the hinder toe is wanting or rudimentary; and in the Ostrich both this and the next toe are absent, so that the foot consists of no more than two toes.

The digestive system in Birds consists of the beak, tongue, gullet, stomach, intestine, and cloaca, with certain accessory glands. There are no teeth, and the beak is employed, in different birds, for holding and tearing the prey, for prehension, for climbing, and in some cases as an organ of touch, being in these last instances more or less soft, and supplied with nervous filaments. In many Birds, too, the base of the bill is surrounded by a circle of naked skin, constituting what is called the "cere," and this too serves as an organ of touch. The tongue of birds can rarely be looked upon as an organ of taste, since it is generally cased in horn, like the mandibles. It is principally employed as an organ of prehension, but it is soft and fleshy in the Parrots, and in them, doubtless, acts as an organ of taste. Salivary glands are always present, but they are rarely of large size, and are often of extremely simple structure. In accordance with the length of the neck, the gullet is usually very long in birds, and is generally very dilatable. In the flesh-eating and grain-eating Birds the gullet is dilated (fig. 205, *c*) into a pouch which is called the "crop," and is situated in the lower part of the neck, just in front of the merry-thought. This may be simply a dilatation of the tube of the gullet, or it may be a single or double pouch. The function of the crop is to detain the food, for a longer or shorter period according to its nature, before it is submitted to the action of the proper digestive organs. In the Pigeons, the food which has been previously softened in the crop is returned to the mouth, and supplied to the young in

a state suitable for digestion. The gullet, after leaving the crop, shortly opens into a second cavity, called the "proventriculus," which is the true digesting stomach, and is richly supplied with glands which secrete the digestive fluid or gastric juice (*p*). This, in turn, opens into a muscular cavity which is called the "gizzard" (*g*), and which leads into the commencement of the small intestine. The characters of the gizzard vary with the nature of the food. In the Birds of Prey, which live on an easily digested animal diet, the walls of the gizzard are thin and membranous. In the grain-eating

Fig. 205.—Digestive system of the common Fowl (after Owen). *o* Gullet; *c* Crop; *p* Proventriculus; *g* Gizzard; *sm* Small intestine; *k* Intestinal caeca; *l* Large intestine; *cl* Cloaca.

Birds, such as the Fowls, whose hard food requires to be crushed before it can be properly digested, the walls of the gizzard are extremely thick and muscular, and the inner lining is hard and horny. In these Birds the gizzard constitutes a kind of grinding apparatus, like the stones of a mill; whilst the "crop" may be compared to the "hopper" of the mill, since it supplies to the gizzard "small successive quantities of food as it is wanted" (Owen). The grinding action of the gizzard is further assisted by the small pebbles and gravel which, as is well known, so many birds are in the habit of swallowing. These pebbles take the place of teeth,

and there can be no doubt that they are in many cases essential to health, the bird being otherwise unable to triturate its food properly. The intestinal canal extends from the gizzard to the cloaca (*cl*), and is comparatively short. The secretions of the liver and pancreas are poured into the commencement of the small intestine. The commencement of the large intestine is furnished in most Birds with two blind tubes or "cæca" (*k*). These vary considerably in length in different Birds, and are sometimes wanting; whilst their exact function is still questionable. The large intestine is seldom more than a tenth part of the length of the body, and is generally conducted straight from the cæca to the cloaca. The *cloaca* is a common cavity which in Birds, as in Reptiles, receives the termination of the intestine and the ducts of the generative and urinary organs (*cl*).

Respiration is effected in Birds more completely, extensively, and actively than in any other class of the *Vertebrata*, and, as the result of this, their average temperature is higher than in any other Vertebrates. This extensive development of the respiratory process is due to the fact that air is admitted in Birds not only to the lungs, but also to a series of air-receptacles which are scattered through various parts of the body, and to the interior of a greater or less number of the bones. The lungs are two in number, of a bright-red colour, and spongy texture, and they are confined to the back part of the chest. They differ from the lungs of Mammals in not being freely suspended in a membranous bag (*pleura*), but in being fixed to the back wall of the chest. The thoracic and abdominal cavities are not separated from one another by a complete partition (midriff or diaphragm) as in the Mammals, but the common thoraco-abdominal cavity is subdivided by means of membranous partitions into a series of cavities or sacs, which are termed the "air-receptacles." These air-sacs are filled with air from the lungs, and vary considerably in size in different Birds. They not only serve greatly to reduce the specific gravity of the body, but also assist largely in the aeration of the blood. Connected with the air-receptacles, and supplementing their action in both of these respects, is a series of cavities occupying the interior of a greater or less number of the bones, and also containing air. In young birds these air-cavities in the bones do not exist, and the bones are simply filled with marrow, as in the Mammals. In the Penguins, which do not fly, none of the bones contain air-cavities or are "pneumatic"; and in the Ostrich only a few of the bones contain air. In the Pelican and Gannet all the bones of the skeleton, except the phalanges of the toes, are permeated by air; and in the Hornbill even these are pneumatic.

The *heart* in all Birds consists of four chambers, and the two sides of the heart are completely separated from one another. In all essential details, as regards the structure of the heart and great vessels, and the course of the circulating fluid, Birds agree with Mammals. The impure venous blood which has traversed the body, is returned by the great veins to the right auricle. From the right auricle it passes into the right ventricle, from which it is driven by the pulmonary artery to the lungs. Having been submitted to the action of the air contained in the lungs, and having been thereby changed into arterial blood, the blood is sent back to the left auricle by means of the pulmonary veins. Thence it passes into the left ventricle, by which it is again propelled throughout the whole body, to return again as venous blood to the right side of the heart. The heart, therefore, of Birds, differs from that of Reptiles in consisting of two sides, each composed of an auricle and ventricle, the right side being wholly concerned with sending the venous blood to the lungs, and the left side being entirely occupied with sending the arterial blood to the body. The right side of the heart is therefore venous, the left side arterial. In all Reptiles, on the other hand, the two circulations—namely, that through the lungs, and that through the body—communicate with one another, either in the heart itself or in its immediate neighbourhood ; so that both the lungs and the body are supplied with a mixture of venous with arterial blood. Though the heart of Birds resembles that of Mammals in general structure, its cavities are “relatively stronger, their valvular mechanism is more perfect, and the contractions of this organ are more forcible and frequent in Birds, in accordance with their more extended respiration and their more energetic muscular actions” (Owen). The urinary organs of Birds consist of two elongated kidneys, which open by means of their ducts (the ureters) into the cloaca, along with the termination of the intestine and the ducts of the reproductive organs. As a general rule, the female bird is provided with only a single ovary—that of the left side—and all Birds, without exception, are oviparous. The egg is always enclosed in a calcareous shell, and is mostly developed after expulsion from the body, by the process of “incubation” or “brooding”—a process for which birds are especially adapted, in consequence of their very high average temperature. The young bird, when ready for an independent existence, perforates the shell by means of a temporary calcareous excrescence developed upon the point of the upper mandible of the bill. In some Birds, mostly in the case of those which live upon the ground, the young are able to run about and look for food directly after they come out of the egg (*Aves præcoces*), as is seen in the common Fowl. In most Birds, however, the young

are liberated from the egg in a perfectly helpless and naked condition, and require to be fed by their parents for a longer or shorter time, before they are able to take care of themselves. Most of these Birds (*Aves altrices*), such as our common Song-birds, reside in trees, and build more or less elaborate nests.

As regards their *nervous system*, the brain of Birds is relatively larger than the brain of Reptiles, but it is destitute of those folds or convolutions which form so marked a feature in the brain of most Mammals. The organs of sense, with the exception of touch and taste, are well developed in Birds, vision especially being generally extremely acute. The eyes are always well developed, and in no Bird are they ever wanting or rudimentary. The chief peculiarity of the eye of Birds is, that its anterior portion (*cornea*) forms the segment of a much smaller circle than does the eyeball proper; so that the whole eye assumes a conical shape. Another peculiarity is, that the form of the eye is maintained by means of a circle of from thirteen to twenty bony plates, which are placed in the front portion of the fibrous coat of the eye (*sclerotic*). Eyelashes are almost universally absent; but in addition to the ordinary upper and lower eyelids, Birds possess a third membranous eyelid—the *membrana nictitans*—which is placed on the inner side of the eye. This nictitating membrane is sometimes transparent, sometimes pearly white, and it can be drawn over the front of the eye like a curtain, moderating the too great intensity of the light. As regards the organ of hearing, the chief point to remark is, that Birds possess no *external* ear, by means of which the undulations of sound can be collected and transmitted to the internal ear. In some Birds, however, as the Ostrich, the external opening of the organ of hearing is provided with a circle of feathers, which can be raised and depressed at will. In the nocturnal Birds, also (such as Owls), the external opening of the ear is protected by a musculo-membranous valve, foreshadowing the gristly external ear of Mammals. The sense of smell is apparently seldom very acute in Birds; and even the Birds of Prey appear to seek their food mainly by the sight. The external nostrils are usually placed on the sides of the upper mandible, near its base, and form simple perforations which sometimes communicate from side to side. In the curious *Apteryx* of New Zealand, the nostrils are placed at the extreme end of the elongated beak. Sometimes the nostrils are defended by bristles, and sometimes by a cartilaginous scale.

Before passing on to a consideration of the divisions of Birds, a few words may be said on the *migrations* of Birds. In temperate and cold climates, only certain birds remain constantly in the same region in which they were originally hatched. Those which do so are called

“Permanent Birds” (*aves manentes*). Other Birds, such as the Woodpeckers, migrate from place to place without following any very definite course. These are called “Wandering Birds” (*aves erraticæ*), and their movements are chiefly conditioned by the scarcity or abundance of food in any particular locality. Other Birds, however, at certain seasons of the year, undertake long journeys, usually uniting for this purpose into larger or smaller flocks. Such birds—of which the Swallows are a familiar instance—are properly called “Migratory Birds” (*aves migratoriæ*); and their movements are conditioned by the necessity of having a certain average temperature, without which they cannot live, and also by the necessity of finding a climate suitable for the bringing up of the young. Thus the Migratory Birds of cold regions, when the cold season comes on, travel to warmer countries; but when the hot season of these regions approaches, they migrate back again to temperate zones.

CHAPTER XXIX.

DIVISIONS OF BIRDS.

BIRDS may be variously divided, but for our present purpose it is most convenient to regard them as divided into the following three great primary divisions or sub-classes :—

1. RATITÆ.—This division comprises the Running Birds, which cannot fly, such as the Ostriches, Emus, and Cassowaries. It is characterised by the fact that the sternum has no median ridge or keel for the attachment of the great pectoral muscles. The sternum is therefore raft-like (Lat. *rates*, a raft), hence the name given to this section. The barbs of the feathers are separate.

2. CARINATÆ.—This comprises all living Birds except the preceding, and is characterised by the fact that the sternum is furnished with a prominent median ridge or keel (*carina*) ; hence the name applied to the division. Under this head are included six smaller divisions or orders.

3. ODONTORNITHES.—This sub-class comprises three orders of fossil Birds, the essential characteristic of which is that they possessed true teeth, sunk in distinct sockets or grooves in the jaws.

SUB-CLASS I. RATITÆ.

ORDER CURSORES.

The Running or Cursorial Birds, comprising the Ostrich, Cassowary, Emu, Rhea, and Apteryx, are characterised by the rudimentary condition of the wings, which are useless as organs of flight, and by the compensating length and strength of the legs. In accordance with this condition of the limbs, the bones have few air-cells, and the breast-bone is destitute of the prominent ridge or keel to which the great muscles of the wings are attached (fig. 206, A). The two sides of the pelvis are united together below in the Ostrich, and in all the pelvic arch has great strength and stability. The legs

are extremely powerful, and the hinder toe is wanting in all except the *Apteryx*, in which it is present in a rudimentary condition. The front toes (fig. 206, C and E) are either two or three in number, and are furnished with strong blunt claws or nails. The feathers present the remarkable peculiarity that the barbs, instead of being connected by means of the barbules, are disconnected and separate from one another, thus coming to resemble hairs in appearance.

The African Ostrich (*Struthio camelus*), which is one of the best-known members of this order, inhabits the desert plains of Africa and Arabia, and is the largest of living birds, attaining a height of

Fig. 206.—Morphology of Cursores. A, Sternum of the Ostrich (*Struthio camelus*): *s* Scapula; *c* Coracoid. B, Side view of the pelvis of the Ostrich: *i* Ilium; *p* Pubis; *is* Ischium; *f* Femur. C, Foot of *Apteryx australis*. D, Tarso-metatarsus of the *Apteryx*, showing the hallux placed high up on its posterior surface. E, Foot of the *Rhea americana*.

from six to eight feet. The head and neck are nearly naked, and the quill-feathers of the wings and tail have their barbs wholly separate, constituting the ostrich-plumes of commerce. The legs are extremely strong, and the feet have only two toes each. The Ostriches run with extraordinary speed, and can outstrip the fastest horse. They are polygamous, each male having several females, and they keep together in larger or smaller flocks. The American Ostriches or Rheas are much smaller than the African Ostrich, and have the head feathered, whilst the feet are furnished with three toes each. They inhabit the great plains of tropical America, and are polygamous. The Emeu (*Dromaius*) is exclusively confined to

Australia. In size it nearly equals the African Ostrich, standing from five to seven feet in height, and it is not uncommonly kept as a domestic pet. The Cassowaries are found in the Malayan Archipelago, North Australia, and New Guinea. The best known is the Galeated Cassowary which was first brought alive to Europe by the Dutch. It stands about five feet in height, and possesses a singular horny crest upon the head. The last group of the living Cursorial Birds is the curious genus *Apteryx* of New Zealand. In the species of this remarkable genus (fig. 207) the beak is extremely long and slender, and the nostrils are placed at the extremity of the upper

Fig. 207.—The *Apteryx australis* of New Zealand, showing the hair-like feathers, and the rudimentary great toe on the back of the foot.

mandible. The legs are comparatively short, and there is a rudimentary hind-toe, provided with a claw. The feathers of the general plumage are long and hair-like, and the wings are altogether rudimentary.

It is worth noting that in New Zealand are found the remains of a number of gigantic Cursorial Birds which are now extinct, but which seem to have been in existence when the island was first inhabited by man. They are known to the Maories as “Moas,” and the principal genus is *Dinornis*.

In very many respects the various Birds which are here included

in the order *Cursores*, are so different from one another, that they may be regarded as forming divisions of equal, or nearly equal, value to the "orders" which form the sub-class *Carinatæ*.

SUB-CLASS II. CARINATÆ.

This sub-class includes all the living Birds which have the power of flight, and it therefore comprises the great majority of the entire class of *Aves*. The Carinate Birds, however, are so similar to one another in their general characters that they can with difficulty be split up into minor sections. For our present purposé, however, we may divide them into the six orders of the Swimming Birds (*Natatores*), the Waders (*Grallatores*), the Scratchers (*Rasores*), the Climbers (*Scansores*), the Perchers (*Insessores*), and the Birds of Prey (*Rapttores*), which orders are more or less natural groups, with the exception of the order *Scansores*.

ORDER I. NATATORES.

The order of the Swimming Birds comprises birds which are as much at home in the water as upon land, or even more so. In

Fig. 208.—A, Head of the Grey Lag Goose. B, Foot of the Domestic Goose

accordance with their aquatic mode of life, the *Natatores* have a boat-shaped body, generally elongated, and usually having a

long neck. The legs are short, and are placed behind the centre of gravity of the body ; this position enabling them to act admirably as swimming paddles, at the same time that it renders the gait upon dry land comparatively awkward and shuffling. The toes in all the *Natatores* are *webbed* to a greater or less extent, or, in other words, are united by a membrane (fig. 208, B). In many the web or membrane between the toes is stretched completely from toe to toe, but in others the membrane is divided between the toes, so that the feet are only imperfectly webbed. As their aquatic mode of

Fig. 209.—Penguin (*Aptenodytes patagonicus*).

life exposes them to great reductions of temperature, the body in the Natatorial Birds is closely covered with feathers, with a thick covering of down next the skin. They are further protected against becoming wet whilst in the water by the great development of the oil-gland at the tail, by means of which the dense plumage is kept constantly oiled. As a rule, the Natatorial Birds are polygamous, each male having several females ; and the young are hatched in a condition not requiring assistance from their parents, being able to swim about and procure food for themselves as soon as they are liberated from the egg.

Amongst the more important types of the *Natatores* may be enumerated the Penguins (*Spheniscidae*), the Auks (*Alcidae*), the Gulls and Terns (*Laridae*), the Petrels (*Procellariidae*), the Pelicans (*Pelicanus*), the Cormorants (*Phalacrocorax*), the Gannets (*Sula*), the Ducks (*Anatidae*), the Geese (*Anserinae*), and the Swans (*Cygnidae*).

The Penguins and Auks, with their allies the Divers, Guillemots, and Grebes, have rudimentary, or at any rate small, wings, and are all more at home in the water than upon land. In the Penguins (fig. 209), the wings are rudimentary, and covered with a scaly skin. They are used by the bird as fins in swimming under water. The Penguins are confined to the southern hemisphere. The Gulls, Terns, and Petrels, on the contrary, are all birds of powerful flight, and some of them, such as the Albatross, are habitually found hundreds of miles from the nearest land. The Pelicans, with their allies the Cormorants, Frigate-birds, and Darters, are excellent fliers, and also not uncommonly perch on trees, which few Natorial birds do. They are distinguished by having the hinder toe directed inward, and united to the innermost of the front toes by a continuous membrane. The Ducks, Geese, and Swans have the bill very much flattened (fig. 208 A), and covered by a soft skin. The edges of the bill are also furnished with a series of transverse plates, which form a kind of fringe or "strainer," by means of which these birds sift the mud in which they habitually seek their food.

ORDER II. GRALLATORES.

The Wading Birds for the most part frequent moist situations, such as marshes and shallow ponds, the shore of the sea or the banks of rivers or lakes, though some of them keep entirely, or almost entirely, to the dry land. In accordance with their semi-aquatic, amphibious habits, the Waders are distinguished by the great length of their legs—the increase in length being chiefly due to the elongation of the tarso-metatarsus. The legs (fig. 210, A) are also unfeathered and naked as far as the lower end of the tibia, at any rate. There are three anterior toes, and usually a short hind-toe; but the toes are never completely webbed, though they are sometimes partially palmate. The wings are long, and the power of flight is usually considerable; but the tail is very short, and its function as a rudder is chiefly transferred to the long legs, which are stretched out behind in flight. The beak is almost always of great length, generally longer than the head (fig. 210, B), and usually more or less pointed, though it is sometimes flattened. In the Avocet (C) the bill is curved upwards, instead of being straight, or bent downwards, as is generally the case. The typical Waders, as before said,

spend most of their time wading about in shallow water, feeding upon small fishes, shell-fish, worms, and insects. Others, such as the Storks, live mostly upon the land, and are more or less exclusively vegetable feeders.

Amongst the more important Gallatorial birds are the Rails (*Rallidæ*), Water-hens (*Gallinulæ*), Cranes (*Gruidæ*), Herons (*Ardeidæ*), Storks (*Ciconinæ*), Snipes (*Scolopacidæ*), Sandpipers (*Tringidæ*), Curlews (*Numenius*), Plovers (*Charadriidæ*), and Bustards (*Otidæ*).

The Rails are more or less terrestrial in their habits, but inhabit marshes and fens. Good examples are the Marsh-hen (*Rallus elegans*) and the Virginia Rail (*R. virginianus*) of North America, and

Fig. 210.—Gallatores. A, Leg and Foot of Curlew; B, Head of Snipe; C, Beak of Avocet.

the Corn-crake (*Crex pratensis*) of Europe. The Water-hens (*Gallinula*) and Coots (*Fulica*) are aquatic or semi-aquatic, swimming and diving with the greatest ease. The Cranes are in the main vegetable-feeders, and inhabit dry plains. The Herons (fig. 211), Egrets, Bitterns, and Night Herons, form a beautiful family of Wading Birds, represented in almost every portion of the known world. Nearly allied to these are the brilliantly coloured Ibises (*Tantalina*), which inhabit all warm countries. The *Ciconinæ* are all large birds, and comprise the Storks and Adjutant; while the Spoonbills are mainly separated from them by their flattened, spoon-shaped bill. The *Scolopacidæ*, comprising the Snipes and Woodcocks, the *Tringidæ* (or Sandpipers), the Curlews (*Numenius*), and various other allied Birds, are distinguished from the preceding by the possession of a long, soft, slender bill, which is used in probing the ground for

food. In the *Charadriidæ* are comprised the Oyster-catchers, Turnstones, Lapwings, Plovers, Thick-knee, and many other familiar Birds. Lastly, the *Otidæ* comprise only the Bustards, which are ex-

Fig. 211.—Grallatores. Common Heron (*Ardea cinerea*).

clusively confined to the Old World, and make a decided approach to the Rasorial Birds.

ORDER III. RASORES.

The Scratching Birds—or as they are often called, the Gallinaceous Birds—are characterised by the fact that the upper mandible of the bill is convex and vaulted (fig. 213), and has a membranous space at its base, in which the nostrils are pierced. The nostrils are also covered by a cartilaginous scale. The legs are strong and muscular, and are often covered with feathers as far as the ankle-joint. There are four toes (fig. 212, A), three in front, and a short hind-toe placed on a higher level than the others. All the toes, in the typical members of the order, are provided with strong blunt claws, suitable for scratching. The food of the *Rasores* consists chiefly of hard grains and seeds, and in accordance with this, they have a large crop, and an extremely strong and muscular gizzard. They generally lay their eggs upon the ground, and they are mostly polygamous,

each male having several mates. The Doves, however, pair for life. The males take no part in building the nest or in hatching the eggs; and the young are generally precocious, being able to run about and provide themselves with food from the moment they quit the egg. The wings are usually weak, and the flight feeble, and accompanied with a whirring sound; but many of the Pigeons are powerful fliers.

The order *Rasores* is divided into two very well-marked sections or sub-orders, called respectively the *Gallinacei* and *Columbacei*. In

Fig. 212.—A, Foot of Black-cock (*Tetrao tetrix*). B and C, Upper and under views of the foot of the Wood-pigeon (*Columba palumbus*).

the *Gallinacei* are all the typical forms of the order, and the characters of this section are therefore the same as those of the order itself. They are distinguished from the *Columbacei* mainly by being less fully adapted for flight, their bodies being much heavier, comparatively speaking, their legs and feet stronger, and their wings shorter. The hind-toe (great toe) is placed on a higher level than the three front toes (fig. 212, A), and merely touches the ground in walking. The foot is therefore specially adapted for living on the ground rather than for perching on trees. They are also polygamous; and the males may possess

“spurs,” and are usually more brilliantly coloured than the females.

The leading families of the Gallinaceous Birds are : 1. The *Tetronidæ*, or Grouse family, comprising the true Grouse and Black Game (*Tetrao*), the Ptarmigans (*Lagopus*), the Ruffed Grouse (*Bonasa*), &c. 2. The *Perdicidæ* or Partridge family, comprising the Partridges (*Perdix*), Quails (*Coturnix*), Virginian and Mountain Quails (*Oryzopsis*), Crested Quails (*Lophortyx*), &c. 3. The *Phasianidæ*, or Pheasant family, comprising the various Pheasants (*Phasianus*), the Domestic and Jungle Fowls (*Gallus*), the Turkeys (*Meleagris*),

the Guinea-fowls (*Numida*), and the Pea-fowl (*Pavo*). 4. The *Megapodidæ*, or Mound-builders, comprising only some singular Australian and Indian birds, which build enormous mounds, in which they deposit their eggs. 5. The *Cracidæ*, or Curassow family, comprising the large South and Central American birds known as Curassows and Guans. 6. The *Pteroclidæ*, or Sand-grouse, of the Old World, which, in their long and pointed wings, make an approach to the Pigeons. 7. The *Tinamidæ*, or Tinamous, of South America, in which the tail is short, or may be wholly wanting.

Fig. 213.—Rasores. Rock-pigeon (*Columba livia*).

The *Columbacei* comprise the Pigeons and Doves, and they are separated from the typical *Rasores* by being much more fully adapted for flight. They are furnished with strong wings and are good fliers; and in place of being ground-birds, their habits are generally to a great extent arboreal, in accordance with which the feet are slender, and are adapted for perching, the great toe being placed on a level with the other toes (fig. 212, B). They are also not polygamous, and their voice is of a much more gentle, soft, and melancholy character. (Hence the name of *Gemitores* applied to this section, whilst the *Gallinacei* are called the *Clamatores*.) Besides the true

Pigeons and Doves, this sub-order includes also the remarkable extinct bird the Dodo, which was of gigantic size, comparatively speaking, and inhabited the island of Mauritius up to the commencement of the seventeenth century.

ORDER IV. SCANSORES.

The order of *Scansores* or Climbing Birds is very shortly and easily defined, having no other distinctive and exclusive peculiarity, except the fact that the feet have four toes, of which two are turned backwards and two forwards (fig. 214, B). Of the two toes which are turned backwards, one is the proper hind-toe, and the other is the outermost toe. This arrangement of the toes enables the Scansorial birds to climb with great ease and readiness. Their powers of flight are usually very moderate, and below the general average, and their food consists of insects and fruits of various kinds. Their nests are usually made in the hollows of old trees, but some (Cuckoos) have the remarkable habit of depositing their eggs in the nests of other birds. They are never polygamous, and the young are born in a naked and helpless condition.

Fig. 214.—A, Skull of a Parrot (*Psittacus erythacus*). B, Foot of the same: a Hallux; b Index; c Middle toe; d Outer or ring toe. (After Blanchard.)

Upon the whole, we must regard the order of the *Scansores* as an artificial assemblage, comprising birds which have little in common save the adaptations which fit them for an essentially scansorial life. Bearing this in mind, we may include in the *Scansores* the following families: 1. The *Cuculide*, or Cuckoo family, comprising the true Cuckoos and some allied birds. They are remarkable for the fact that many of them are “parasitic”; that is to say, they lay their eggs in the nests of other birds. The yellow-billed Cuckoo (*C. americanus*), however, of the United States, builds a nest for itself and brings up its own young, as do others of the family. 2. The *Picidae*, or Woodpecker family, comprising many familiar

birds, all of which climb and run up trees with the greatest facility. They live mostly on insects, which they catch by darting out their

Fig. 215.—The Owl-Parrot (*Strigops habroptilus*), New Zealand.

long, worm-like, barbed tongue. 3. The *Psittacidae*, or Parrot family, comprising the true Parrots, the Cockatoos, the Lories, the Parra-

Fig. 216.—Head of Toucan.

keets, and the Macaws. They are all natives of hot climates, and are mostly remarkable for their brilliant plumage, and loud, harsh,

and grating voices. The beak (fig. 215) is hooked, and is used as a kind of third foot in climbing, but some move about actively on the ground. 4. The *Rhamphastide*, or Toucans, distinguished by their enormously large and cellular bills, the sides of which are serrated (fig. 216). They live in deep forests, in small flocks, and are confined to tropical America. 5. The *Trogonide*, or Trogons, which inhabit the most retired recesses of the forests of the intertropical regions of both hemispheres, and are distinguished by their resplendent plumage. 6. The Barbets (*Bucconide*), of the warmer parts of the New and Old Worlds; and 7. The Plantain-eaters (*Musophagide*) of Africa.

ORDER V. INSESSORES.

The sixth order of Birds is that of the *Insessores* or *Perchers*, often spoken of as the Passerine Birds. They are defined by Owen as follows: "Legs slender, short, with three toes before and one behind, the two external toes united by a very short membrane" (fig. 217, E and F).

"The *Perchers* form by far the most numerous order of birds, but are the least easily recognisable by distinctive characters common to the whole group. Their feet, being more especially adapted to the delicate labours of nidification" (building the nest), "have neither the webbed structure of those of the *Swimmers*, nor the robust strength and destructive talons which characterise the feet of the *Birds of Rapine*, nor yet the extended toes which enable the *Wader* to walk safely over marshy soils and tread lightly on the floating leaves of aquatic plants; but the toes are slender, flexible, and moderately elongated, with long, pointed, and slightly curved claws.

"The *Perchers*, in general, have the females smaller and less brilliant in their plumage than the males; they always live in pairs, build in trees, and display the greatest art in the construction of their nests. The young are excluded in a blind and naked state, and are wholly dependent for subsistence during a certain period on parental care. The brain arrives in this order at its greatest proportionate size; the organ of voice here attains its utmost complexity; and all the characteristics of the bird, as power of flight, melody of voice, and beauty of plumage, are enjoyed in the highest perfection by one or other of the groups of this extensive and varied order."

The structure, then, of the feet gives the definition of the order, but the minor subdivisions are founded on the nature of the beak; this organ varying in form according to the nature of the food, which may be "small or young birds, carrion, insects, fruit, seeds, vegetable juices, or of a mixed kind." In accordance with this

character, the *Insessores* have been divided into four great sections, as follows :—

1. *Conirostres*,—in which the bill is strong and on the whole conical, broad at the base, and tapering with considerable rapidity to the

Fig. 217.—A, Head of Hoopoe (*Upupa epops*), showing the tenuirostral type of beak. B, Head of Red-backed Shrike (*Lanius collurio*), showing the dentirostral type of beak. C, Head of White-bellied Swift (*Cypselus melba*), showing the fissirostral type of beak. D, Head of Corn-bunting (*Emberiza miliaria*), showing the conirostral type of beak. E, Foot of the Yellow Wagtail (*Motacilla sulphurea*). F, Foot of a Finch (*Fringilla*).

point (fig. 217, D). The upper mandible is not markedly toothed at its lower margin. Good examples of the conirostral beak are to be found in the Sparrows, Finches, Buntings, Crows, &c. The greater part of the *Conirostres* are omnivorous, eating anything which may come in their way; but some are granivorous, subsisting upon grains

and seeds. To this section belong the (Hornbills) *Buceridæ*, the Starlings (*Sturnidæ*), the Crows, Jays, and Magpies (*Corvidæ*), the Crossbills (*Loriadæ*), and the numerous Finches and Larks (*Fringillidæ*).

2. *Dentirostres*.—The Birds of this section are characterised by the fact that the upper mandible of the beak is notched or toothed on its lower margin near the tip (fig. 217, B). They all feed upon animal food, especially upon insects. In this section are the Shrikes (*Laniidæ*), the Fly-catchers (*Muscicapidæ*), the Thrushes (*Merulidæ*), and the Warblers (*Sylviadæ*).

3. *Tenuirostres*.—In this section the beak is long and slender, gradually tapering to a point (fig. 217, A). The toes are generally very long and slender, especially the hinder toe. The Humming-birds feed upon the wing, and amongst these are some of the most fragile and brightly coloured of all the Birds. Others, however, live upon insects, which they catch upon the ground or on the trunks of trees, and some of these approach nearly to the *Dentirostres* in many of their characters. Amongst the more important groups included in this section are the Creepers (*Certhidæ*), the Honey-eaters (*Meliphagidæ*), the Humming-birds (*Trochilidæ*), and the Hoopoes (*Upupidæ*).

4. *Fissirostres*.—The beak in the Fissirostral Perchers (fig. 217, C) is generally short, and remarkably wide in its gape, and the opening of the bill is protected by a number of bristles. This arrangement is in accordance with the habits of the *Fissirostres*, the typical forms of which live upon insects and take their prey upon the wing. The most typical *Fissirostres*, in fact, such as the Swallows and Goat-suckers, fly about with their mouths open, and the insects which they catch in this way are prevented from escaping, partly from the bristles which border the gape, and partly by a sticky secretion within the mouth. The most typical Fissirostral Birds are the Swallows and Martins (*Hirundinidæ*), the Goat-suckers (*Caprimulgidæ*), and the Swifts (*Cypselidæ*); but to these the Bee-eaters (*Meropidæ*) and the King-fishers are usually added.

ORDER VI. RAPTORES.

The Birds of Prey are characterised by the form of the beak, which is adapted for tearing animal food (fig. 218, B). The upper mandible is the longest, hooked at its point, "strong, curved, sharp-edged, and sharp-pointed, often armed with a lateral tooth" (Owen). The body is extremely muscular; the legs are robust, short, with three toes in front and one behind; all the toes armed with strong, curved, crooked claws or talons (fig. 218, A). They all feed upon the flesh

of other animals, which they either kill for themselves or find dead, and their flight is generally extremely rapid and powerful. They are not polygamous, and the female is larger than the male. They usually build their nest in lofty and inaccessible situations, and seldom lay more than four eggs. The young are hatched in a naked and helpless condition.

The *Raptores* are divided into two sections—the Nocturnal Birds

Fig. 218.—*Raptores*. A, Foot of Peregrine Falcon; B, Head of Buzzard.

of Prey, which hunt at night, and the Diurnal Birds of Prey, which hunt by day. In the former section is only the single family of the Owls (*Strigidæ*), in which the eyes are large, and are directed forwards (fig. 219), whilst the plumage is exceedingly soft and loose, so as to render their flight almost noiseless. The Owls, for the most

Fig. 219.—A, Foot of Tawny Owl; B, Head of White Owl.

part, hunt their prey in the twilight or on moonlight nights, and they live mostly upon field-mice and small birds, but they will also eat insects and frogs. In the section of the diurnal *Raptores* are the Falcons and Hawks, the Eagles and the Vultures. In all these the eyes are smaller than in the Owls, and are placed laterally, and the plumage is not soft. They usually possess extraordinary powers of

flight. The wings are long and pointed, the sternal keel is greatly developed, the pectoral muscles are of large size, and many of them exhibit powers of locomotion more rapid than those enjoyed by any other members of the animal kingdom.

SUB-CLASS III. ODONTORNITHES.

ORDER I. SAURURÆ.

This order includes only the single extinct Bird, the *Archæopteryx*, which has been found in the Oolitic rocks of Germany. The *Archæopteryx* was about as big as a common Rook, and shows many singular points of resemblance to the true Reptiles. It differs from all living birds in having two free claws to the wing, and in possessing a long lizard-like tail. Instead of the ploughshare-shaped bone which ter-

Fig. 220.—*Archæopteryx*. Tail and detached bones.

minates the tail in living birds (fig. 204, B), the tail in *Archæopteryx* (fig. 220) is very long, and consists of about twenty distinct and separate vertebrae, each of which supports a pair of quill-feathers. The tail, therefore, except for the presence of feathers, must have been very like that of a Reptile. As in all the Birds of this sub-class, the jaws were furnished with conical pointed teeth.

ORDER II. ODONTOLCE.

This order comprises only a single extinct Bird, the extraordinary *Hesperornis regalis* of the Cretaceous rocks of North America, for the discovery and description of which science is indebted to Pro-

fessor Marsh. In this Bird (fig. 221) we have a gigantic diving-bird, standing some five feet in height, but with the wings quite rudimentary, so that the power of flight was entirely absent. The tail was not elongated, as it is in *Archæopteryx*, but consists of about twelve vertebræ, of which the last three or four are amalgamated

Fig. 221 —Skeleton of *Hesperornis regalis*, restored. (After Marsh.)
About one-tenth of the natural size.

to form a single mass. The bodies of the vertebræ have the form usual among Birds. The jaws are furnished with numerous conical recurved *teeth*, sunk in a deep continuous groove. The metacarpal bones are wanting, and the sternum is destitute of a keel.

ORDER III. ODONTOTORMÆ.

This order comprises only some singular fossil Birds from the Cretaceous rocks of North America, of which the genus *Ichthyornis*

is the type. In *Ichthyornis*, as in *Hesperornis*, the jaws are furnished with numerous conical teeth, but those are sunk in distinct sockets. The wings are well developed, and the bird must have possessed considerable powers of flight. The sternum has a keel, and the metacarpal bones are anchylosed with one another. Lastly, there is the extraordinary character that *the bodies of the vertebræ* were *biconcave*, and in this respect resemble the vertebræ of most fishes and of many Amphibians and Reptiles. The size of *Ichthyornis dispar*, the only known species of the genus, seems to have been about equal to that of a Pigeon.

MAMMALIA.

CHAPTER XXX.

CLASS V. MAMMALIA.

THE *Mammalia* include all the ordinary Quadrapeds, and may be shortly defined as comprising Vertebrate Animals in which *some part or other of the skin is always provided with hairs, and the young are nourished for a longer or shorter time by means of a special fluid—the milk—secreted by special glands—the mammary glands.* These two peculiarities are of themselves sufficient to separate the Mammals from all other classes of the Vertebrate sub-kingdom. In addition, however, to these two leading characteristics, the following points are of scarcely less importance :—

1. The skull is united with the spinal column by means of *two* articulating surfaces or condyles, instead of one, as in the Reptiles and Birds.

2. The lower jaw consists of two halves, each composed of a single piece, and united in front. The lower jaw, also, is always jointed directly to the skull, and there is no quadrate bone.

3. The heart consists—as in Birds—of four distinct chambers, two auricles and two ventricles. The right and left sides of the heart are completely separated from one another, and there is never any direct communication between the blood sent to the lungs and that sent to the body. The red corpuscles of the blood (fig. 163, *a*), are, in the great majority of cases, in the form of circular discs, and they never contain any internal solid particle or nucleus.

4. The cavities of the chest (thorax) and abdomen are separated from one another by a muscular partition, which is called the midriff or diaphragm, and is the chief agent in respiration.

5. The respiratory organs are in the form of two lungs, placed in the chest, and never communicating with air-receptacles situated in different parts of the body. In no case and at no period of life are gills or branchiæ present.

As regards the skeleton of the *Mammalia*, it is not necessary to add much to what was said in speaking of the *Vertebrata* generally. With few exceptions, the spinal column is divisible into the same regions as in man—namely, the neck or cervical region, the back or dorsal region, the loins or lumbar region, the sacral region, and the tail or caudal region (see fig. 159). In spite of the great differences observable in the length of the neck in different Mammals, the number of vertebrae which form the cervical region is extraordinarily constant, being almost invariably *seven*. In this respect the Giraffe, which is the longest-necked of Mammals, agrees with the Whale, which can hardly be said to have a neck at all. The vertebrae of the back or dorsal region are mostly thirteen in number, but are often more. In man there are only twelve; and in some cases there are only eleven or ten. The lumbar vertebrae are usually six or seven in number; five in Man; rarely less than four. The sacral vertebrae are usually amalgamated to form a single bone—the *sacrum*—but this is wanting in the Whales. The number of vertebrae in the tail or caudal region varies from four to as many as five-and-forty, and they are usually freely movable upon one another. The thoracic cavity or chest in Mammals is always enclosed by a series of ribs; the number of which varies with the number of the dorsal vertebrae. As a rule, the ribs are united to the breast-bone or sternum in front, not by bony pieces, as in birds, but by cartilages. Only the front ribs reach the sternum, and these are called the “true” ribs; the hinder ribs fall short of the breast-bone, and are called the “false” ribs. The sternum is composed of several pieces, placed one behind the other, but usually amalgamated to form a single bone. It is usually long and narrow in shape, and is only rarely furnished with any ridge or keel, as it is in Birds. The regular number of limbs in the Mammals is four, two anterior and two posterior; and for this reason the Mammals are often spoken of as Quadrupeds. Some Mammals, however, such as the Whales and Dolphins, have only the anterior limbs, and many of the Amphibia and Reptiles walk upon four legs. As regards the structure of the fore-limbs (fig. 160), the general conformation of the limb has been previously noted. The shoulder-blade or *scapula* is never wanting, and is generally broad and flat. The coracoid bones, which form such a marked feature in the pectoral arch of the Birds, are incomplete, and are fused with the scapula, of which they form the so-called “coracoid process.” In the Monotrematous Mammals alone are the coracoids distinct bones, sufficiently developed to articulate with the sternum. The collar-bones or clavicles are often rudimentary or absent, and, when present, are never united into a single bone. The humerus presents

nothing special; and the radius and ulna are usually present in the fore-arm, though they may be fused with one another, or the ulna may be wanting.

Fig. 222.—A, Fore-leg of Ox (*Bos taurus*). B, Hind-leg of Stag (*Cervus elaphus*). *ca*, Carpus; *ta* Tarsus; *c* "Canon-bone," composed of the united metacarpals or metatarsals of the third and fourth digits.

Fig. 223.—Fore-leg of Horse. *ca* Carpus; *m* Metacarpal of the third digit; *s* "Splint-bone," or rudimentary metacarpal; 1, First phalanx or "great pastern"; 2, Second phalanx or "small pastern"; 3 Third phalanx or "coffin-bone."

The fore-arm is succeeded by the small bones which compose the wrist or "carpus." These are eight in number in Man, but vary in different Mammals from five to eleven.

The metacarpus in Man and in most Mammals consists of five

cylindrical bones, articulating proximally with the carpus, and distally with the phalanges of the fingers. The most remarkable modification of this normal state of things occurs in the Ruminants and in the Horse. In the Ruminants (fig. 222, A and B), in which the foot is cleft, and consists of two perfect toes only, there are two metacarpal bones in the embryo; but these are anchylosed together in the adult, and form a single mass which is known as the "canon-bone" (fig. 222, c). In the Horse (fig. 223), in which the foot consists of no more than a single digit, there is only a single metacarpal bone, on each side of which are two little bony spines—the so-called "splint-bones"—which are attached superiorly to the carpus, and are to be regarded as rudimentary metacarpals.

The normal number of digits is five, but they vary from one to five. The middle finger is the longest, and most persistent of the digits of the fore-limb; and in the Horse it is the only one which is left (fig. 223). The thumb is very frequently absent. In the Ruminants there are only two fingers which are functionally useful, these carrying the hoofs. Normally, each digit is composed of three short bones or *phalanges*, the innermost digit (the thumb) having two. The extremity of the digit is usually protected by a nail, claw, or hoof.

While the fore-limbs are never wanting, the hind-limbs are absent in the so-called "Mutilated Mammals" (namely, the Cetaceans and Sirenians). The bones of the hind-limb correspond with those of the fore-limb; and the foot (*pes*) corresponds with the hand (*manus*), consisting normally of five digits, but subject to the same abortion of parts as occurs in the case of the anterior limb.

Teeth are present in the great majority of Mammals; but they are only present in the embryo of the whalebone Whales, and are entirely absent in the genera *Echidna*, *Manis*, and *Myrmecophaga*. In the Duck-mole (*Ornithorhynchus*) the so-called teeth are horny, and the same was the case in the extinct *Rhytina* amongst the *Sirenia*. In all other Mammals the teeth have their ordinary structure of dentine, enamel, and crusta petrosa, these elements being variously disposed in different cases, and the enamel being occasionally wanting. In no Mammals are the teeth ever anchylosed with the jaw; and in all, the teeth are implanted into distinct sockets or alveoli, which, however, are very imperfect in some of the Cetacea.

Many Mammals have only a single set of teeth throughout life, and these are termed by Owen "monophyodont." In most cases, however, the first set of teeth—called the "milk" or "deciduous" teeth—is replaced in the course of growth by a second set of

“permanent” teeth. The deciduous and permanent sets of teeth do not necessarily correspond to one another; but no Mammal has ever *more* than these two sets. The Mammals with two sets of teeth are called by Owen “diphyodont.”

In Man and many other Mammals the teeth are divisible into four distinct groups (fig. 224), which differ from one another in position, appearance, and function; and which are known respectively as the *incisors*, *canines*, *præmolars*, and *molars*.

“Those teeth which are implanted in the præmaxillary bones, and in the corresponding part of the lower jaw, are called ‘incisors,’ whatever be their shape or size. The tooth in the maxillary bone which is situated at or near to the suture with the præmaxillary, is the ‘canine,’ as is also that tooth in the lower jaw which, in opposing it, passes in front of its crown when the mouth is closed. The other teeth of the first set are the ‘deciduous molars’; the teeth which displace and succeed them vertically are the ‘præmolars’;

Fig. 224.—Teeth of the right side of the lower jaw of the Chimpanzee (after Owen).

i Incisors; *c* Canine tooth; *pm* Præmolars; *m* Molars.

the more posterior teeth, which are not displaced by vertical successors, are the ‘molars’ properly so called” (Owen). The deciduous dentition, therefore, of a diphyodont Mammal consists of only three kinds of teeth—incisors, canines, and molars. The incisor and canine teeth of the deciduous set are replaced by the teeth which bear the same names in the permanent set. The deciduous “molars,” however, are replaced by the permanent “præmolars,” and the “molars” of the permanent set of teeth are not represented in the deciduous series, only existing once, and not being replaced by successors.

All these kinds of teeth are not necessarily present, and the teeth furnish most important characters for separating the various orders of Mammals from one another. For this reason it is usual to express the number of the teeth in any particular animal by an arithmetical formula, called the *dental formula*. For example, the

formula for the portion of the jaw of the Chimpanzee figured above (fig. 224) would be as follows :—

$$i\ 2;\ c\ 1;\ pm\ 2;\ m\ 3.$$

But this is only one half of the lower jaw, and the dental formula must include both sides, so that it would be :—

$$i\ 2-2;\ c\ 1-1;\ pm\ 2-2;\ m\ 3-3.$$

That this would be the formula is at once evident, when it is remembered that the two sides of the jaw of course contain exactly the same teeth. Still, the formula as given above only includes the lower jaw, and to render it perfect it must take in the teeth of the upper jaw as well. This is effected by placing the figures in two rows separated by short lines, all the figures in the upper row referring to the upper jaw, and those in the lower row to the lower jaw; the short dashes between the figures of each row still indicating the teeth on the two sides of the mouth. The complete formula would therefore run as follows :—

$$\begin{array}{ccccccc} i & 2-2 & ; & c & 1-1 & ; & pm & 2-2 & ; & m & 3-3 & = & 32. \\ 2 & 2 & ; & & 1-1 & ; & & 2-2 & ; & & 3-3 & & \end{array}$$

In this way the *dentition*—that is to say, the number and arrangement of the teeth—can be presented in a manner which can be instantly recognised by the eye. It must be remembered, however, that the formula seldom exhibits the regularity of the one of the Chimpanzee given above. The teeth are not necessarily the same in both jaws, and in many cases some may be altogether wanting. To show this there is subjoined the dental formula of a typical Ruminant animal, such as a sheep :—

$$\begin{array}{ccccccc} i & 0-0 & ; & c & 0-0 & ; & pm & 3-3 & ; & m & 3-3 & = & 32. \\ 3-3 & ; & & 1-1 & ; & & 3-3 & ; & & 3-3 & & \end{array}$$

From this formula it will be seen that the sheep has 32 teeth in both jaws taken together. The upper incisors and canines are wanting, and there are three premolars and three molars on each side of the upper jaw. In the lower jaw there are six incisors, two canines, and the same number of premolars and molars as in the upper jaw.

As regards the digestive system of Mammals, the alimentary canal and digestive glands have on the whole the same general structure and arrangement as in man (pp. 223, 224). Some very remarkable modifications, however, in the structure of the stomach and in the termination of the intestine, occur in certain Mammals; but these will be noticed in speaking of the orders in which they occur.

The cavity of the abdomen in Mammals is always separated from that of the thorax by a complete muscular partition—the diaphragm. The abdomen contains the greater part of the alimentary canal, the liver, pancreas, kidneys, and other organs. The thorax contains chiefly the heart and lungs. The *heart* is contained in a membranous sac—the pericardium—and consists of two auricles and two ventricles. The heart consists functionally of two sides, each having an auricle and a ventricle, which communicate with one another by apertures, so guarded by valves that the blood can pass from the auricle into the ventricle, but not, under ordinary circumstances, from the ventricle to the auricle. There is in the adult no direct communication between the two sides of the heart. The course of the circulation is indicated in the subjoined diagram (fig. 225), and is shortly as follows: The venous blood, which has become impure by passing through the tissues, is returned by the great veins to the *right* auricle, from which it passes into the right ventricle. From here it is driven through a great vessel, called the pulmonary artery, to the lungs, where it is submitted to the action of the air, and becomes arterial blood. It is then returned to the heart by a series of vessels called the pulmonary veins, and is poured into the *left* auricle, from which it passes into the left ventricle. From the left ventricle it is propelled to all parts of the body by a great systemic vessel, which is called the aorta.

Fig. 225.—Diagram of the circulation in a Mammal. (The cavities containing venous blood are marked black, those containing arterial blood are left white.) *a* Right auricle; *v* Right ventricle; *p* Pulmonary artery carrying venous blood to the lungs; *pv* Pulmonary veins carrying arterial blood from the lungs; *a'* Left auricle; *v'* Left ventricle; *b* Aorta carrying arterial blood to the body; *c* Vena cava, carrying venous blood to the heart.

The *lungs* of Mammals are two in number, and differ from those of Birds in being freely suspended in membranous bags. They are spongy and cellular throughout, and they never communicate by apertures on their surface with air-sacs placed in different parts of the body.

The *nervous system* of Mammals is chiefly remarkable for the

great proportionate development of the brain, as compared with the spinal cord.

In the higher Mammals, also, the two halves (hemispheres) of the greater brain (*cerebrum*) are connected together by a great band or bridge of nervous tissue, constituting what is known as the *corpus callosum*. This structure is not a conspicuous feature in the two lowest orders of the Mammalia. The senses, as a rule, attain great perfection in the Mammals; and the only sense which can ever be said to be entirely wanting is that of sight. Eyes, however, are always present, though they may be rudimentary; and in those Mammals which are said to be "blind," it is not generally that the eyes are wanting, but that the skin passes unbrokenly over the eyeball. Even in these cases, however, it is not impossible that there may be some perception of light through the skin. An external ear for collecting sounds is usually present; but it is wanting in the Whales and Dolphins, and in some of the Seals.

The *skin* is invariably furnished over a greater or less part of its surface with the epidermic appendages known as *hairs*, which differ from feathers chiefly in not splitting up as they are produced. In the Scaly Ant-eater (*Manis*), the hairs are aggregated together so as to form horny scales; and in the Hedgehog, Porcupine, and other animals, many of the hairs are developed into long spines or prickles. In the Armadillos, again, the skin is more or less covered by an armour of bony plates. The only apparent exception to the universal presence of hair on some part or other of the integument of all Mammals is constituted by the true Cetaceans (Whales and Dolphins), many of which are without hair when grown up. Some, however, such as the Whales, have a few bristles in the neighbourhood of the mouth even when adult. And the Dolphins, which are totally hairless when grown up, exhibit tufts of hair upon the muzzle before they are born.

With the exception of the singular Monotremes, which are now known to be oviparous, all Mammals produce their young alive, and the young animal is always born in a helpless condition, and is nourished for a longer or shorter time by means of the milk of the mother. The milk is secreted by special organs, called the *mammary glands*, which are present in both sexes, but are normally undeveloped in the male. The number and position of the mammary vary a good deal in different cases, but they are always placed on the lower surface of the body, and their ducts almost always open upon a special eminence, called the teat or nipple. In the Monotremes, however, the mammary glands open by simple slits in the skin of the abdomen, and not by distinct nipples. In ordinary Mammals the milk is obtained by voluntary suction on the part of

the young, but in the Marsupials (Kangaroos, Opossums, &c.) the milk is forced into the mouth of the young animal by the action of a special muscle.

It will be sufficient for our present purpose to divide the *Mammalia*, in accordance with the way in which the young are developed, into three primary sections—viz., the *Placental Mammals*, the *Non-placental Mammals*, and the *Oviparous Mammals*. In the *Placental Mammals*, not only are the young brought forth alive, but they are nourished within the body of the mother by means of a structure called the *placenta*, through which the nutrient materials of the mother's blood reach the young. In consequence of this, the young of the Placental Mammals can be retained within the body for a considerable period, and when born, they are able to obtain their natural food—the milk—by their own exertions. This section includes all the higher groups of Mammals. In the *Non-placental Mammals*, on the other hand, the young are born alive, but at an extremely early period of their development, before there is any necessity that a placenta should be formed for the nourishment of the foetus. In these cases, therefore, the young, when born, are much more immature and helpless than in the case of the Placental Mammals. So helpless are they, that they are even unable to suck, and have in most cases to be fixed by the mother herself upon the teats, whilst the milk is forced into their mouths by a muscle which is spread over the mammary gland. This section includes only the Marsupials or Pouched Mammals. Lastly, in the *Oviparous Mammals*, the young are not born alive but are produced as eggs, as in the Birds and Reptiles. The young, however, are liberated from the egg at a very early period of their development, and are then nourished by the milk of the mother. This section includes only the Monotrematous Mammals—viz., the Duck-mole (*Ornithorhynchus*) and the Spiny Ant-eater (*Echidna*).

Adopting the above primary sections as practically sufficient in an elementary work, the whole class of the *Mammalia* may be divided into the following fourteen orders:—

DIVISION A.—OVIPAROUS MAMMALS.

Order 1.—*Monotremata*.

DIVISION B.—NON-PLACENTAL MAMMALS.

Order 2.—*Marsupialia*.

DIVISION C.—PLACENTAL MAMMALS.

Order 3.—*Edentata*.

Order 4.—*Sirenia*.

- Order 5.—*Cetacea*.
- Order 6.—*Ungulata*.
- Order 7.—*Dinocerata*.
- Order 8.—*Tillodontia*.
- Order 9.—*Toxodontia*.
- Order 10.—*Hyracoidea*.
- Order 11.—*Proboscidea*.
- Order 12.—*Carnivora*.
- Order 13.—*Rodentia*.
- Order 14.—*Cheiroptera*.
- Order 15.—*Insectivora*.
- Order 16.—*Quadrumana*.
- Order 17.—*Bimana*.

CHAPTER XXXI.

ORDERS OF MAMMALIA.

ORDER I. MONOTREMATA.

THE order of the Monotremes comprises only two very remarkable genera of Mammals—namely, *Ornithorhynchus* (the Duck-moles), and *Echidna* (the Spiny Ant-eaters), which are characterised by the singular combination in their structure of Reptilian or Avian peculiarities with features of a purely Mammalian type. That they are genuine Mammals is shown by their possession of hair, by the presence of mammary glands, by the nature of their red blood-corpuscles, by the structure of the lower jaw, and by the fact that the skull articulates with the vertebral column by two occipital condyles. On the other hand, they resemble the Reptiles or Birds, or both, as regards the termination of the intestine in a cloaca, the structure of the pectoral arch, and the want of true teeth, and in the still more important fact—but lately clearly established—that they produce their young in the form of eggs.

As regards their more important characters, the *Monotremata* are distinguished as follows:—

The alimentary canal terminates, as in Birds and Reptiles, in a dilated “cloaca,” which not only receives the termination of the intestine, but also the ducts of the urinary and reproductive organs. The skull has the bones so amalgamated in the adult that the majority of the sutures are obliterated, as occurs also in Birds. There are no true teeth; but in *Ornithorhynchus* the jaws carry horny plates (fig. 226, B and C), which act as teeth. The pectoral arch, which supports the fore-limbs, resembles that of Birds in several respects, but especially in the fact that the coracoid bones are distinct, and are not amalgamated with the shoulder-blade. There is no complete pouch developed on the abdomen of the females, but there are the so-called “marsupial bones.” These are two small bones which arise from the front of the pelvis. They are really to be regarded as formed by a conversion into bone of the tendons of

one of the muscles of the abdomen. There are no external ears. The mammary glands have no nipples, but open either on a flat surface (*Ornithorhynchus*), or into a small "mammary pouch" (*Echidna*). It has recently been shown by Mr Caldwell that the Monotremes are not viviparous, as all other Mammals are, but that they resemble the Reptiles and Birds in being oviparous. The Duck-mole lays two eggs—about three-quarters of an inch in length—which it deposits in the burrow in which it lives; and the *Echidna* lays one such egg, which it is stated to place in the small pouch of skin surrounding the openings of the mammary glands. Recent observations also show that the Monotremes further resemble the Reptiles in the fact that

Fig. 226.—A, Skull of *Echidna hystrix*. B, Side view of the skull of *Ornithorhynchus paradoxus*, and C, lower jaw of the same, viewed from above, showing the horny dental plates (*m*).

the temperature of the body is much below that of the remaining types of the Mammals.

Of the two living genera of Monotremes, the Duck-mole (*Ornithorhynchus*) is found exclusively in Australia inhabiting streams and ponds, in the banks of which it constructs burrows forty or fifty feet in length. The body is like that of a small Otter, covered with a short brown fur, and having a broad flattened tail (fig. 227). The jaws have no teeth, but carry horny plates, which officiate as teeth (fig. 226, B and C). The margins of the jaw are also sheathed in horn, forming a kind of flattened beak, very like that of a Duck (fig. 227). Hence the name of "Duck-billed Animal" sometimes given to the *Ornithorhynchus*. The feet are webbed, and the males

have a spur on the hind-legs. The only known species is the *Ornithorhynchus paradoxus*.

The other genus of Monotremes comprises the Spiny Ant-eaters (*Echidna* or *Tachyglossus*), which are not unlike large hedgehogs in appearance. The snout is very long, and is enclosed in a continuous skin till close upon its extremity, where there is a small aperture for the protrusion of a long and flexible tongue. There are no teeth, or any organs to act as teeth. The feet have five toes each, and are

Fig. 227. - Monotremata. *Ornithorhynchus paradoxus*, Australia.

furnished with strong digging-claws, but the toes are not webbed. The skin is covered with strong prickly spines interspersed with bristly hair. The common Australian species (*Echidna hystrix*) measures from fifteen to eighteen inches in length, and is a nocturnal animal. It lives in burrows, and feeds upon insects, which it captures by protruding its long sticky tongue. Another species is found in Tasmania; and two species are known to occur in New Guinea.

ORDER II. MARSUPIALIA.

The name of *Marsupials* is derived from the fact that the females of this order are furnished with an abdominal pouch or *marsupium* (sometimes very imperfect), within which the nipples are situated. When born, the young are placed by the mother within this pouch, where they adhere to the teats, and can be carried about without injury. Even when further advanced, the young often betake themselves to the shelter of the marsupium. No placenta is present, and the young when born are therefore in a very imperfectly developed state. The so-called "marsupial bones" (fig. 228) are present, and

as they spring from the front of the pelvis they no doubt serve to support the pouch; but this cannot be their sole use, as they exist in the males, and also in the Montremes, in whom there is no pouch. All Marsupials possess teeth, and the pectoral arch has now the same form as in the higher Mammals, the coracoid bones being now amalgamated with the shoulder-blade. The cranial bones are distinct. The intestine does not terminate in a cloaca.

Though the *Marsupialia* form an extremely natural order, sharply separated from the other Mammals, they include a large number of varied forms. In fact, this order, from its being the almost exclusive possessor of a continent so large as Australia, has to discharge, in the general economy of nature, functions which are elsewhere performed by several orders. As regards their geographical distribution, with the single excep-

Fig. 228.—One side of the pelvis of a Kangaroo, showing the "marsupial bones" (*m*) after Owen.

tion of the family *Didelphide* (the true Opossums), the whole order of the Marsupials is exclusively confined to Australia, Van Diemen's Land, New Guinea, and the adjacent islands.

The Marsupials may be primarily divided into the vegetable-eating and the rapacious or carnivorous forms—the former characterised by the absence or rudimentary condition of the canine teeth, the molars having broad, grinding crowns; whilst in the latter there are well-developed canines, and the molars are not adapted for grinding. Of the vegetable-eating forms, the best known are the Kangaroos (*Mac-*

ropodidae), distinguished by the remarkable disproportion between the hind and fore limbs, the former being by far the longest and strongest. By their long hind-legs, assisted by a powerful tail, the Kangaroos can perform astonishing jumps, and, in fact, leaping is their mode of progression when pursued.

The typical Kangaroos live on the great grassy plains of Australia; but the Tree Kangaroos spend a great part of their time in trees, and the Rock Kangaroos affect mountainous districts. The Kangaroo-bear or Native Sloth (*Phascogaleos cinereus*), has no tail, and has the body covered with a short, dense fur, whilst the ears are tufted. The fore-feet can be used as hands, and the toes are all

Fig. 229.—The female of *Didelphys dorsigera*, one of the South American Opossums, carrying its young upon its back.

furnished with strong curved claws. It is a harmless nocturnal animal, and spends most of its existence in trees. The typical group, however, of the vegetable-eating Marsupials is that of the Phalangiers, comprising a large number of small animals which live in trees, and generally possess a prehensile tail. The most familiar example is the Australian "Opossum" (*Phalangista vulpina*), which is largely hunted by the natives. In the so-called "flying" Phalangiers, again, the tail is not prehensile, and the animal takes extensive leaps from tree to tree, by means of a fold of skin which stretches between the body and the fore and hind limbs.

Of the carnivorous Marsupials, the Bandicoots (*Perameles*), the Native Devil (*Dasyurus*), the Native Tiger (*Thylacinus*), and the

American Opossums (*Didelphidæ*), may be mentioned. The Bandicoots are little, rabbit-like Australian animals, which live upon insects, and seem to fill the place held in the Old World by the Hedgehogs and the Shrew-mice. The species of *Dasyurus*, though of small size, are very ferocious; and the Thylaciné grows to the size of a shepherd's dog, and is quite capable of destroying animals as big as sheep. About twenty species of *Didelphidæ* are known, and they are all exclusively confined to the American continent. They are all of small size, have prehensile tails, and mostly live among trees. The best-known species is the Virginian Opossum (*Didelphys Virginiana*). Another species of Opossum, the *Didelphys dorsigera* (fig. 229), carries its young about on its back, the young clinging to the mother by twining their prehensile tails round hers.

ORDER III. EDENTATA OR BRUTA.

This order of Placental Mammals comprises the Ant-eaters, Armadillos, and Sloths, and is characterised by the fact that the teeth are not covered with enamel, have no complete roots, and are never re-

Fig. 230.—A, Side-view of the skull of *Bradypus cuculliger*; B, Side-view of the skull of *Dasyurus gigas*. (After Giebel.)

placed by a second set. As a rule, the teeth (fig. 230) are simple cylinders, placed at a little distance from each other. Further, in none of the *Edentates* are there any central incisor teeth, and in all

but one there are no incisors at all. In two genera only are there no teeth ; so that the name *Edentata* is not a very appropriate one. In all, the toes are furnished with long and powerful claws.

The order *Edentata* is conveniently divided into two great sections, in accordance with the nature of the food, the one section being herbivorous, the other insectivorous. In the former section is the single group of the Sloths (*Bradypodidae*). In the latter are the two groups of the Armadillos (*Dasypodidae*) and the various species of Ant-eaters.

The Sloths (*Bradypodidae*) are exclusively confined to South America, inhabiting the vast primeval forests of this continent.

Fig. 231.—The Three-banded Armadillo (*Tolypeutes conurus*), one-third of the natural size. (After Murie.)

They are in every way adapted for an arboreal life, and are “destined to be produced, to live, and to die on trees.” They are very awkward when upon the ground ; but the feet are furnished with extremely long curved claws, so that the animal is enabled to move about freely suspended back downwards from the branches of the trees.

The second family of the *Edentata* is that of the *Dasypodidae* or Armadillos. These are also found exclusively in South America, but they are very different in their habits. The Armadillos (fig. 231) are burrowing animals, furnished with strong digging-claws

and well-developed collar-bones. The jaws are provided with numerous simple molars (fig. 230, B), which attain the enormous number of nearly one hundred in the Great Armadillo (*Dasypus gigas*). The upper surface of the body is covered with a coat of mail, formed of hard bony plates or shields united at their edges. A portion of this armour covers the head and shoulders, and another portion protects the hind-quarters; whilst between these is generally a variable number of movable bands which run transversely across the body and give the necessary flexibility to this singular integumentary skeleton. In most species this flexibility is so great that the animal can roll itself up like a hedgehog.

The remaining South American Edentates are the Hairy Ant-eaters, of which the best known is the Great Ant-eater (*Myrmeco-*

Fig. 232.—*Manis pentadactyla*, one of the Scaly Ant-eaters or Pangolins, showing the armour of horny plates.

phaga jubata). The body in this family is covered with hair, the tail is long, and the teeth are altogether wanting. They feed chiefly upon ants and termites, which they catch by protruding their long and sticky tongues, having previously broken into the nest by means of their strong curved claws.

The *Edentata* are represented in the Old World by only two genera. One of these is the genus *Manis*, comprising the Scaly Ant-eaters or Pangolins, which are exclusively confined to Asia and Africa. In these singular animals (fig. 232) the body and tail are covered by a flexible armour, composed of horny plates or scales overlapping like the tiles of a roof. The other genus is *Orycteropus*, comprising only the so-called Ground Hog of South Africa; which also lives upon insects, and burrows by means of its strong digging-claws.

As regards the geographical distribution of the *Edentata*, it is to be remembered that the order has a very limited range at the present day. The true Ant-eaters, the Armadillos, and the Sloths, are exclusively confined to South America, in which country a group of gigantic extinct Edentates existed in the later portion of the Tertiary epoch. The Scaly Ant-eaters are common to Asia and Africa; and the Ground Hog is confined to South Africa.

ORDER IV. SIRENIA.

This order comprises only certain large marine Mammals, known as Dugongs and Manatees, which were long classed with the Whales and Dolphins (*Cetacea*). They agree with the Whales in the adaptation of the body to an aquatic life, especially in the facts that the anterior limbs are converted into swimming-paddles (figs. 233, 234), the hind-limbs are wholly wanting, and the hinder end of the body

Fig. 233.—A, Side-view of young *Manatus Americanus*. B, the same viewed from above; n Nostrils. (After Murie.)

forms a powerful caudal fin, which is placed so as to strike the water horizontally, and not vertically as in Fishes. They differ from the *Cetacea* in having the nostrils placed at the anterior part of the head, and in having molar teeth with flat crowns, adapted for a vegetable diet. Fleshy lips are present, the upper one usually with a moustache, and the skin is covered with scanty bristles. The head is not disproportionately large as compared with the

body, and there is a tolerably distinct neck. They are vegetable-eaters, feeding chiefly upon sea-weeds, and haunting the mouths of rivers and estuaries, and sometimes ranging hundreds of miles inland.

The only existing *Sirenia* are the Manatees (*Manatus*) and the Dugongs (*Halicornis*), often called "Sea-cows." The Manatees (fig. 233) are found on the east coast of America and on the west coast of Africa. They are large awkward animals, attaining a length of from eight to ten or fifteen feet, and their flesh is said to be very palatable and wholesome. The Dugongs differ little in appearance and habits from the Manatees. They are found on the coasts of the

Fig. 234.—*Sirenia*. Skeleton of the Manatee (*Manatus Americanus*).

Indian Ocean and the north coast of Australia, and are often killed and eaten. They attain a length of from eighteen to twenty feet. The bones of the skeleton are remarkable for their extreme hardness and density.

Besides these living forms, the *Sirenia* were represented by a gigantic species which formerly inhabited Behring Island on the coast of Kamtchatka. This animal was described by M. Steller who accompanied Behring on his second expedition, and he named it *Rhytina*. This enormous animal attained a length of twenty-five feet, and a circumference of twenty feet, and it appears to have been completely exterminated, no specimen having been seen for more than a century.

ORDER V. CETACEA.

This order comprises the Whales, Dolphins, and Porpoises, and it is characterised by the complete adaptation of its members to a watery life. The body (fig. 235) is completely fish-like in form, the fore-limbs are converted into swimming paddles, and the hind-limbs are completely wanting; whilst the hinder end of the body forms an extremely powerful, horizontal caudal fin. Sometimes

there is a dorsal fin as well. The nostrils may be single or double, but always are placed on the top of the head, constituting the "blow-hole." The body is very sparingly furnished with hairs, or is wholly without them in the adult. The head is generally of disproportionately large size as compared with the body, and is rarely separable from the trunk by any distinct constriction or neck. There is no sacrum; the pelvis is only represented in a rudimentary form; and the hind-limbs are either wholly wanting, or are present only as rudiments, concealed within the muscles. Lastly, the adult is either wholly destitute of teeth, or possesses only a single set, which are always conical in shape, and are never divisible into distinct groups. All the true *Cetacea* are carnivorous, living upon animal food.

Chief amongst the Cetaceans in importance and zoological interest

Fig. 235. Spermaceti Whale (*Physeter macrocephalus*).

are the Whalebone Whales (*Balenida*), in which the adult is destitute of teeth, though the young Whale possesses teeth which never cut the gum. The place of teeth is taken by a series of transverse plates of whalebone or *baleen*, which are used as a kind of screening apparatus or filter to separate from the sea-water the minute Molluscs and Jelly-fishes upon which these enormous animals live. The most important member of this family, from a commercial point of view, is the Greenland Whale (*Balena mysticetus*), which yields most of the whale-oil and whalebone of commerce. The Greenland Whale attains a length of from forty to sixty feet, and of this enormous length about a third is taken up by the head alone. The oil is derived from a thick layer of fat or "blubber," which is situated

under the skin, and serves to protect the body from cold. Though an inhabitant of the sea, the Whale is obliged to come to the surface to breathe, and in so doing it ejects from the blow-hole what looks like a column of water, the whole operation being known to the whalers as "blowing." The true nature of this act is now hardly questionable, and it appears certain that the apparent jet of water is in reality, mainly if not entirely, due to the condensation of the moisture which is contained in the air expelled from the lungs. The old view was that "blowing" consisted in the Whale ejecting through the nose the water which had previously been filtered through the baleen-plates of the mouth; but it appears to be quite certain that this view, at any rate, is not the correct one. The Rorquals or Finner Whales resemble the Greenland Whale in most respects, but the skin is furrowed with deep plaits or folds, and there is a dorsal fin, placed on the back. Some of these attain a gigantic

Fig. 236.—Cetacea. The common Dolphin (*Delphinus delphis*).

size (eighty feet or more), but they are seldom captured, as their commercial value is small.

The Toothed Whales (*Odontoceti*) are best known by the Sperm Whale (fig. 235), an animal as large or larger than the Greenland Whale, but distinguished by having numerous conical teeth, a single blow-hole, and a curiously truncated head. Sperm Whales yield an excellent oil, and the singular fatty substance which is known as "spermaceti." They also yield the substance called "ambergris," which is used as a perfume; but this is probably a product of disease.

The last family of the *Cetacea* needing mention is that of the *Delphinidae*, comprising the Dolphins (fig. 236) and Porpoises. They have numerous conical teeth in both jaws, and the nostrils open by a single aperture on the top of the head. The Dolphins are mostly inhabitants of the sea, but there are fresh-water forms which inhabit the rivers of South America and Southern Asia. The Porpoises are exclusively marine, and occur in all seas. The most remarkable of the *Delphinidae* is the Narwhal or Sea-unicorn, which is found in

the Arctic seas, and which attains a length of as much as fifteen feet in the body alone. The chief peculiarity of the Narwhal is in the dentition. The females, as a rule, have no front teeth, the upper jaw alone having two rudimentary canines which never cut the gum. In the males, however, whilst the lower jaw is without teeth, one of the two canines of the upper jaw (the left one) is enormously developed, and grows throughout the life of the animal. It forms a tusk of from eight to ten feet in length, the whole surface of which is spirally twisted. The function of this extraordinary tooth is doubtless offensive.

ORDER VI. UNGULATA.

This order is often spoken of as that of the Hoofed Quadrupeds, and is one of the largest and most important of the orders of Mammalia. The order is characterised by having all the four limbs, and by having that portion of the toe which touches the ground encased in a greatly expanded nail or *hoof*. There are never more than four full-sized toes to each leg, and owing to the presence of hoofs the limbs are useless for grasping, and are only of use in locomotion and in supporting the weight of the body. There are always two sets of teeth, and the molars have broad crowns adapted for grinding vegetable substances.

The *Ungulata* are divided into two great primary sections, according as the toes are even or odd in number :—

A. Perissodactyla, or Odd-toed Ungulates, in which the toes are odd in number—either one or three.¹ If horns are present, they are not in pairs (in any living form).

B. Artiodactyla, or Even-toed Ungulates, in which the toes are even in number—either two or four; and if horns are present, they are in pairs.

Section A. Perissodactyla.—The living Perissodactyle Ungulates are the Rhinoceros, the Tapirs, and the Horse and its allies. The *Rhinoceroses* are extremely large and bulky brutes, having a very thick and nearly hairless skin, usually thrown into deep folds. The feet (fig. 237, B) are furnished with *three* toes each, all encased in hoofs. The nose (fig. 238) is furnished with one or two horns, composed of longitudinal fibres compacted together, and not having any central core of bone. When there is only one horn, it is, of course, unsymmetrical; and when there are two, these are not paired, but (except

¹ The fore-feet of the Tapirs are even-toed, but the hind-feet are perissodactyle; and in some extinct types we find five toes to the foot.

in some fossil forms) one is always placed behind the other in the middle line of the head, and the hinder one is much the shortest. The various species of Rhinoceros are found in India, Java, Suma-

Fig. 238.—Head of two-horned Rhinoceros (*R. bicornis*).

tra, and Africa, inhabiting marshy places, and feeding chiefly on the foliage of trees.

The Tapirs (*Tapiridae*) have four toes to each of the fore-legs, but

only *three* toes on the hind-legs, so that they are really odd-toed. The nose forms a short movable proboscis, used in stripping off the leaves of trees. They are large, clumsy, pig-like animals, which inhabit South America, Sumatra, Borneo, and Malacca.

The third and last family of the living Perissodactyle Ungulates is that of the *Equidae*, comprising the Horses, Asses, Zebras, and Quaggas. In this family, so far as existing types are concerned, the foot carries only a single toe (the third toe), which is furnished with a broad hoof (fig. 223). Upon the end of this toe the animal walks, and the *Equide* are, therefore, often spoken of as "Solipedes." The second and fourth toes are present in a rudimentary form as little bony splints (the so-called "splint-bones"), hidden under the skin (fig. 223); but in certain extinct types these lateral toes are more or less developed, and carried hoofs, the foot thus becoming three-toed.

There is a continuous series of incisor teeth in both jaws, and in the males canines are present. The dental formula is—

$$i \begin{array}{c} 3-3 \\ 3-3 \end{array}; c \begin{array}{c} 1-1 \\ 1-1 \end{array} \text{ (or none) }; pm \begin{array}{c} 3-3 \\ 3-3 \end{array}; m \begin{array}{c} 3-3 \\ 3-3 \end{array} = 40.$$

All the domestic varieties of Horses appear to be descended from the single species *Equus caballus*, which seems to have been primitively a native of Central Asia, in which country another species of Horse has been recently discovered. When the American continent was discovered, it certainly possessed no living horse, but the Horse has now become completely naturalised there, and we know that America formerly possessed about twenty species of Horses, all of which are now extinct. In the genus *Asinus* are the Asses, Zebras, and Quaggas. The Wild Asses are natives of Asia and North Africa; but it is not quite certain from what species the domestic Ass is descended. The Zebras and Quaggas are exclusively African, and are distinguished by their beautifully striped and banded bodies.

Section B. Artiodactyla.—The Even-toed Ungulates may be divided into the two groups of the *Omnivora* and the *Ruminantia*, the former comprising the Hippopotamuses and the Swine, while the latter includes the Oxen, Deer, Camels, &c.

Of the Omnivorous Artiodactyles, the Hippopotamuses constitute a small group, comprising massive, thick-skinned Ungulates, with four-toed feet. The common *Hippopotamus amphibius* inhabits all the great rivers of Africa, living upon plants, and swimming and diving with great facility. The molar teeth have flat crowns, of a peculiar double-trefoil pattern; but the canines are very large, and the lower ones in particular form enormous tusks, with a chisel-

shaped edge (fig. 239), and these are the principal weapons by which the animal defends itself.

The Pigs, Peccaries, and Wart-hogs constitute the family *Suidæ*, and have usually four toes to each foot, though sometimes the hind-feet have only three toes. All the toes are hoofed, but it is only two which support the weight of the body, the remaining toe or toes being placed at some elevation on the back of the foot (fig. 237,

Fig. 239.—Skull of *Hippopotamus amphibius*, side-view.

C). The snout is truncated and cylindrical, and is capable of extensive movement. The tail is very short, or is represented only by a tubercle. The molar and præmolar teeth have tuberculated crowns (fig. 240), and the Pigs are very miscellaneous feeders.

Of the Swine the most important and best known is the Wild Boar (*Sus scrofa*), from which most of our domestic varieties of Swine have sprung. Another form is the Babyroussa (*Sus baby-*

Fig. 240.—Grinding surface of the molar and præmolar teeth of a Peccary (*Dicotyles labiatus*). (After Giebel.)

rusa), which inhabits the Indian Archipelago, and is remarkable for the great size and backward curvature of the upper canine teeth. The Wart-hogs (*Phacochærus*) are African, and derive their name from the possession of a fleshy wart under each eye. The Peccaries are exclusively American, the best-known species being the Collared Peccary (*Dicotyles torquatus*). They are not at all unlike small pigs both in appearance and habits, but they present various striking

anatomical peculiarities, which distinguish them from the Swine of the Old World.

The *Ruminantia* form a most natural group of the *Ungulata*, characterised by the structure of the foot, the dentition, and the structure of the stomach.

The *foot* is "cloven," consisting of a symmetrical pair of toes, encased in hoofs, and looking as if produced by the cleavage of a single hoof. The two functional toes (fig. 222) are the third and fourth toes (the middle and ring toes); but the second and fifth toes (the index and little toe) may be present in a rudimentary form on

Fig. 241.—Skull of a hornless Sheep: *i* Incisors; *c* Canines; *m* Molars and præmolars. (After Cuvier.)

the back of the foot. In no case, however, are these lateral toes so far developed as to touch the ground in walking on a hard surface.

As regards the *dentition*, the typical state of things is that there should be no incisor or canine teeth in the upper jaw (fig. 241), but that the lower jaw should have six incisors and two canines, which are all similar in size and form, and constitute a continuous and un-interrupted series of *eight* teeth placed in the front of the lower jaw. There are six back teeth (præmolars and molars) on each side of each jaw, and these have grinding surfaces, the enamel ridges of which form double crescents. The typical dental formula, therefore, for a Ruminant is—

$$\begin{array}{c} i \ 0-0 \\ 3-3 \end{array}; \begin{array}{c} c \ 0-0 \\ 1-1 \end{array}; \begin{array}{c} pm \ 3-3 \\ 3-3 \end{array}; \begin{array}{c} m \ 3-3 \\ 3-3 \end{array} = 32.$$

In the absence of incisor teeth in the upper jaw, the lower incisors bite against a callous pad of hardened gum. The Camel tribe differs in its dentition from the above typical formula, and certain exceptions likewise occur in the males of some other forms, and in one or two other less important instances.

The *stomach* in the Ruminants is complex, and is divided into several compartments, this being in accordance with their mode of eating. They all, namely, "ruminate" or "chew the cud"; that is to say, they first swallow their food unmasticated, and then bring it up again after a longer or shorter period in order to chew it. This is effected as follows (fig. 242): The gullet opens at a point between the first two compartments or stomachs, of which the largest lies to the left and is called the "paunch," whilst the smaller right cavity is called the "honeycomb bag" (*reticulum*). The paunch (*rumen*) is

Fig. 242.—Stomach of a Sheep. *o* Gullet; *r* *Rumen* or paunch; *h* *Honeycomb bag* or *reticulum*; *p* *Many-plies* or *psalterium*; *a* *Abomasum* or fourth stomach.

the cavity into which the food is first received, and here it is moistened and allowed to soak for some time. After the food has lain sufficiently long in the paunch, it passes into the "honeycomb bag," from which it is ultimately returned in successive portions to the mouth by a reversed action of the muscles of the gullet. After having been thoroughly chewed, and prepared for digestion, the food is now swallowed a second time. On this occasion, however, instead of passing into the paunch, the masticated food is conveyed into the third stomach. This is known as the "many-plies" or "*psalterium*," because its lining membrane is thrown into a number of longitudinal folds, like the leaves of a book. The *psalterium* opens by a wide aperture into the fourth and last stomach, known as the "*abomasum*." This is a cavity of considerable size, which secretes the true digestive fluid (gastric juice), and it is here that the food is really digested.

The abomasum terminates, of course, in the commencement of the small intestine.

The *Ruminantia* include a number of families of which it is only possible to notice the leading characters.

The family *Camelidæ* comprises the Camel and Dromedary of the Old World and the Llamas of the New, and is characterised by having no horns, by having two incisors in the upper jaw, and a pair of canines in both jaws; whilst the first præmolar tooth in both jaws (or in the upper jaw only) is conical in shape, and is placed at some distance in front of the other back teeth (fig. 243). The foot consists of only two toes, covered with imperfect nail-like hoofs, and destitute of the two supplementary toes. The soles of the feet are covered with a callous horny integument upon which the animal walks. In the Camels the toes are conjoined below by a callous pad, and the back is furnished with one or two fleshy

Fig. 243.—Side-view of skull of *Camelus Bactrianus*: *i* Upper incisor; *c c* Canines; *pm* Isolated præmolar. (After Giebel.)

humps. The Arabian Camel or Dromedary has but one hump, and its structure admirably adapts it for a beast of burden in the sandy deserts of Arabia and Africa. One special provision toward this end is the possession of large cells in the paunch, in which a great quantity of water can be stored up, thus enabling the animal to travel for days without drinking. The Bactrian Camel resembles the Dromedary in most respects, but it possesses two humps. The place of the Camels of the Old World is filled in South America by the Llamas and Alpacas (*Luchenia*), which have separate toes, and have no hump. The Llama is extensively used as a beast of burden, but the Alpaca is chiefly of value for its long wool, which is largely manufactured.

The small family of the *Tragulidæ* includes the little deer-like animals which are known as "Chevrotains. These are very like the true Musk-deer (which are now placed with the *Cervidæ*), and have

no horns, while the canine teeth are developed in both jaws, and the upper canines of the males are tusk-like. The *Tragulidæ* are found in India, the Indian Archipelago, and Africa.

The family *Cervidæ* includes the true Deer and the Musk-deer, and is characterised by the fact that the forehead carries two solid bony antlers, which are not hollow, and are usually much branched (fig. 244). With the single exception of the Reindeer, these appendages are exclusively confined to the males, and are *deciduous*; that is to say, they are only produced at certain seasons (annually, at the breeding season), and they are shed and reproduced before the commencement of the next breeding season. They increase in size and in the number of branches every time they are reproduced till in the old males they may attain an enormous size.

Fig. 244.—Side-view of the skull of the Roe buck (*Capreolus caprea*).
(After Giebel.)

Among the more familiar of the Deer may be mentioned the Elk, or Moose (*Alces Americanus*) of Scandinavia and North America; the Reindeer and Caribou (*Cervus tarandus*) of Northern Europe, Asia, and North America; the Red Deer (*Cervus elaphus*) of Europe; the Wapiti (*C. Canadensis*) of Canada; and the Roe buck (*Capreolus caprea*) of Northern Europe.

Of the Giraffes or *Camelopardalidæ* there is only a single living form, exclusively confined to the African continent. Both sexes have two pairs of short horns, carried on the forehead; but these are persistent, and are covered with a hairy skin. The neck is extremely long, and the fore-legs much longer than the hind-legs. It is the largest of living Ruminants, and measures as much as from fifteen to eighteen feet in height.

The *Cavicornia* or *Hollow-horned* Ruminants comprise the Oxen,

Sheep, Goats, and Antelopes, and are characterised by having horns, which may be present in one or both sexes, and consist of a horny sheath surrounding a central bony axis, or "horn-core" (fig. 245). The horns are persistent, and are not periodically shed, and there is usually only a single pair, though sometimes there are two pairs. In the Prong-buck Antelope alone, the horny sheath which surrounds the horn-core is annually shed and reproduced. In their dentition, and in other respects, the *Cavicornia* are to be regarded as being the most typical examples of the *Ruminantia*, and they include a number of animals which are of the highest utility to man.

Fig. 245.—Skull of the Cape Buffalo (*Bubalus caffer*), viewed from above, showing the horn-cores. (After Cuvier.)

The Antelopes form a very extensive group, closely resembling the true Deer, but distinguished by the possession of *hollow* horns, in place of *solid* antlers. Most of the Antelopes are African, and there are only two European forms (the Chamois being one), while America possesses only the Prong-buck (*Antilocapra furcifer*). Among the more familiar African species may be mentioned the Koodoo (fig. 246), the Gnu, the Gemsbok, and the Springbok. The Sheep and the Goats (*Ovinae*) are closely allied to one another, and are well known by their domestic varieties. All the Sheep are natives of the Old World, with the exception of the "Big-horn" (*Ovis montana*) of the Rocky Mountains. Among the true Oxen

(*Bovidae*) the most important species is the domestic Ox (*Bos taurus*) with its innumerable varieties. The true Buffalos (*Bubalus*) are natives of Asia and Africa, and are characterised by their wide horns united at the base (fig. 245). The American Buffalo (*Bison Americanus*), or Bison as it is properly called, is distinguished by its

Fig. 246.—Antelopidæ. Head of the Koodoo (*Strepsiceros Koodoo*).

enormous head, shaggy mane, and conical hump between the shoulders. America also possesses another singular Ox (or Sheep) in the person of the Musk Ox (*Ovibos moschatus*), which is found north of the 60th parallel, and is remarkable for its small size and long woolly coat.

ORDER VII. DINOCERATA.

This order comprises only some extraordinary extinct animals found in the Tertiary deposits (Eocene) of North America. In *Dinoceras*, which may be taken as the type of the group, we have an animal of large size, resembling the Elephants in most of the details of the skeleton, with five well-developed toes on the fore-feet, and with four functional toes on the hind-feet, the hallux being rudimentary. No trunk or "proboscis" was present, but there are three pairs of bony processes, or "cores," which seem to have carried as many horny protuberances, one pair being on the nasal bones, another on the upper jaws, and the third (the largest) on the frontal bones. The upper jaw is without incisors, but carries huge tusk-like canines; and a series of six small præmolars and molars is present on each side. In the lower jaw are six incisors, small canines, and a corresponding series of præmolars and molars.

ORDER VIII. TILLODONTIA.

This is another extinct order of Mammalia, comprising some singular fossil quadrupeds from the Tertiary deposits (Eocene) of North America. The animals included in this order resemble the Beasts of Prey (*Carnivora*) most

closely as regards the general structure of the skeleton, and especially as to the conformation of the feet; but they possess also characters which ally them to the *Ungulata* and to the *Rodentia*. One of the most striking characters is the presence in the front of each jaw of a pair of huge incisor teeth, which resemble the corresponding teeth of the Rodent animals in having chisel-shaped crowns, and in growing throughout the life of the animal.

ORDER IX. TOXODONTIA.

This is a third extinct order of Mammals, comprising certain large fossil quadrupeds from the later Tertiary deposits of South America, the true relationships of which are quite uncertain. The molar and premolar teeth have flat grinding crowns, but they grow from permanent pulps, and continue growing throughout the life of the animal—a feature specially characteristic of many Rodents. The incisors resemble those of the Ungulates generally, and the canines are small, and in the upper jaw are deciduous.

ORDER X. HYRACOIDEA.

This order includes only a single small genus (*Hyrax*), of which only two or three species are known. They are all gregarious little animals, mostly living in holes of the rocks, and capable of domestication. One species (*Hyrax Capensis*) occurs commonly in South Africa, and is known to the Dutch colonists as the “Badger.” Another species (*Hyrax Syriacus*) occurs in the rocky parts of Arabia and Palestine, and is believed to be the “coney” of Scripture. They present many curious points of resemblance to the gigantic Rhinoceros, and are often placed in the same order, the similarity being especially great as regards the form of the molar teeth. The incisor teeth of the upper jaw are long and curved, with sharp cutting edges, and they grow from a permanent pulp, thus resembling the teeth of the genuine Rodents (such as the Rabbit or Beaver).

ORDER XI. PROBOSCIDEA.

The only living animals which belong to the order of the Proboscideans are the Elephants, of which there are only two well-marked existing species—namely, the Indian Elephant and the African Elephant. The name of the order is derived from the fact that the nose is prolonged into a long cylindrical trunk, or “proboscis,” which is highly muscular, and which terminates in a finger-shaped lobe, below which are placed the apertures of the nostrils (fig. 247). The proboscis is the sole organ of prehension possessed by the animal, and is employed to take up water, and also to introduce into the mouth the vegetable substances upon which the Elephant feeds. The Elephants, in fact,

are unable to apply the mouth directly to the ground, either for feeding or for drinking, owing to the peculiar form of the incisor teeth. The upper incisors of the Elephants, namely, are two in number, and constitute long tusks, which grow throughout the entire life of the animal, and which in old individuals may reach a length of six or seven feet (fig. 247). There are no lower incisor teeth, and canine teeth are wanting in both the upper and lower jaws. Each jaw, however, usually exhibits a pair of exceedingly large molar teeth (fig. 248), which are transversely ridged, and which are

Fig. 247.—Skull of the Indian Elephant (*Elephas Indicus*). *i* Tusk-like upper incisors; *m* Lower jaw, with grinding molars, but without incisors; *n* Nostrils, placed at the extremity of the proboscis.

used in triturating the foliage or herbage on which the animal feeds. The entire structure of the Elephant is exceedingly massive, and the skin is thick, and sparingly furnished with hair. The feet have five toes each, but all the toes do not carry hoofs, and the animal walks upon a thick pad of horny skin, which forms the lower end of each foot.

The recent Elephants are exclusively confined to the tropical regions of the Old World, in the forests of which they live in herds. Only two living species are known—the Asiatic Elephant (*Elephas Indicus*) and the African Elephant (*E. Africanus*). There can be no

doubt, however, but that the Mammoth (*Elephas primigenius*) existed in Europe within the human period.

The Indian Elephant inhabits India and the Indian Archipelago, and has five hoofs on the fore-feet, but only four on the hind-feet. Like the Ceylon Elephant, which is a mere variety, the males alone possess well-developed tusks. The African Elephant has four hoofs on the fore-feet, and only three on the hind-feet, while it is smaller and darker in colour than the Indian species. Both sexes also possess tusks, though those of the males are largest.

Besides many extinct forms of Elephants, there formerly existed

Fig. 248.—Lower jaw of the Indian Elephant (*Elephas Indicus*) viewed from above, showing the molar teeth. Greatly reduced in size.

Elephantine animals belonging to two allied genera—viz., *Deinotherium* and *Mastodon*. In the *Mastodons* the whole structure of the animal was closely similar to that of the Elephants; but the molar teeth had tubercular and not ridged crowns; and there were sometime two tusk-like lower incisors in addition to the regular upper tusks. In *Deinotherium*, on the other hand, there were no tusks in the upper jaw; but there were two tusk-like incisors in the lower jaw, the front of which was abruptly bent, so that the tusks pointed vertically downwards.

ORDER XII. CARNIVORA.

The twelfth order of Mammals is that of the *Carnivora* or Beasts of Prey, comprising the Lions, Tigers, Wolves, Dogs, Cats, Hyænas, Seals, Walruses, &c. The *Carnivora* are distinguished by possessing two sets of teeth, which are simply enamelled, and are always of three kinds, incisors, canines, and molars, differing from one another in size and shape. The incisor teeth are generally six in each jaw; the canines are always two in each jaw, and are much longer and larger than the other teeth. The præmolars and molars are mostly cutting teeth, furnished with sharp uneven edges, but one or more of the hinder teeth have tuberculate crowns. The molars, too, graduate from a cutting to a tuberculate form as the diet is strictly carnivorous or becomes more or less miscellaneous.

The dentition (fig. 249) differs considerably in different members of the order, but subjoined is the dental formula of the Cats (*Felidæ*), which are the most typical examples of the *Carnivora*—

$$i \begin{array}{c} 3-3 \\ 3-3 \end{array}; c \begin{array}{c} 1-1 \\ 1-1 \end{array}; pm \begin{array}{c} 3-3 \\ 2-2 \end{array}; m \begin{array}{c} 1-1 \\ 1-1 \end{array} = 30.$$

Fig. 249.—Permanent dentition of the Lion (*Felis leo*). In the upper jaw the letter p^3 indicates the upper carnassial, while in the lower jaw the letter m indicates the lower carnassial.

In the typical and most highly specialised *Carnivores* (such as the *Felidæ*), the last præmolar in the upper jaw, and the first molar in the lower jaw (fig. 249, pm^3 and m) are specially developed, and are known as the “carnassial” teeth, having a sharp cutting-edge; whereas in other cases the corresponding teeth are blunt and “tuberculated.” Even in their most trenchant condition, the carnassial tooth commonly has a more or less developed tuberculated process

or heel, on the inside of its cutting edge. In various Carnivores a number, or all, of the præmolars and molars may be "tuberculate," their crowns being adapted for bruising rather than cutting. As a general rule, the shorter the jaw, and the fewer the præmolars and molars, the more carnivorous is the animal. The jaws are so articulated as to admit of vertical but not of horizontal movements; and the sharp-edged back-teeth are thus enabled to act like the blades of a pair of scissors.

Besides the strictly flesh-eating dentition of the *Carnivora*, the order is distinguished by always having the feet provided with strong curved claws; and the collar-bones (*clavicles*) are either quite rudimentary, or are altogether absent. The *Carnivora* are divided into the following three sections, founded upon the nature of the limbs:—

1. *Pinnigrada* (fig. 250, B), in which both the fore and hind legs are short, and the feet form broad, webbed, swimming-paddles. The hind-feet are placed very far back, nearly in a line with the axis of the body, and they form with the hinder end of the body a powerful caudal fin. In this section are the Seals and Walruses.

Fig. 250.—Feet of Carnivora (after Owen). A, *Plantigrada*, Foot of Bear; B, *Pinnigrada*, Hind-feet of Seal; C, *Digitigrada*, Foot of Lion.

2. *Plantigrada* (fig. 250, A), comprising the Bears, in which the whole, or nearly the whole, of the foot is applied to the ground, so that the animal walks upon the *soles* of the feet.

3. *Digitigrada* (fig. 250, C), comprising the Cats, Lions, Tigers, Dogs, &c., in which the heel is raised from the ground, and the animal walks upon tiptoe.

The Seals and Walruses, forming the family *Pinnigrada*, are distinguished from the other *Carnivora* by their adaptation to an aquatic mode of life. In this respect they agree with the thoroughly aquatic Whales and Dolphins, but they differ from both the *Cetacea* and the *Sirenia*, not only in their dentition, but also in always having well-developed *hind-limbs*. The Seals (fig. 251) are characterised by having tricuspidate præmolar and molar teeth, the lower incisors being often reduced to four, and the canine teeth not being of excessive size. They form a very numerous family, of which species are found in most seas out of the limits of the tropics. They abound, however, especially in the seas of the Arctic and Antarctic regions. They are largely captured both for their oil and for their fur. The Walrus or Morse (*Trichecus*) is distinguished from the true Seals by the fact that in the adult only two of the

Fig. 251.—Greenland Seal (*Phoca Groenlandica*).

upper incisors are present; whilst the upper canines are enormously developed, and form two pointed tusks—fifteen inches or more in length—which are directed downwards between the small lower canines, and project considerably below the chin. The Walrus is a large heavy animal, from ten to fifteen feet in length, which is found in flocks in the Arctic seas, and is hunted both for its blubber and for the ivory of the tusks.

The *Plantigrade Carnivora* apply the whole or the greater part of the sole of the foot to the ground in walking; and this portion of the foot is nearly or altogether destitute of hairs, except in the White Bear. The most typical members of the *Plantigrada* are the Bears (*Ursidae*), of which the common Brown Bear and the White or Polar Bear are familiar examples. The Bears are much less purely carnivorous than the majority of the order, and, in accordance with their omnivorous habits, the teeth do not exhibit

the typical carnivorous characters. The incisors and canines have their usual carnivorous form, but the hinder præmolars and the molars are furnished with broad tubercular crowns. The claws are large, curved, and strong, but are not retractile. The tongue is smooth, the ears small and erect, the tail short, the nose mobile, and the pupil circular. Most of the Bears are only carnivorous in so far that they eat flesh when they can get it; but a great part of their food consists of roots, acorns, honey, and even insects.

Nearly related to the true Bears are the familiar Racoons (*Procyon*) of America, the Coatis (*Nasua*) of South America, and the Wah (*Ælurus*) of India.

The only remaining Plantigrades of importance are the Badgers (*Meles*) of Europe, Asia, and America, the Gluttons or Wolverines (*Gulo*) of the same continents, and the Honey-badgers (*Mellivora*) of Africa.

Forming a kind of transition between the *Plantigrada* and the *Digitigrada* is a group of *Carnivora* which comprises numerous forms, such as the Weasels, Otters, and Civets, which apply part, but not the whole, of the sole of the foot to the ground.

The Weasels (*Mustelidæ*) have short legs, and elongated worm-like bodies, with a stealthy, gliding mode of progression. Good examples are the Polecat, the Mink, the Ermine, and the Sable. The three last named furnish the beautiful and valuable furs known by their names. Here also belongs the Skunk (*Mephitis*), celebrated for its intensely disagreeable odour when alarmed or irritated. The Otters are nearly allied to the Weasels, but have webbed feet adapted for swimming. The great Sea-otter yields a very valuable fur. The Civets and Genettes (*Viverridæ*) all belong to the Old World. The true Civet-cat inhabits North Africa, and is furnished with a pouch which secretes the peculiar fatty substance which is used as a perfume under the name of "civet."

The typical group of the *Carnivora* is that of the *Digitigrada*, comprising the three tribes of the Dogs (*Canidæ*), the Hyænas (*Hyenidæ*), and the Cats (*Felidæ*). The family *Canidæ* comprises the true Dogs, the Wolves, the Foxes, and the Jackals, all characterised by their pointed muzzles, smooth tongues, and non-retractile claws, and by the fact that the fore-feet have five toes, whilst the hind-feet have only four. In the *Hyenidæ*, comprising the Hyænas, there are only four toes to all the feet, the muzzle is rounded, the tongue is rough, and the hind-legs are shorter than the fore-legs. The Hyænas are ill-conditioned, ferocious animals, which occur in Africa, Asia Minor, Arabia, and Persia.

The most highly carnivorous, and therefore the most typical, group of the *Carnivora* is that of the Cats or *Felidæ*, comprising the Lions,

Tigers, Leopards, Panthers, Cats, and others. In all these the animal walks lightly upon the tips of the toes, and the soles of the feet are hairy. The jaws are short, and owing to this and to the great size of the muscles which move the lower jaw, the head assumes a

Fig. 252.—Side-view of the skull of the Lion.

rounded form, with a short muzzle. The molars and præmolars (figs. 249 and 252) are fewer in number than in any other of the *Carnivora*—hence the shortness of the jaws: and they are all furnished with cutting edges, except the single molar in the upper jaw,

Fig. 253.—Bones and ligaments of the toe of a Cat, showing the claw retracted (A) and protruded (B).

which is tuberculate. The legs are nearly of equal length, and the hind-feet have only four toes, whilst the fore-feet have five toes each. All the toes are furnished with strong curved retractile claws, which, when not in use, are withdrawn within sheaths by the action of elastic ligaments (fig. 253). The tongue is armed with horny

eminences, which render it rough and prickly, and adapt it for the office of licking flesh from the bones of the prey. They are all extremely light upon their feet, and excessively muscular; and all have the habit of seizing their prey by suddenly springing upon it. In this section are the Lion (*Felis leo*), the Tiger (*Felis tigris*), the Jaguar (*Felis onca*), the Puma (*Felis concolor*), the Leopard (*Felis leopardus*), the Lynxes, and the true Cats.

The Lions are entirely confined to the Old World, inhabiting Southern Asia and Africa. The males are maned, and the tail is tufted. The Royal Tiger is exclusively Asiatic, as are most of the Tiger-cats, but some of the latter are American. The Spotted Cats or Leopards are represented, among others, by the Leopard and Cheetah of the Old World and the well-known Jaguar of the American continent. The Puma is also American, but its colour is uniform. The Lynxes are distinguished by their tufted ears, and are found both in the Eastern and Western hemispheres.

ORDER XIII. RODENTIA.

In this order are a number of small animals, characterised by the absence of canine teeth, and the possession of two long curved incisor teeth in both jaws, which are separated by a wide interval from the molars (fig. 254). There are seldom more than two incisors in the upper jaw (sometimes four), but there are never more than

Fig. 254.—A, Side-view of the skull of a Rodent (*Cynomys*). B, Molar teeth of the upper jaw of the Beaver (*Castor fiber*). (After Giebel.)

two in the lower jaw. The molar teeth are few in number (rarely more than four on each side of each jaw). The feet are usually furnished with five toes each.

The most characteristic point about the Rodents is to be found in the structure of the incisor teeth, which are adapted for con-

tinuous gnawing. They grow from persistent pulps, and consequently continue growing as long as the animal lives. They are large, long, and curved, and are covered in front with a layer of hard enamel, so that the softer parts of the tooth are placed behind (fig. 254, A). The result of this is, that as the tooth is used in gnawing, the softer parts behind wear away more rapidly than the hard enamel in front, and thus the crown of the tooth acquires by use a chisel shape, bevelled away behind, and the enamel forms a persistent cutting-edge. The Rodents are almost all of small size, and are very prolific. They subsist principally, if not entirely, on vegetable matters, especially the harder parts of plants, such as the bark and roots. Many possess the power of building very elaborate nests, and most of them hibernate (*i.e.*, remain torpid throughout the winter). They are very generally distributed over the whole world.

The order *Rodentia* comprises a large number of families, of which

Fig. 255.—The Beaver (*Castor fiber*).

little more than the names of the principal ones can be mentioned. The most important families of Rodents are the following : 1. *Leporidae*, comprising the Hares and Rabbits. The Hares generally occur in temperate regions, but some are African, and one species occurs in the Arctic regions, while the common American Hare (*Lepus Americanus*) extends from Canada to Mexico. 2. *Caviidae*, comprising the Capybaras, Guinea-pigs, &c. The Capybara is the largest of living Rodents, and is not unlike a small pig. It is a native of South America, and leads an amphibious life. Here also belong the Agoutis (*Dasyprocta*) of South America and the West Indies, and the Pacas of South America. 3. *Hystriidae*, comprising the Porcupines, and characterised by the fact that the body is covered with longer or shorter spines or quills mixed with bristly hairs. Most of the Porcupines live in burrows, and are much like the Rabbits in

their habits, but some are furnished with prehensile tails, and live in trees. 4. *Castoridæ* or Beaver family, comprising the Beaver. The Beaver (fig. 255) has webbed feet and a scaly tail, and the fur is an article of considerable value. It inhabits both North America and Europe. The Musquash resembles the Beaver in many respects, and is also a native of Northern America; but the Coypu is South American. 5. *Muridæ*, comprising the Mice, Rats, Hamster, Lemmings, &c. The Rats and Mice are too well known to require more than merely to be mentioned. 6. *Dipodidæ*, comprising the Jerboas of the Old World, and the Jumping Mice of America. 7. *Myovidæ*, comprising the Dormice, which must not be confounded with the true Mice on the one hand, or with the Shrew Mice on the other hand. 8. *Sciuridæ*, comprising the Squirrels, Flying Squirrels, and Marmots. The Flying Squirrels do not really fly, but like the "flying" Phalangers, they take long leaps from tree to tree by means of laterally extended folds of skin. The Marmots, unlike the typical Squirrels, are ground-animals, and live in burrows. An excellent example is afforded by the Prairie-dog (*Cynomys Ludovicianus*) of North America.

ORDER XIV. CHEIROPTERA.

This order is undoubtedly one of the most distinctly circumscribed orders in the whole class of the *Mammalia*, and comprises only the Bats. In many respects, however, it might be well to

Fig. 256.—Skeleton and outline of Bat (*Phyllostoma hastatum*). d_1 Thumb; d_2 Fore-finger; d_3 Middle finger; *sc* Shoulder-blade; *cl* Collar-bone; *f* Thigh-bone; *t* Tibia; *d* Toes.

regard the order as merely a modified branch of the *Insectivora*, just as the *Pinnigrada* are regarded as a modified offshoot of the *Carnivora*.

The *Cheiroptera* or Bats are essentially characterised by the fact that the fore-limbs are much longer than the hind-limbs, and have several of the fingers enormously elongated (fig. 256). These enormously lengthened digits are united by an expanded leathery membrane or "patagium," which not only stretches between the fingers, but is also extended between the fore and hind limbs, and is attached to the sides of the body (fig. 257). The patagium thus formed often includes the tail, and is nearly or quite naked or destitute of hairs on both sides. It is used as an organ of true flight, and, in accordance with this, there are well-developed collar-bones (clavicles), and the breast-bone is furnished with a ridge for the attachment of the pectoral muscles. Of the fingers of the hand

Fig. 257.—*Cheiroptera*. *Vespertilio discolor*, one-half the natural size.

at least three are destitute of nails. The mammary glands are placed upon the chest. Teeth of three kinds are always present, and the canines are always well developed.

The Bats are all twilight-loving or nocturnal animals, and they are the only Mammals which possess the power of true flight, though several others can make extended leaps from tree to tree. The eyes are small, but the ears are very large, and their sense of touch is most acute. During the day they retire to caves or crevices in rocks, where they suspend themselves by the hind-feet, which are provided with curved claws. In their flight, though they can turn with great ease, they are by no means as rapid and active as the

true Birds. The tail is sometimes very short, sometimes moderately long, and is usually included in a continuation of the patagium, which extends between the hind-legs. The body is covered with hair, but the patagium is usually nearly or quite hairless. Most of the Bats hibernate.

The *Cheiroptera* are conveniently divided into the two sections of the Insectivorous and Frugivorous Bats. In the first section are all the smaller Bats, which universally live upon insects. In this section we must also place the Vampire Bats, which are of comparatively large size, and some of which have the habit of sucking the blood of sleeping animals. In the second, or fruit-eating section of the *Cheiroptera* are only the Fox-bats (*Pteropidae*), which are especially characteristic of the Pacific Archipelago, inhabiting Australia, Java, Sumatra, Borneo, &c., but occurring also in Asia and Africa. They are amongst the largest of the Bats, one species—the *Pteropus edulis* or Kalong—attaining a length of from four to five feet from the tip of one wing to the tip of the other.

ORDER XV. INSECTIVORA.

The next order of Mammals is that of the *Insectivora*, which comprises a number of small animals, very similar in many respects to the Rodents, but wanting the peculiar incisors of that order, and also being provided with clavicles. All the three kinds of teeth are present, but the dentition is very various, and the only common

Fig. 258. Skull of the common Hedgehog (*Erinaceus Europæus*).

character is, that the crowns of the molar teeth (fig. 258) are furnished with small pointed eminences or cusps, adapted for crushing insects. All the toes have claws; there are usually five toes to each foot, and most of the *Insectivora* are *plantigrade*—that is to say, walk upon the soles of the feet. They are all small, and they exist

over the whole world, except in Australia and South America, where their place is taken by Marsupials, such as the Opossums.

The *Insectivora* are divided into several families, of which the following are the most important. The Moles (*Talpidae*, fig. 259) are distinguished by having the body covered with hair, the feet short and formed for digging, and the toes furnished with strong, curved claws. There is no external ear, and the eyes are either extremely small, or are completely concealed beneath the fur. They are all nocturnal, burrowing animals. The Star-nosed Moles (*Condylura*) are American, but their habits are like those of the European Mole (*Talpa Europæa*, fig. 259). The Golden Moles (*Chrysochloris*) are African, and are remarkable for the iridescence of their fur. The Shrews (*Soricidae*) are very like the true Mice in external appearance, but they are really widely different. The body is covered with hair, the feet are not adapted for digging, and there are mostly external ears, while the eyes are well developed. No division of the

Fig. 259.—Insectivora. Mole (*Talpa Europæa*).

Insectivora is more abundant or more widely distributed than the *Soricidae*, and one of the Shrews is probably the smallest of existing Mammals, not exceeding two and a half inches in length, counting in the tail.

The so-called "Elephant-shrews" (*Macroscelidæ*) of Africa form another family. They are distinguished by their immensely elongated trunk-like nose, and their long Kangaroo-like hind-legs.

Another family (*Erinaceidæ*) includes the well-known Hedgehogs, which have the power of rolling themselves into a ball at the approach of danger, and which have the upper surface of the body covered with short prickly spines, forming a protective armour. The common European Hedgehog (*Erinaceus Europæus*, fig. 260) is the type of the family, but other species occur in Africa and India. The "Tenrecs" (*Centetes*) of Madagascar are closely allied to the

Hedgehogs, but have no power of rolling themselves up. The "Banxings" (*Tupaia*) of the Indian Archipelago have a long, compressed tail, and live mostly in trees.

Before passing on to the next order, a few words must be said about a curious transitional form, which has been alternately placed in the *Cheiroptera*, the *Insectivora*, or the *Quadrumana*, or has been regarded as the type of a separate order. The animals alluded to are the so-called Flying Lemurs (*Galeopithecus*), of which more than

Fig. 260.—Insectivora. The Hedgehog (*Erinaceus Europæus*).

one species is known as inhabiting the Indian Archipelago. The leading characteristic in these singular animals is the possession of a flying membrane, which extends as a broad expansion from the nape of the neck to the arms, from the arms to the hind-legs, and from the hind-legs to the tail. The fingers are not elongated, and do not support a "patagium," so that the animal has no power of true flight, but can simply take extended leaps from tree to tree. The *Galeopithecæ* live chiefly upon small insects and birds, and they should probably be regarded as aberrant forms of the *Insectivora*.

ORDER XVI. QUADRUMANA.

The sixteenth order of Mammals is that of the *Quadrumana*, comprising the Apes, Monkeys, Baboons, and Lemurs. The charac-

teristic of this order is, that the innermost toe (great toe) of the hind-limbs can be *opposed* to the other toes, so that the hind-feet become prehensile hands. The term "opposed" simply implies that the toe can be so adjusted as regards the extremities of the other toes, that any object can be grasped between them, just as the thumb of the human hand can be "opposed" to any of the fingers. The fore-feet may be destitute of a thumb, but when this is present, it, too, is generally opposable to the other digits, so that the animal becomes truly four-handed or "quadrumanous."

The *Quadrumana* are divided into three very natural sections, separated from one another both by their anatomical characters and their geographical distribution.

Section A. Strepsirhina.—Characterised by having the nostrils twisted or curved, and placed at the end of the nose, whilst the second toe of the hind-feet is furnished with a claw. The *Quadru-*

Fig. 261.—Side-view of the skull of a Lemuroid (*Nycticebus* or *Stenops tardigradus*).
(After Giebel.)

mana of this section are chiefly referable to Madagascar as their geographical centre, but they spread from Madagascar westwards into Africa, and eastwards to the Indian Archipelago. In this family are the Aye-aye (*Cheiromys*), the Loris (*Nycticebidæ*), and the Lemurs (*Lemuridæ*).

The Aye-aye is confined to Madagascar, and is not unlike a large squirrel in appearance, having a long bushy tail. The incisors grow from permanent pulps, like those of Rodents, and there are no canines. The Loris and Slow Lemurs have either no tail or a rudimentary one, and they are confined to Southern Asia, and the great islands of the Indian Archipelago. The true Lemurs (fig. 261) are principally natives of Madagascar, and are often spoken of as "Madagascar cats." They have a soft, woolly fur, and a long tail, which is prehensile. The second toe of the hind-foot has a long and pointed claw.

Section B. Platyrrhina.—This section includes those monkeys in

which the nostrils are simple, and are placed far apart; the thumbs of the fore-feet are wanting, or, if present, are hardly opposable; and the tail is generally prehensile. The Platyrrhine Monkeys are exclusively confined to South America, occurring especially in Brazil, and they are all adapted for a more or less purely arboreal life. The best-known members of this section are the Marmosets (*Hapalidæ*), and the great family of the *Cebidæ*, comprising the Spider-monkeys, the Howlers, and others. The Howlers (*Myctes*) are remarkable for having a bony drum at the summit of the wind-pipe, by which the voice is rendered extraordinarily resonant, and peculiarly weird and terrifying to those who hear it.

As regards their dentition, the Platyrrhine Monkeys differ from the Old World Monkeys, as also from Man, in having an additional præmolar on each side of each jaw. They have, therefore, three præmolars on each side of each jaw, instead of only two. On the other hand, they have either three molars on each side, as have the Old World Monkeys and Man, or they have only two. The dental formula of the Marmoset is—

$$i \frac{2-2}{2-2}; c \frac{1-1}{1-1}; pm \frac{3-3}{3-3}; m \frac{2-2}{2-2} = 32.$$

The dental formula of the Howlers (*Myctes*) is—

$$i \frac{2-2}{2-2}; c \frac{1-1}{1-1}; pm \frac{3-3}{3-3}; m \frac{3-3}{3-3} = 36.$$

Section C. Catarhina.—In this, the highest section of the *Quadrumanæ*, the nostrils are oblique and placed close together, and the thumbs of all the feet are opposable, so that they are truly “quadrumanous.” The dental formula agrees with that of Man :—

$$i \frac{2-2}{2-2}; c \frac{1-1}{1-1}; pm \frac{2-2}{2-2}; m \frac{3-3}{3-3} = 32.$$

The incisor teeth, however, are prominent and projecting, and the canines, especially in the males, are large and pointed, whilst the teeth form an uneven series. The tail is never prehensile, and is sometimes absent. Cheek-pouches are often present. In one single instance (*Colobus*) the thumbs of the fore-limbs are wanting.

With the single exception of a Monkey which occurs on the Rock of Gibraltar, all the Catarhine Monkeys are confined to Africa and Asia. The most typical forms of the section are the *Semnopithecæ* and *Macaques* of Asia. Less typical are the Baboons, which inhabit Africa, and are amongst the most repulsive of all the *Quadrumanæ*. In these the tail is always short, and often quite rudimentary. The head is large, and the muzzle greatly prolonged, having the nostrils at its extremity. The skull (fig. 262) is furnished with great bony

ridges which serve for the attachment of muscles. More than any other of the Monkeys they employ the fore-limbs in terrestrial progression, running upon all-fours with the greatest ease.

Fig. 262.—Side-view of the skull of a Baboon (*Cynocephalus ursinus*). (After Giebel.)

The third family of the Catarrhine Monkeys is that of the *Anthropoid* Apes, so called from their making a nearer approach to Man in

Fig. 263.—Quadrumanus. *Cercopithecus mona*, a Catarrhine Monkey, one-seventh of the natural size.

anatomical structure than is the case with any other Mammal. The Anthropoid Apes are distinguished by having no tail nor cheek-pouches. The limbs are short—shorter than the fore-limbs—and

the animal can progress in an erect or semi-erect posture. At the same time the hind-feet are strictly prehensile, since the thumbs are opposable to the other toes. The canine teeth of the males are very long, strong, and pointed, but this is not the case in the females.

In this tribe are the Gibbons, the Chimpanzee, the Orang-outang, and the Goriila. The Gibbons form the genus *Hyllobates*, and they belong to Asia, India, and the Indian Archipelago. The anterior limbs in these monkeys are extremely long, and the hands nearly or quite touch the ground when the animal stands erect. The Orang-outang (*Simia*) has no cheek-pouches, and the hips are covered with hair. The arms are of excessive length, and the hind-legs very short. When young, the head of the Orang-outang is not very different from that of a child, but as the animal grows, the bones of

Fig. 264.—A, Skull of the Orang-outang ; B, Skull of a European adult.

the face gradually lengthen, whilst the skull remains much about the same ; great bony ridges are developed for the attachment of the muscles which act upon the jaws ; the incisors project ; the canine teeth of the males become long and pointed, till ultimately the muzzle becomes as pronounced and well marked as in the Carnivorous animals (fig. 264, A). The only unquestionable species of Orang is the *Simia satyrus*, which inhabits Sumatra, Borneo, and the other larger islands of the Indian Archipelago. The Chimpanzee and Gorilla both belong to Africa, and form the genus *Troglodytes*. The Chimpanzee is a native of Western Africa, and has the arms much shorter proportionately than in the Gibbons and Orangs. Still they are much longer than the hind-limbs, and reach below the knees. The hands are naked to the wrist, and the face is also naked

and much wrinkled. The Gorilla is in most respects like the Chimpanzee, but is much larger, attaining a height of fully five feet. It is a native of Lower Guinea and Equatorial Africa, and is enormously strong and very ferocious. It is now generally looked upon as the highest of the Anthropoid Apes.

ORDER XVII. BIMANA.

In this order stands Man alone, and little, therefore, needs to be said on this head. Man is distinguished *zoologically* from all other Mammals by his habitually erect posture and progression upon two legs. The lower limbs are exclusively devoted to progression and to supporting the weight of the body. The fore-limbs are shorter than the legs, and have nothing to do with progression. The thumb can be opposed to the other fingers, and the hands are therefore prehensile. The fingers and toes are furnished with nails; but the innermost digit of the foot (the great toe) is not capable of being opposed to the other toes, so that the foot is useless as a grasping organ. The foot is broad and plantigrade, the whole sole being applied to the ground in walking.

The teeth are thirty-two in number, and they form a nearly even and uninterrupted series, without any gap or interval. The dental formula is—

$$\begin{matrix} i & 2-2 \\ 2 & -2 \end{matrix}; \begin{matrix} c & 1-1 \\ 1 & -1 \end{matrix}; \begin{matrix} pm & 2-2 \\ 2 & -2 \end{matrix}; \begin{matrix} m & 3-3 \\ 3 & -3 \end{matrix} = 32.$$

The brain is more largely developed, and more richly furnished with large and deep foldings or convolutions, than is the case in any other Mammal. Lastly, Man is the only terrestrial Mammal in which the body is not furnished with a general covering of hair.

The purely *anatomical* distinctions between Man and the other Mammals are thus seen to be not very striking, and *of themselves* they would hardly entitle Man to the position of forming a distinct order in the class Mammalia. When, however, we take into account the vast *mental* differences, both intellectual and moral, between Man and the highest of the brutes, and when we reflect that this mental difference must have *some* physical correspondence, it becomes a question whether the group *Bimana* should not have the value of a distinct sub-kingdom, whilst there can be little hesitation in giving Man at least a *class* to himself.

In the words of Dr Pritchard, “the sentiments, feelings, sympathies, internal consciousness, and mind, and the habitudes of mind and action thence resulting, are the real and essential characteristics of humanity.”

APPENDIX.

PRINCIPAL DIVISIONS OF THE ANIMAL KINGDOM.

NOTES.—1. The examples of the various orders given in this table are not a complete list of all included in the orders, but are typical forms.

2. In some places, where the scientific name is the same as the common name, or where the animal is not indigenous to this country, the scientific name is omitted.

SECTION I.—INVERTEBRATES.

Vital organs contained in a single tube. No internal skeleton; limbs, when present, turned toward main mass of the nervous system. Page 11.

SUB-KINGDOM I.—PROTOZOA.

Masses of protoplasm, usually minute and unicellular. No definite “body-cavity” or nervous system. Digestive system rudimentary. Page 18.

Class A. Gregarinida.—Parasites; no mouth; no power of throwing out “pseudopodia.” Page 21.

Class B. Rhizopoda.—No mouth; possess power of throwing out “pseudopodia.” *Orders 4, as follows:* 1. **Monera.** Ex.: Proto-genes.—2. **Amœbea.** Ex.: Amœba, Diffugia.—3. **Foraminifera.** Ex.: Lagenæ, Nodosaria, Globigerina.—4. **Radiolaria.** Ex.: Thalassicolla, Polycystina, Collozoa.

Class C. Infusoria.—Have power of becoming “encysted.” Usually possess a mouth; armed with vibrating cilia, “flagella” or suckers. *Orders 3:* 1. **Ciliata.** Ex.: Paramœcium, Bell-animalcule (Vorticella).—2. **Flagellata.** Ex.: Euglena.—3. **Suctoria.** Ex.: Podophyra.

Porifera (Sponges) is an intermediate group bet. Protozoa and Cœlenterata.—Ex.: Spongilla, Euplectella.

SUB-KINGDOM II.—CÆLENTERATA.

Radially symmetrical; mouth opens into a space which represents alimentary cavity; body-wall of two layers; no circulatory system; imperfect nervous system; distinct reproductive organs.

Class A. Hydrozoa.—Walls of digestive sac not separated from general body-cavity; reproductive organs external.

Sub-class I. Hydroida (Hydroid Zoophytes).—*Orders 4*: 1. **Hydrida**. Ex.: Fresh-water Polype (Hydra).—2. **Corynida**. Ex.: Pipe-coralline (Tubularia).—3. **Sertularida**. Ex.: Sea-firs (Sertularia).—4. **Medusidæ** (Jelly-fishes). Ex.: Trachynema, Æginida. Page 58.

Sub-class II. Siphonophora (Oceanic Hydrozoa).—*Orders 2*: 5. **Calycophoridæ**. Ex.: Praya.—6. **Physophoridæ**. Ex.: Portuguese Man-of-War (Physalia). Page 72.

Sub-class III. Lucernarida (Sea-blubbers).—*Orders 2*: 7. **Lucernariadæ**. Ex.: Lucernaria, Hidden-eyed Medusæ.—8. **Rhizostomidæ**. Ex.: Rhizostoma. Page 76.

Sub-class IV. Graptolitidæ (extinct).—Page 80.

Sub-class V. Hydrocorallinæ.—Ex.: Millepora, Stomatopora (fossil). Page 81.

Class B. Actinozoa.—Stomach opening below into body-cavity, but separated from body-walls by "perivisceral space," which is divided into vertical compartments by "mesenteries," to which reproductive organs are attached. *Orders 4*: 1. **Zoantharia**. Tentacles round, in multiples of six. Ex.: Sea-Anemones (Actinidæ), Reef-building Corals, Corals with central axis.—2. **Alcyonaria**. Tentacles fringed, eight in number. Ex.: Dead-men's-fingers (Alcyonium), Organ-pipe Coral (Tubipora), Fan-corals (Gorgonidæ), Heliopora.—3. **Rugosa** (extinct).—4. **Ctenophora**. Swim by cilia. Ex.: Pleurobrachia, Venus's Girdle (Cestum). Page 83.

SUB KINGDOM III.—ECHINODERMATA.

Marine organisms, bilaterally symmetrical when young, pentamerous arrangement of parts in adult. Alimentary canal separate from body-cavity; water-vascular system employed in locomotion; nervous system radiate; integument hardened by lime spicules or plates. *Orders 7*: 1. **Echinoidea** (Sea-urchins). Ex.: Sea-eggs (Echinus).—2. **Asteroidea** (Star-fishes). Ex.: Cross-fish (Asterias), Sun-stars (Solaster), Cushion-stars (Goniaster).—3. **Ophiuroidea** (Brittle-stars). Ex.: Sand-stars (Ophiura), Brittle-stars (Ophiocoma).—4. **Crinoidea** (Sea-lilies). Ex.: Feather-stars (Comatula), Medusa-head (Pentacrinus), Stone-lily (Encrinurus).—5. **Cystoidea** (extinct).—6. **Blastoidea** (extinct).—7. **Holothuroidea** (Sea-cucumbers). Ex.: Trepangs (Holothuria). Page 97.

SUB-KINGDOM IV.—ANNULOSA.

Elongated body, bilaterally symmetrical, divided into segments which are arranged along an antero-posterior axis. Lateral appendage sometimes present. Nervous system in anterior part of body or a double gangliated chain placed vertically. Page 112.

Division I. Scolecida.—Imperfectly segmented; no lateral appendages; branched water-vessels; nervous system in anterior part of body. Page 113.

Section A. Platyelmia.—*Orders 3*: 1. **Tæniada.** Ex.: Tape-worm.—2. **Trematoda.** Ex.: Liver-fluke (*Distoma*).—3. **Turbellaria.** Ex.: Planarians, Ribbon-worms (*Nemertes*). Page 114.

Section B. Nematelmia.—*Orders 3*: 1. **Acanthocephala.** Ex.: Echinorhynchus.—2. **Gordiaceæ.** Ex.: Hair-worm.—3. **Nematoidea.** Ex.: Vinegar-eel (*Anguillula*), Round-worm (*Ascaris*), Thread-worm (*Oxyuris*), Muscle-worm (*Trichina*). Page 121.

Section C. Rotifera (Wheel-Animalcules).—Ex.: Crown-Animalcule (*Stephanoceros*). Page 124.

Division II. Anarthropoda.—Body segmented; lateral appendages, when present, not articulated to the body. Page 127.

Class I. Gephyrea.—Ex.: Spoon-worm. Page 128.

Class II. Annelida (Ringed worms).—*Orders 3*: 1. **Hirundinea.** Ex.: Medicinal Leech (*Sanguisuga*), Horse-leech (*Hæmopsis*).—2. **Oligochætæ.** Ex.: Earth-worms (*Lumbricidæ*), Water-worms (*Nais*).—3. **Polychætæ.** Ex.: Tube-worms (*Serpula*). Page 128.

Division III. Arthropoda (Articulata).—Jointed appendages articulated to the body. Page 136.

Class I. Crustacea.—Respiration aquatic; more than four pairs of legs; two pairs of antennæ; calcareous external skeleton; pass through metamorphosis. *Orders 11*: 1. **Decapoda.** Ex.: Lobster (*Homarus*), Hermit Crabs (*Pagurus*), Crabs (*Cancer*).—2. **Stomapoda.** Ex.: Locust-shrimp (*Squilla*).—3. **Isopoda.** Ex.: Wood-lice (*Oniscus*), Slaters (*Ligia*).—4. **Amphipoda.** Ex.: Sand-hopper (*Talitrus*), Fresh-water shrimp (*Gammarus*).—5. **Merostomata.** Ex.: King-crabs (*Limulus*).—6. **Trilobita** (extinct).—7. **Phyllopoda.** Ex.: Brine Shrimp (*Artemia*).—8. **Cladocera.** Ex.: Branched-horned Water-flea (*Daphnia*).—9. **Copepoda.** Ex.: Cyclops.—10. **Ostracoda.** Ex.: Water-fleas (*Cypris*).—11. **Cirripedia.** Ex.: Barnacles (*Lepas*), Acorn-shells (*Balanus*). Page 137.

Class II. Arachnida.—Respiration aerial by pulmonary sacs or air-tubes. Antennæ converted into jaws; head and thorax amalgamated. Four pairs of legs; abdomen without limbs. *Orders 4*: 1. **Podosomata.** Ex.: Sea-spider (*Pycnogonum*).—2. **Acarina.** Ex.: Mites (*Acarus*), Ticks (*Ixodes*).—3. **Pedipalpi.** Ex.: Scorpions.—4. **Araneida.** Ex.: House Spider (*Tegenaria*). Page 151.

Class III. Myriapoda.—Respiration aerial. Head distinct; body consists of many rings; legs more than eight, partly borne upon the abdomen. One pair of antennæ. *Orders 2*: 1. **Chilopoda.** Ex.: Centipedes.—2. **Chilognatha.** Ex.: Millipedes. Page 157.

Class IV. Insecta.—Respiration aerial by tracheæ. Head, thorax,

and abdomen distinct. Three pairs of legs in adult, borne on thorax; no limbs on abdomen. *Orders 13*: 1. **Anoplura**. Ex.: Lice (Pediculus).—2. **Mallophaga**. Ex.: Bird-lice.—3. **Collembola**. Ex.: Spring-tails.—4. **Thysanura**. Ex.: Lepisma.—5. **Hemiptera**. Ex.: Plant-lice (Aphides), Boat-fly (Nepa), Cochineal, Cicada.—6. **Orthoptera**. Ex.: Crickets (Acheta), Grasshopper (Gryllus), Locust (Acridium), Cockroach (Blatta).—7. **Neuroptera**. Ex.: Dragon-flies (Libellulidæ), May-flies (Ephemera), White Ants (Termites).—8. **Aphaniptera**. Ex.: Fleas (Pulex).—9. **Diptera**. Ex.: House-fly (Musca), Gnats and Mosquitoes (Culicidæ).—10. **Lepidoptera** (Butterflies and moths).—11. **Hymenoptera**. Ex.: Bees (Apidæ), Wasps (Vespidæ), Ants (Formicidæ), Gall-flies (Cynipidæ), Saw-flies, Ichneumon, etc.—12. **Strepsiptera**. Ex.: Stylops.—13. **Coleoptera** (Beetles). Page 160.

SUB-KINGDOM V.—MOLLUSCA.

Soft-bodied animals, usually protected by a shell. Distinct alimentary canal; distinct heart in higher forms. Nervous system consists of a single ganglion or three scattered pairs of ganglia. Page 183.

A. Molluscoidea.—Nervous system a single ganglion or pair of ganglia. Imperfect heart or none. *Classes 3*:

I. Polyzoa.—Form compound growths. Ex.: Sea-mats (Flustra), Lace-coral (Fenestella). Page 187.

II. Tunicata.—Enclosed in a leathery case. Ex.: Sea-squirts (Ascidia). Page 191.

III. Brachiopoda.—Bivalves. Mouth furnished with fringed "arms." Ex.: Lamp-shells (Terebratula). Page 193.

B. Mollusca Proper.—Nervous system of three pairs of ganglia. Heart of at least two chambers. *Classes 4*:

I. Lamellibranchiata.—Gills leaf-like. Ex.: Oyster (Ostrea), Scallop (Pecten), Mussel (Mytilus). Page 196.

II. Gasteropoda.—Univalve, or shell wanting; large foot on under side of body. Ex.: Whelks (Buccinum), Land-snails (Helix), Slugs (Limax). Page 201.

III. Pteropoda.—Wing-like appendages attached to head. Ex.: Cleodora. Page 206.

IV. Cephalopoda.—Eight or more "arms" surrounding mouth. Ex.: Calamaries (Loligo), Cuttle-fish (Octopus), Paper Nautilus (Argonauta), Pearly Nautilus (Nautilus). Page 206.

SECTION II.—VERTEBRATES.

SUB-KINGDOM VI.—VERTEBRATA.

Body composed of two tubes, one containing the nervous axis, the other the digestive, circulatory, and sympathetic systems. Skeleton

internal, usually with a backbone; limbs never exceeding two pairs, articulated and turned away from the great nerve masses. Cerebro-spinal nervous system. Page 218.

Class I. Pisces (Fishes).—Breathe by gills; heart usually of two chambers; limbs converted into fins; blood cold. Page 228. *Orders* 6: 1. **Pharyngobranchii**. Ex.: Lancelet (Amphioxus). Page 237.—2. **Marsipobranchii**. Ex.: Lamprey (Petromyzon), Hag-fish (Myxine). Page 239.—3. **Teleostei** (Bony Fishes). Ex.: Eels (Muraenidæ), Herrings (Clupeidæ), Salmon and Trout (Salmonidæ), Cod and Haddock (Gadidæ), Flat-fishes (Pleuronectidæ), Perch (Percidæ), Mackerel (Scomberidæ). Page 241.—4. **Ganoidei**. Ex.: Bony Pike (Lepidosteus), Paddle-fish (Spatularia), Sturgeon (Sturio).—5. **Elasmobranchii**. Ex.: Sharks (Carcharidæ), Dog-fishes (Scylliadae), Saw-fishes (Pristis), Rays and Skates (Raiidæ).—6. **Dipnoi**. Ex.: Mud-fish (Lepidosiren).

Class II. Amphibia.—Undergo metamorphosis, breathing when young by gills and in mature state by lungs, either alone or associated with gills; blood cold. *Orders* 4: 1. **Orphiomorpha**. Ex.: Cæcilia.—2. **Urodela** (Tailed Amphibians). Ex.: Water-newt (Triton), Axolotl (Siredon), Mud-eel (Siren), Salamander.—3. **Anoura** (Tailless Amphibians). Ex.: Frog (Rana), Toad (Bufo), Surinam Toad (Pipa), Tree-toad (Hyla).—4. **Labyrinthodontia** (extinct). Page 249.

Class III. Reptilia.—Breathe by lungs; circulation imperfect; blood cold; skin secretes "plates." Skull jointed to backbone by a single condyle. *Orders* 9: 1. **Chelonia**. Ex.: Turtles (Cheloniidæ), Soft Tortoises (Trionycidæ), Terrapins (Emydidæ), Land Tortoises (Testudinidæ).—2. **Ophidia**. Ex.: Vipers (Viperidæ), Rattlesnakes (Crotalidæ), Sea-snakes (Hydrophidæ), Boas and Pythons (Boidæ).—3. **Lacertilia**. Ex.: Lizards (Lacerta), Iguanas, Monitors, Chameleons.—4. **Crocodylia**. Ex.: Crocodiles, Alligators, Gavials.

The following orders are extinct: 5. **Ichthyopterygia**. Ex.: Ichthyosaurus.—6. **Sauropterygia**. Ex.: Plesiosaurus.—7. **Pterosauria**. Ex.: Pterodactyl.—8. **Anomodontia** (Dicynodon).—9. **Deinosauria**. Ex.: Iguanodon.—10. **Theriodontia**. Page 257.

Class IV. Aves (Birds).—Oviparous vertebrates having double circulation, warm blood, lungs connected with air-sacs, and a covering of feathers. Skull with single "condyle"; fore-limbs converted into wings. Page 278.

Sub-class I. Ratitæ.—Sternum without median ridge for attachment of pectoral muscles. *Orders* 1: 1. **Cursores** (Runners). Ex.: Ostrich (Struthio), Emu (Dromaius), Cassowary, Apteryx. Page 290.

Sub-class II. Carinatæ.—Sternum furnished with median ridge. *Orders* 9: 1. **Natatores** (Swimmers). Ex.: Penguins (Spheniscidæ),

Gulls (*Laridæ*), Ducks (*Anatidæ*), Geese (*Anserinæ*), Swans (*Cygnidæ*).—2. **Grallatores** (Waders). Ex.: Rails (*Rallidæ*), Water-hens (*Gal-linulæ*), Cranes (*Gruidæ*), Snipes (*Scelopacidæ*).—3. **Rasores** (Scratch-ers). Ex.: Grouse, Partridge, Turkey, Domestic Fowl, Doves, Pigeons.—4. **Scansores** (Climbers). Ex.: Woodpeckers (*Picidæ*), Parrots, Toucans, Trogons.—5. **Insessores** (Perchers). Ex.: Crows, Jays (*Corvidæ*), Larks, Blackbirds, Orioles (*Merulidæ*), Humming-birds (*Trochilidæ*), Swallows (*Hirundinidæ*), Kingfishers (*Alcedinidæ*), Wrens (*Certhidæ*).—6. **Raptores** (Birds of Prey). Ex.: Owls (*Strigidæ*), Hawks (*Falconidæ*), Eagles (*Aquilina*), Vultures.

The following orders are extinct: 7. **Saururæ**.—8. **Odontolcæ**.—9. **Odontotormæ**. Page 293.

Class V. Mammalia.—Viviparous; young nourished by milk. Skin provided with hairs; skull united to backbone by two "condyles." Heart four-chambered; diaphragm separates chest and abdomen; no air-sacs. Page 309.

A. Oviparous Mammals.—Young produced as eggs, but soon liberated. *Order 1:* **Monotremata**. Ex.: Duck-mole, Spiny Anteater. Page 319.

B. Non-Placental Mammals—Young not nourished in a placenta. *Order 2:* **Marsupialia**. Ex.: Kangaroo (*Macropodidæ*), Opossums (*Didelphidæ*). Page 322.

C. Placental Mammals.—Young nourished in a placenta. *Orders 11:* 3. **Edentata**. Ex.: Sloths (*Bradypodidæ*), Armadillos (*Dasypodidæ*), Ant-eaters.—4. **Sirenia**. Ex.: Manatees (*Manatus*), Dugongs (*Halicore*).—5. **Cetacea**. Ex.: Whalebone Whales (*Balæ-nidæ*), Dolphins and Porpoises (*Delphinidæ*). Page 324.—6. **Ungu-lata** (Hoofed Quadrupeds). **A. Perissodactyla** (Odd-toed). Ex.: Rhinoceros, Tapir, Horse (*Equus*). **B. Artiodactyla** (Even-toed). Ex.: Hippopotamus, Swine (*Suida*), Oxen (*Bovidæ*), Reindeer (*Cervidæ*), Camel (*Camelidæ*).—7. **Dinocerata** (extinct).—8. **Tillodontia** (extinct).—9. **Toxodontia** (extinct).—10. **Hyracoidea**. Ex.: Hyrax.—11. **Proboscidea**. Ex.: Elephant.—12. **Carnivora**. Ex.: Cats, Tigers, Lions (*Felidæ*), Dogs, Wolves, Foxes (*Canidæ*), Hyænas, Seals, Bears, Weasels, etc. Page 331.—13. **Rodentia**. Ex.: Hares and Rabbits (*Leporidæ*), Guinea-pigs (*Cavidæ*), Beavers (*Castoridæ*), Rats and Mice (*Muridæ*), Squirrels (*Sciuridæ*).—14. **Cheiroptera** (Bats).—15. **Insectivora**. Ex.: Moles (*Talpidae*), Shrew-mice (*Soricidæ*), Hedge-hogs (*Erinaceidæ*).—16. **Quadrumana**. Ex.: Apes, Monkeys, Baboons, Lemurs.—17. **Bimana**. Man (*Homo Sapiens*). Page 349.

GLOSSARY.

- AB-DO'MEN** (Lat. *abdo*, I conceal). The posterior cavity of the body, containing the intestines and others of the viscera. In many Invertebrates there is no separation of the body-cavity into thorax and abdomen, and it is only in the higher *Annulosa* that a distinct abdomen can be said to exist.
- AB-ER'RANT** (Lat. *aberro*, I wander away). Departing from the regular type.
- AB-NOR'MAL** (Lat. *ab*, from; *norma*, a rule). Irregular; deviating from the ordinary standard.
- AB-O-MA'SUM**. The fourth cavity of the complex stomach of the Ruminants.
- A-BRANCH'I-ATE** (Gr. *a*, without; *brachia*, gills). Destitute of gills or branchiæ.
- A-CA-LE'PHÆ** (Gr. *akalēphe*, a nettle). Applied formerly to the Jelly-fishes or Sea-nettles, and other Radiate animals, in consequence of their power of stinging, derived from the presence of microscopic cells, called "thread-cells," in the integument.
- A-CAN-THO-CEPH'A-LA** (Gr. *akantha*, a thorn; *kephale*, head). A class of parasitic worms in which the head is armed with spines.
- A-CAN-THO-ME-TRI'NA** (Gr. *akantha*; and *metra*, the womb). A family of *Protozoa*, characterized by having radiating siliceous spines.
- A-CAN-THO-PTER-YG'-I-I** (Gr. *akantha*, spine; *pteryx*, wing). A group of bony fishes with spinous rays in the front part of the dorsal fin.
- A-CAR'I-NA** (Gr. *akari*, a mite). A division of the *Arachnida*, of which the Cheese-mite is the type.
- AC-CRE'TION**.
- A-CEPH'A-LOUS** (Gr. *a*, without; *kephale*, head). Not possessing a distinct head.
- A-CE-TAB'U-LA** (Lat. *acetabulum*, a cup). The suckers with which the cephalic processes of many *Cephalopoda* (Cuttle-fishes) are provided.
- A-CE-TAB'U-LUM**. The cup-shaped socket of the hip-joint in Vertebrates.
- AC'RI-TA** (Gr. *akritos*, confused). A term sometimes employed as synonymous with *Protozoa* or the lowest division of the animal kingdom.
- AC-TI-NOM'ERES** (Gr. *aktin*, a ray; *meros*, a part). The lobes which are mapped out on the surface of the body of the *Ctenophora*, by the ctenophores, or comb-like rows of cilia.
- AC-TIN-O-SO'MA** (Gr. *aktin*; and *soma*, body). Employed to designate the entire body of any *Actinozoön*, whether this be simple (as in the Sea-anemones), or composed of several zooids (as in most Corals).
- AC-TIN-O-ZO'A** (Gr. *aktin*; and *zoön*, an animal). That division of the *Ctenoterata* of which the Sea-anemones may be taken as the type.
- AD-EL-AR-THRO-SO'MA-TA** (Gr. *adelos*, hidden; *arthros*, joint; *soma*, body). An order of the *Arachnida*.
- AD-DUC'TOR**.
- A-E'RI-AL**.
- A-GAM'IC** (Gr. *a*, without; *gamos*, marriage). Applied to all forms of reproduction in which the sexes are not directly concerned.

- AL-LAN-TOID'E-A.** The group of *Vertebrata* in which the fœtus is furnished with an allantois, comprising the Reptiles, Birds, and Mammals.
- AL-LAN-TOIS'** (Gr. *allas*, a sausage). One of the "membranes" of the fœtus in certain Vertebrates.
- AL-VE'O-LI** (Lat. dim. of *alvus*, belly). Applied to the sockets of the teeth.
- AM-BU-LA'CRA** (Lat. *ambulacrum*, a place for walking). The perforated spaces or "avenues" through which are protruded the tube-feet, by means of which locomotion is effected in the *Echinodermata*.
- AM-BU-LA-TO-RY** (Lat. *ambulo*, I walk). Formed for walking. Applied to a single limb, or to an entire animal.
- A-MET-A-BOL'IC** (Gr. *a*, without; *metabole*, change). Applied to those insects which do not possess wings when perfect, and which do not, therefore, pass through any marked metamorphosis.
- AM'NI-ON** (Gr. *amnos*, a lamb). One of the fœtal membranes of the higher Vertebrates.
- AM-NI-O'TA.** The group of *Vertebrata* in which the fœtus is furnished with an amnion, comprising the Reptiles, Birds, and Mammals.
- A-MŒ'BA** (Gr. *amoibos*, changing). A species of Rhizopod, so called from the numerous changes of form which it undergoes.
- A-MŒ'BI-FORM.** Resembling an *Amœba* in form.
- A-MOR-PHO-ZO'A** (Gr. *a*, without; *morphe*, shape; *zo'n*, animal). A name sometimes used to designate the *Sponges*.
- A-MOR'PHOUS.**
- AM-PHI'E-I-A** (Gr. *amphi*, both; *bios*, life). The Frogs, Newts, and the like, which have gills when young, but can always breathe air directly when adult.
- AM-PHI-CŒ'LOUS** (Gr. *amphi*, at both ends; *koulos*, hollow). Applied to vertebræ which are concave at both ends.
- AM'PHI-DISCS** (Gr. *amphi*, at both ends; *diskos*, a quoit, or round plate). The spicula which surround the gemmules of *Spongilla*, and resemble two toothed wheels united by an axle.
- AM-PHI-OX'US** (Gr. *amphi*, at both ends; *oxus*, sharp). The Lancelet, a little fish, which alone constitutes the order *Pharyngobranchii*.
- AM-PHI-PNEUS'TA** (Gr. *amphi*, both; *pneo*, I breathe). Applied to the "perennibranchiate" Amphibians which retain their gills through life.
- AM-PHI-P'O-DA** (Gr. *amphi*; and *pous*, a foot). An order of *Crustacea*.
- A'NAL** (Lat. *anus*, the vent). Connected with the anus, or situated near the anus.
- AN-AL-LAN-TOID'E-A.** The group of *Vertebrata* in which the embryo is not furnished with an allantois.
- A-NAL'O-GOUS.** Applied to parts which perform the same function.
- AN-AM-NI-O'TA.** The group of *Vertebrata* in which the embryo is destitute of an amnion.
- AN-ARTH-RO-P'O-DA** (Gr. *a*, without; *arthros*, a joint; *pous*, foot). That division of *Annulose* animals in which there are no articulated appendages.
- ANCH-Y-LO'SIS** or **ANK-Y-LO'SIS** (Gr. *ankulos*, crooked). The union of two bones by osseous matter, so that they become one bone, or are immovably joined together.
- AN-DRO-G'Y-NOUS** (Gr. *anēr*, a man; *gune*, a woman). Synonymous with hermaphrodite, and implying that the two sexes are united in the same individual.
- AN'DRO-PHORES** (Gr. *anēr*, a man; and *phero*, I carry). Applied to medusiform gonophores of the *Hydrozoa*, which carry the spermatozoa, and differ in form from those in which the ova are developed.
- AN-NEL'I DA** (a Gallicised form of *Annulata*). The Ringed Worms, which form one of the divisions of the *Anarthropoda*.
- AN-NU-LA-TED.** Composed of a succession of rings.
- AN-NU-LOI'DA** (Lat. *annulus*, a ring; Gr. *eidōs*, form). The sub-kingdom comprising the *Echinodermata* and the *Scolecida* (= *Echinozoa*).
- AN-NU-LO'SA** (Lat. *annulus*). The sub-kingdom comprising the *Anarthropoda* and the *Arthropoda* or *Articulata*, in all of which the body is more or less evidently composed of a succession of rings.

- AN-O-MO-DON'TI-A** (Gr. *anomos*, irregular; *odous*, tooth). An extinct order of Reptiles, often called *Dicynodontia*.
- AN-O-MU'RA** (Gr. *anomos*, irregular; *oura*, tail). A tribe of Decapod *Crustacea*, of which the Hermit-crab is the type.
- AN-O-PLU'RA** (Gr. *anoplos*, unarmed; *oura*, tail). An order of Apterous Insects.
- Δ-NOU'RA** (Gr. *a*, without; *oura*, tail). The order of *Amphibia* comprising the Frogs and Toads, in which the adult is destitute of a tail. Often called *Batrachia*.
- AN-TEN'NÆ** (Lat. *antenna*, a yard-arm). The jointed horns or feelers possessed by the majority of the *Articulata*.
- AN-TEN'NULES** (dim. of *antennæ*). Applied to the smaller pair of antennæ in the *Crustacea*.
- AN'THRO-POID**.
- AN-TI-BRA'CHI-UM** (Gr. *anti*, in front of; *brachion*, the arm). The fore-arm of the higher Vertebrates, composed of the *radius* and *ulna*.
- ANT'LEERS**. Properly the branches of the horns of the Deer tribe (*Cervidæ*), but generally applied to the entire horns.
- AN'TLI-A** (Lat. *antlia*, a pump). The spiral trunk or proboscis with which Butterflies and other Lepidopterous Insects suck up the juices of flowers.
- APH-A-NIP'TE-RA** (Gr. *aphanos*, inconspicuous; *pteron*, a wing). An order of Insects comprising the Fleas.
- AP LA-CEN-TA-LI-A**. The section of the *Mammalia*, comprising the two divisions of the *Didelphia* and *Monodelphia*, in which the young is not furnished with a placenta.
- AP'O-DA** (Gr. *a*, without; *podes*, feet). Applied to those fishes which have no ventral fins. Also to the footless *Caciliæ* among the *Amphibia*.
- AP'O-DAL**. Devoid of feet.
- AP-O-DEM'A-TA** (Gr. *apodaio*, I portion off). Applied to certain chitinous septa which divide the tissues in *Crustacea*.
- AP'TE-RA** (Gr. *a*, without; *pteron*, a wing). A division of Insects, which is characterized by the absence of wings in the adult condition.
- AP'TER-OUS**. Devoid of wings.
- AP'TER-YX** (Gr. *a*, without; *pterus*, a wing). A wingless bird of New Zealand, belonging to the order *Cursores*.
- A-QUAT'IC**.
- A-QUIF'E-ROUS**.
- A-RACH'NI-DA** (Gr. *arachne*, a spider). A class of the *Articulata*, comprising Spiders, Scorpions, and allied animals.
- AR-A-NE'I-DA**.
- AR-BO-RES'CENT**. Branched like a tree.
- AR-CHÆ-OP'TE-RYX** (Gr. *archaios*, ancient; *pterus*, wing). The singular fossil bird which alone constitutes the order of the *Saururæ*.
- ARCH-EN-CEPH'A-LA** (Gr. *archo*, I overrule; *egkephalos*, brain). The name applied by Owen to his fourth and highest group of *Mammalia*, comprising Man alone.
- AR-E-NA'CE-OUS**. Sandy, or composed of grains of sand.
- AR-THROP'O-DA**.
- AR-TIC-U-LA'TA** (Lat. *articulus*, a joint). A division of the animal kingdom, comprising Insects, Centipedes, Spiders, and Crustaceans, characterized by the possession of jointed bodies or jointed limbs. The term *Arthropoda* is now more usually employed.
- AR-TI-O-DAC'TY-LA** (Gr. *artios*, even; *daktulos*, a finger or toe). A division of the hoofed quadrupeds (*Ungulata*) in which each foot has an even number of toes (two or four).
- AS-CID-I-OI'DA** (Gr. *askos*, a bottle; *eidōs*, a form). A synonym of *Tunicata*, a class of Molluscous animals, which have the shape, in many cases, of a two-necked bottle.
- A-SEX'U-AL**. Applied to modes of reproduction in which the sexes are not concerned.
- A-SIPH'O-NATE**. Not possessing a respiratory tube or siphon. (Applied to a division of the *Lamellibranchiate* Molluscs.)

- AS'TER-OID (Gr. *aster*, a star; and *eidōs*, form). Star-shaped, or possessing radiating lobes or rays like a star-fish.
- AS-TE-ROID'E-A. An order of *Echinodermata*, comprising the Star-fishes, characterized by their rayed form.
- A-STOM'A-TOUS (Gr. *a*, without; *stoma*, mouth). Not possessing a mouth.
- AR'LAS (Gr. the god who holds up the heavens). The first vertebra of the neck, which articulates with and supports the skull.
- A'TRI-UM (Lat. for a hall). Applied to the great chamber or "cloaca," into which the intestine opens in the *Tunicata*.
- AU-REL'LA (Lat. *aurum*, gold). Applied to the chrysalides of some *Lepidoptera*, on account of their exhibiting a golden lustre.
- AU'RI-CLE (Lat. dim. of *auris*, ear). Applied to one of the cavities of the heart, by which blood is driven into the ventricle.
- AU-TOPH'A-GI (Gr. *autos*, self; *phago*, I eat). Applied to birds whose young can run about and obtain food for themselves as soon as they escape from the egg.
- A'VES (Lat. *avis*, a bird). The class of the Birds.
- AV-I-CU-LA'RI-UM (Lat. *avicula*, dim. of *avis*, a bird). A singular appendage, often shaped like the head of a bird, found in many of the *Polyzoa*.
- AXIS (Gr. *axōn*, a pivot). The second vertebra of the neck, upon which the skull and atlas usually rotate.
- AZ'Y-GOS (Gr. *a*, without; *zeugon*, yoke). Single; without a fellow.
- BAC-TE'RI-UM (Gr. *bakterion*, a staff). A kind of staff-shaped filament which appears in organic infusions after they have been exposed to the air.
- BAL'AN-CERS.
- BA-LAN'I-DÆ (Gr. *balanos*, an acorn). A family of sessile *Cirripedes*, commonly called "Acorn-shells."
- BA-LEEN' (Lat. *balæna*, a whale). The horny plates which occupy the palate of the true or "whale-bone" Whales.
- BAT'I-DES (Gr. *battos*, a bramble). The family of the *Elasmobranchii*, comprising the Rays.
- BA-TRA'CHI-A (Gr. *batrachos*, a frog). Often loosely applied to any of the *Amphibia*, but sometimes restricted to the Amphibians as a class, or to the single order of the *Anoura*.
- BI'FID (Lat. *bis*, twice; *findo*, I cleave). Cleft into two parts; forked.
- BI-LAT'ER-AL (Lat. *bis*, twice; *latus*, a side). Having two symmetrical sides.
- BI-MA'NA (Lat. *bis*, twice; *manus*, a hand). The order of *Mammalia* comprising Man alone.
- BI'E-DAL (Lat. *bis*, twice; *pes*, foot). Walking upon two legs.
- BI-RA'MOUS (Lat. *bis*, twice; *ramus*, a branch). Applied to a limb which is divided into two branches (*e. g.*, the limbs of *Cirripedes*).
- BI'VALVE (Lat. *bis*, twice; *valvæ*, folding-doors). Composed of two plates or valves; applied to the shell of the *Lamellibranchiata* and *Brachiopoda*, and of the carapace of certain *Crustacea*.
- BLAS-TOID'E-A (Gr. *blastos*, a bud; and *eidōs*, form). An extinct order of *Echinodermata*, often called *Pentremites*.
- BRACH-I-OP'O-DA (Gr. *brachion*, an arm; *pous*, the foot). A class of the *Mollusca*, often called "Lamp-shells," characterized by possessing two fleshy arms continued from the sides of the mouth.
- BRACH'UM (Gr. *brachion*, arm). Applied to the upper arm of Vertebrates.
- BRACH-Y-U'RA (Gr. *brachus*, short; *oura*, tail). A tribe of the Decapod *Crustaceans* with short tails (*i. e.*, the Crabs).
- BRAC'TS. (See *Hydrophyllia*.)
- BRAD-Y-POD'I-DÆ (Gr. *bradus*, slow; *podes*, feet). The family of *Edentata* comprising the Sloths.
- BRANCH'I-A (Gr. *bragchia*, the gills of fishes). A respiratory organ adapted to breathe air dissolved in water.
- BRANCH'I-ATE. Possessing gills or branchiæ.
- BRAN-CHIF'E-RA (Gr. *bragchia*, gills; and *phero*, I carry). A division of *Gas-*

- teropodous Molluscs*, in which the respiration is aquatic, and the respiratory organs are mostly in the form of distinct gills.
- BRANCH-I-O-GAS-TE-ROF'O-DA (= Branchifera).
- BRAN-CHI-OP'O-DA (Gr. *bragchia*; and *pous*, foot). A legion of *Crustacea*, in which the gills are supported by the feet.
- BRAN-CHI-OS'TE-GAL (Gr. *bragchia*, gills; *stego*, I cover). Applied to a membrane and rays by which the gills are protected in many fishes.
- BREV-I-LIN'GUI-A (Lat. *brevis*, short; *lingua*, tongue). A division of the *Lacertilia*.
- BREV-I-PEN-NA'TÆ (Lat. *brevis*, short; *penna*, a wing). A group of the *Natorial* Birds.
- BRONCH'I (Gr. *bragchos*, the windpipe). The branches of the windpipe (*trachea*), by which the air is conveyed to the vesicles of the lung.
- BRU'TA (Lat. *brutus*, heavy, stupid). Often used to designate the *Mammalian* order of the *Edentata*.
- BRY-O-ZO'A (Gr. *bruon*, moss; *zo'n*, animal). A synonym of *Polyzoa*, a class of the *Molluscoidea*.
- BUC'CAL (Lat. *bucca*, mouth or cheeks). Connected with the mouth.
- BUE'SI-FORM (Lat. *bursa*, a purse; *forma*, shape). Shaped like a purse; sub-spherical.
- BYS-SIF'E-ROUS. Producing a byssus.
- BYS'SUS (Gr. *bussos*, flax). A term applied to the silky filaments by which the *Pinna*, the common Mussel, and certain other bivalve *Mollusca*, attach themselves to foreign objects.
- CA-DU-CI-BRANCH'I-ATE (Lat. *caducus*, falling off; Gr. *bragchia*, gills). Applied to those *Amphibians* in which the gills fall off before maturity is reached.
- CA-DU'CIOUS. Applied to parts which fall off or are shed during the life of the animal.
- CÆ'CAL (Lat. *cæcus*, blind). Terminating blindly, or in a closed extremity.
- CÆ'CUM (Lat. *cæcus*). A tube which terminates blindly.
- CÆS'PI-TOSE (Lat. *cæspes*, a turf). Tufted.
- CAI-NO-ZO'IC. (See *Kainozoic*.)
- CAL'CAR (Lat. for a spur). Applied to the "spurs" of *Rasorial* Birds; and also to the rudiments of the hind limbs in certain Snakes.
- CAL-CA'RE-OUS (Lat. *calx*, lime). Composed of carbonate of lime.
- CAL'ICE. The little cup in which the polype of a coralligenous *Zoophyte* (*Actinozo'n*) is contained.
- CAL-Y-CO-PHOR'I-DÆ (Gr. *kalux*, a cup; and *phero*, I carry). An order of the oceanic *Hydrozoa*, so called from their possessing bell-shaped swimming organs (*nechocalyces*).
- CA'LYX (Lat. *calyx*, a cup). Applied to the cup-shaped body of *Vorticella* (*Protozoa*), or of a *Crinoid* (*Echinodermata*).
- CAM-PAN-U-LAR'I-DÆ (Lat. *campanula*, a little bell). An order of *Hydroid Zoöphytes*.
- CA-NINE' (Lat. *canis*, a dog). The eye-tooth of *Mammals*, or the tooth which is placed at or close to the premaxillary suture in the upper jaw, and the corresponding tooth in the lower jaw.
- CA-PIT'U-LUM (Lat. dim. of *caput*, head). Applied to the body of a *Barnacle* (*Lepadidæ*), from its being supported upon a stalk or peduncle.
- CAR'A-PACE. A protective shield. Applied to the upper shells of *Crabs*, *Lobsters*, and many other *Crustacea*; also to the case with which certain of the *Infusoria* are provided. Also the upper half of the immovable case in which the body of a *Chelonian* is protected.
- CAR-I-NA'TÆ (Lat. *carina*, a keel). Applied by Huxley to all those birds in which the sternum is furnished with a median ridge or keel.
- CAR-NIV'O-RA (Lat. *caro*, flesh; *voro*, I devour). An order of the *Mammalia*.
- CAR-NIV'O-ROUS (Lat. *caro*, flesh; *voro*, I devour). Feeding upon flesh.
- CAR'NOSE (Lat. *caro*). Fleishy.
- CAR-POPH'A-GA (Gr. *karpos*, fruit; *phago*, I eat). A section of the *Marsupialia*.

- CAR'PUS (Gr. *karpōs*, the wrist). The small bones which intervene between the fore-arm and the metacarpus.
- CA-TAR'RHIN-A (Gr. *kata*, downward; *rhines*, nostrils). A group of the *Quadrupana*.
- CAU'DAL (Lat. *cauda*, the tail). Belonging to the tail.
- CAV-I-COR'NI-A (Lat. *cavus*, hollow; *cornu*, a horn). The "hollow-horned" Ruminants, in which the horn consists of a central bony "horn-core" surrounded by a horny sheath.
- CEN'TRUM (Gr. *kentron*, the point round which a circle is described by a pair of compasses). The central portion or "body" of a vertebra.
- CĒ-PHAL'IC (Gr. *kephale*, head). Belonging to the head.
- CEPH-A-LO-BRANCH'I-ATE (Gr. *kephale*; and *bragchia*, gills). Carrying gills upon the head. Applied to a section of the *Annelida*, which, like the *Serpulæ*, have tufts of external gills placed upon the head.
- CEPH-A-LOPH'O-RA (Gr. *kephale*; and *phero*, I carry). Used synonymously with *Encephala*, to designate those *Mollusca* which possess a distinct head.
- CEPH-A-LOP'O-DA (Gr. *kephale*; and *podes*, feet). A class of the *Mollusca*, comprising the Cuttle-fishes and their allies, in which there is a series of arms ranged round the head.
- CĒPH-A-LO-THO'RAX (Gr. *kephale*; and *thorax*, chest). The anterior division of the body in many *Crustacea* and *Arachnida*, which is composed of the coalesced head and chest.
- CERE. The naked space found at the base of the bill of some birds.
- CER'E-BRAL.
- CER'E-BRUM.
- CER'VI-CAL (Gr. *cervix*, neck). Connected with the region of the neck.
- CES-TOID'E-A (Gr. *kestos*, a girdle). An old name for the *Tæniada*, a class of intestinal worms with flat bodies like tape (hence the name Tapeworms).
- CES-TRAPH'O-RI (Gr. *kestra*, a weapon; *phero*, I carry). The group of *Elasmobranchii* represented at the present day by the Port Jackson Shark.
- CE-TA'CE-A (Gr. *kētos*, a whale). The order of Mammals comprising the Whales and Dolphins.
- CHÆ-TOG'NA-THA (Gr. *chaite*, bristle; *gnothos*, jaw). An order of the *Anarthropoda*, comprising only the oceanic genus *Sagitta*.
- CHEI-ROP'TER-A (Gr. *cheir*, hand; *pteron*, a wing). The order of Mammals comprising the Bats.
- CHE'LE (Gr. *chele*, a claw). The prehensile claws with which some of the limbs are terminated in certain *Crustacea*, such as the Crab, Lobster, etc.
- CHE'LTE. Possessing chelæ; applied to a limb.
- CHE-LIC'E-RÆ (Gr. *chele*, a claw; and *keras*, a horn). The prehensile claws of the Scorpion, supposed to be homologous with antennæ.
- CHE-LO'NI-A (Gr. *chelone*, a tortoise). The order of Reptiles comprising the Tortoises and Turtles.
- CHE-LO-NO-BA-TRA'CHI-A (Gr. *chelone*, a tortoise; *batrachos*, a frog). Sometimes applied to the Amphibian order of the *Anoura* (Frogs and Toads).
- CHI-LOG'NA-THA (Gr. *cheilos*, a lip; and *gnathos*, a jaw). An order of the *Myriapoda*.
- CHI-LOP'O-DA (Gr. *cheilos*; and *podes*, feet). An order of the *Myriapoda*.
- CHI'TINE (Gr. *chiton*, a coat). The peculiar chemical principle, nearly allied to horn, which forms the exoskeleton in many Invertebrate animals, especially in the *Arthropoda* (*Crustacea*, *Insecta*, etc.).
- CHLO'RO-PHYLL (Gr. *chloros*, green; and *phyllon*, a leaf). The green coloring matter of plants.
- CHRO-MAT'O-PHORES (Gr. *chroma*, complexion, or color; and *phero*, I carry). Little sacs which contain pigment-granules, and are found in the integument of Cuttle-fishes.
- CHRY'SA-LIS (Gr. *chrysos*, gold). The motionless pupa of butterflies and moths, so called because sometimes exhibiting a golden lustre.
- CHY-LA'QUE-OUS FLUID. A fluid consisting partly of water derived from the exterior, and partly of the products of digestion (chyle), occupying the body-cavity or perivisceral space in many Invertebrates (*Annelides*, *Echino-*

- derms*, etc.), and sometimes having a special canal-system for its conduction (chylaqueous canals).
- CHYLE** (Gr. *chulos*, juice). The milky fluid which is the result of the action of the various digestive fluids upon the food.
- CHY-LIF'IC** (Gr. *chulos*, juice [chyle]; and Lat. *facio*, I make). Producing chyle. Applied to one of the stomachs, when more than one is present. The word is of mongrel origin; and "chylopoëtic" is more correct.
- CHYME** (Gr. *chumos*, juice). The acid, pasty fluid produced by the action of the gastric juice upon the food.
- CHYME-MASS**. The central, semi-fluid sarcode in the interior of an *Infusorian*.
- CIL-I-A** (Lat. *cilium*, an eyelash). Microscopic, hair-like filaments, which have the power of lashing backward and forward, thus creating currents in the surrounding or contiguous fluid, or subserving locomotion in the animal which possesses them.
- CIL-I-O-GRÁ'DA** (Lat. *cilium*; and *gradior*, I walk). Synonymous with *Ctenophora*, an order of *Actinozoa*.
- CIN'CLI-DES** (Gr. *kikkis*, a lattice). Special apertures in the column-walls of some Sea-anemones (*Actinia*), which probably serve for the emission of the cord-like "craspeda."
- CIR'RI** (Lat. *cirrus*, a curl). Tendril-like appendages, such as the feet of Barnacles and Acorn-shells (*Cirripedes*), the lateral processes on the arms of *Brachiopoda*, etc.
- CIR-RIF'ER-ous** or **CIR-RIG'ER-ous**. Carrying cirri.
- CIR-RI-PE'DIA**, **CIR-RHI-PE'DI-A**, or **CIR-RHOP'O-DA** (Lat. *cirrus*, a curl; and *pes*, a foot). A sub-class of *Crustacea* with curled jointed feet.
- CIR-ROS'TO-MI** (Lat. *cirrus*, a tendril; Gr. *stoma*, mouth). Sometimes used to designate the *Pharyngobranchii*.
- CLA-DOC'E-RA** (Gr. *klados*, a branch; *keras*, a horn). An order of *Crustacea* with branched antennæ.
- CLA'VATE** (Lat. *clavus*, a club). Club-shaped.
- CLAV'I-CLE** (Lat. *clavicula*, a little key). The "collar-bone," forming one of the elements of the pectoral arch of Vertebrates.
- CLO-A'CA** (Lat. for a sink). The cavity into which the intestinal canal and the ducts of the generative and urinary organs open in common, in some Invertebrates (e. g., in Insects), and also in many Vertebrate animals.
- CLYP'E-I-FORM** (Lat. *clypeus*, a shield; and *forma*, shape). Shield-shaped; applied, for example, to the carapace of the King-crab.
- CNI'DÆ** (Gr. *knide*, a nettle). The urticating cells, or "thread-cells," whereby many *Cœlenterate* animals obtain their power of stinging.
- COC'CO-LITHS** (Gr. *kokkos*, a berry; *lithos*, stone). Minute oval or rounded bodies, which are found either free or attached to the surface of *coccospheres*.
- COC'CO-SPHERES** (Gr. *kokkos*; and *sphaira*, a sphere). Spherical masses of sarcode, enclosed in a delicate calcareous envelope, and bearing *coccoliths* upon their external surface. Both *coccospheres* and *coccoliths* are embedded in a diffused plasmodium of sarcode, the whole constituting a low *Rhizopodic* organism.
- COC-CYGE-AL**. Connected with the coccyx.
- COC'CYX** (Gr. *kokkuz*, a cuckoo). The terminal portion of the spinal column in man, so called from its resemblance to a cuckoo's beak.
- CO-COON'** (French *cocon*, the cocoon of the silk-worm; connected with Fr. *coque*, shell, which is derived from the Lat. *concha*). The outer covering of silky hairs with which the pupa or chrysalis of many insects is protected.
- CO-DO-NOS'TO-MA** (Gr. *kodon*, a bell; *stoma*, mouth). The aperture or mouth of the disc (nechocalyx) of a *Medusa*, or of the bell (gonocalyx) of a medusi-form gonophore.
- CÆ-LEN-TE-RA'TA** (Gr. *koilos*, hollow; *enteron*, the bowel). The sub-kingdom which comprises the *Hydrozoa* and *Actinozoa*. Proposed by Frey and Leuckhart in place of the old term *Radiata*, which included other animals as well.
- CÆ-NEN'CHY-MA** (Gr. *koinos*, common; *egchuma*, tissue). The common cal-

- careous tissue which unites together the various corallites of a compound corallum.
- Cœ-NGE'CI-UM (Gr. *koinos*, common; *oikos*, house). The entire dermal system of any *Polyzoa*; employed in place of the terms polyzoary or polypidom.
- CœN'O-SARC (Gr. *koinos*, common; *sarx*, flesh). The common organized medium by which the separate polypites of a compound *Hydrozoa* are connected together.
- COL-E-OP'TER-A (Gr. *koleos* a sheath; *pteron*, wing). The order of Insects (Beetles) in which the anterior pair of wings are hardened, and serve as protective cases for the posterior pair of membranous wings.
- COL-U-BRI'NA (Lat. *coluber*, a snake). A division of the *Ophidia*.
- COL-UM-BA'CE-I (Lat. *columba*, a dove). The division of Rasorial Birds comprising the Doves and Pigeons.
- COL-U-MEL'LA (Lat. dim. of *columna*, a column). In Conchology, the central axis round which the whorls of a spiral univalve are wound. Amongst the *Actinozoa*, it is the central axis or pillar which is found in the centre of the thecæ of many corals.
- COL'UMN. Applied to the cylindrical body of a Sea-anemone (*Actinia*); also to the jointed stem or peduncle of the stalked *Crinoids*.
- COM-MIS'SU-RAL (Lat. *committo*, I solder together). Connecting together; usually applied to the nerve-fibres which unite different ganglia.
- CON'CHA (Lat. for a shell). The external ear by which sounds are collected and transmitted to the internal ear.
- CON-CHIF'E-RA (Lat. *concha*, a shell; *fero*, I carry). Shell-fish. Applied in a restricted sense to the bivalve Molluscs, and used as a synonym for *Lamelli-branchiata*.
- CON'DYLE (Gr. *kondulos*, a knuckle). The surface by which one bone articulates with another. Applied especially to the articular surface or surfaces by which the skull articulates with the vertebral column.
- CON-I-ROS'TRES (Lat. *conus*, a cone; *rostrum*, a beak). The division of Perching Birds with conical beaks.
- CO PEP'O-DA (Gr. *kope*, an oar; *podes*, feet). An order of *Crustacea*.
- COR'A-COID (Gr. *korax*, a crow; *eidōs*, form). One of the bones which enters into the composition of the pectoral arch in Birds, Reptiles, and Monotremes. In most Mammals it is a mere process of the scapula, having, in man, some resemblance in shape to the beak of a crow.
- COR-AL-LIG'EN-OUS. Producing a corallum.
- COR'AL-LITE. The corallum secreted by an *Actinozoa* which consists of a single polype; or the portion of a composite corallum which belongs to, and is secreted by, an individual polype.
- COR-AL'LUM (from the Latin for red coral). The hard structures deposited in, or by, the tissues of an *Actinozoa*—commonly called a "coral."
- CO-RI-A CEUS (Lat. *corium*, hide). Leathery.
- COR'PUS CAL-LO'SUM (Lat. for the "firm body"). The great band of nervous matter which unites the two hemispheres of the cerebrum in the Mammals.
- COR-PUS'CU-LA-TED (Lat. *corpusculum*, a little body or particle). Applied to fluids which, like the blood, contain floating solid particles or "corpuscles."
- CORTI-CAL LAY'ER. The layer of consistent sarcode, which in the *Infusoria* encloses the chyme mass, and is surrounded by the cuticle. Sometimes called the "parenchyma of the body."
- CO-RYN'IDA.
- COS'TÆ (Lat. *costa*, a rib). Applied amongst the *Crinoidea* to designate the rows of plates which succeed the inferior or basal portion of the cup (pelvis). Among the *Corals* the "costæ" are vertical ridges which occur on the outer surface of the theca, and mark the position of the septa within.
- COS'TAL (Lat. *costa*, a rib). Connected with the ribs.
- CRA'NI-UM (Gr. *kranion*, the skull). The bony or cartilaginous case in which the brain is contained.
- CRA'SPE-DA (Gr. *kraspedon*, a margin or fringe). The long, convoluted cords, containing thread-cells, which are attached to the free margins of the mesenteries of a Sea-anemone.

- CRE-PUS'CU-LAR** (Lat. *crepusculum*, dusk). Applied to animals which are active in the dusk or twilight.
- CRI-NOI'DE-A** (Gr. *krinon*, a lily; *eidōs*, form). An order of *Echinodermata*, comprising forms which are usually stalked, and sometimes resemble lilies in shape.
- CROC-O-DIL'IA** (Gr. *krokodeilos*, a crocodile). An order of Reptiles.
- CROP.** A partial dilatation of the gullet, technically called "ingluvies."
- CRUS-TA'CE-A** (Lat. *crusta*, a crust). A class of articulate animals, comprising Crabs, Lobsters, etc., characterized by the possession of a hard shell or crust, which they cast periodically.
- CTEN'O-CYST** (Gr. *kteis*, a comb; *kustis*, a bag or cyst). The sense-organ (probably auditory) which occurs in the *Ctenophora*.
- CTE'NOID** (Gr. *kteis*, a comb; *eidōs*, form). Applied to those scales of fishes, the hinder margins of which are fringed with spines or comb-like projections.
- CTE-NOPH'O-RA** (Gr. *kteis*, a comb; and *phero*, I carry). An order of *Actinozoa*, comprising oceanic creatures, which swim by means of "ctenophores," or bands of cilia arranged in comb-like plates.
- CUR-SO'RES** (Lat. *curro*, I run). An order of *Aves*, comprising birds destitute of the power of flight, but formed for running vigorously (e. g., the Ostrich and Emu).
- CUS'PI-DATE.** Furnished with small pointed eminences or "cusps."
- CU'TI-CLE** (Lat. *cuticula*, dim. of *cutis*, skin). The pellicle which forms the outer layer of the body among the *Infusoria*. The outer layer of the integument generally.
- CU'TIS** (Lat. for skin). The inferior vascular layer of the integument, often called the *cutis vera*, the *corium*, or the *derma*.
- CY'CLOID** (Gr. *kuklos*, a circle; *eidōs*, form). Applied to those scales of fishes which have a regularly circular or elliptical outline with an even margin.
- CY-CLOS'TO-MI.** Sometimes used to designate the Hag-fishes and Lampreys, forming the order *Marsipobranchii*.
- CYST** (Gr. *kustis*, a bladder or bag). A sac or vesicle.
- CYS'TIC.**
- CYS'TI-CA.** The embryonic forms (scolices) of certain intestinal worms (Tapeworms), which were described as a distinct order, until their true nature was discovered.
- CYS-TOI'DE-A** (Gr. *kustis*, a bladder; and *eidōs*, form). An extinct order of *Echinodermata*.
- DE-CAP'O-DA** (Gr. *deka*, ten; *podes*, feet). The division of *Crustacea* which have ten ambulatory feet; also the family of Cuttle-fishes, in which there are ten arms or cephalic processes.
- DE-CID'U-OUS** (Lat. *decido*, I fall off). Applied to parts which fall off or are shed during the life of the animal.
- DE-COL'LA-TED** (Lat. *decollo*, I behead). Applied to univalve shells, the apex of which falls off in the course of growth.
- DEI-NO-SAU'RI-A** (Gr. *deinos*, terrible; *saura*, lizard). An extinct order of Reptiles.
- DEN'DRI-FORM, DEN-DRI'TIC, DEN'DROID** (Gr. *dendron*, a tree). Branched like a tree, arborescent.
- DEN'TAL.**
- DEN-TI-ROS'TRES** (Lat. *dens*, a tooth; *rostrum*, a beak). The group of Perching Birds in which the upper mandible of the beak has its lower margin toothed.
- DER'MA.** (See *Cutis*.)
- DER'MAL** (Gr. *derma*, skin). Belonging to the integument.
- DER-MO-SCLE'RITES** (Gr. *derma*, skin; *skleros*, hard). Masses of spicules which occur in the tissues of some of the *Acyonida* (*Actinozoa*).
- DES-MID'I-Æ.** Minute fresh-water plants, of a green color, without a siliceous epidermis.
- DEU-TER-O-ZO'IDS** (Gr. *deuteros*, second; *zō'n*, animal; *eidōs*, form). The zooids which are produced by gemmation from zooids.

- DEX'TRAL** (Lat. *dextra*, the right hand). Right-handed; applied to the direction of the spiral in the greater number of univalve shells.
- DI'A-PHRAGM** (Gr. *diaphragma*, a partition). The "midriff," or the muselo which in *Mammalia* forms a partition between the cavities of the thorax and abdomen.
- DI-A-STE' MA** (Gr. *dia*, apart; *histemi*, to place). A gap or interval, especially between teeth.
- DI-AS'TO-LE** (Gr. *diastello*, I separate or expand). The expansion of a contractile cavity such as the heart, which follows its contraction or "systole."
- DI-A-TO-MA' CE-E** (Gr. *diatemo*, I sever). An order of minute plants, which are provided with siliceous envelopes.
- DI-BRANCH-I-A'TA** (Gr. *dis*, twice; *bragchia*, gills). The order of *Cephalopoda* (comprising the Cuttle-fishes, etc.), in which only two gills are present.
- DI-CYN-O-DON'TI-A** (Gr. *dis*, twice; *kuon*, dog; *odous*, tooth). An extinct order of Reptiles.
- DI-DEL' PHI-A** (Gr. *dis*, twice; *delphus*, womb). The subdivision of Mammals comprising the Marsupials.
- DIG'IT** (Lat. *digitus*, a finger). A finger or toe.
- DIG-I-TI-GR'A'DA** (Lat. *digitus*; *gradior*, I walk). A subdivision of the *Carnivora*.
- DIG'I-TI-GRADE**. Walking upon the tips of the toes, and not upon the soles of the feet.
- DIM-E-RO-SO'MA-TA** (Gr. *dis*; *meros*, part; *soma*, body). An order of *Arachnida*, comprising the true Spiders, so called from the marked division of the body into two regions, the cephalothorax and abdomen. The name *Araneida* is often employed for the order.
- DIM'Y-A-RY** (Gr. *dis*, twice; *mus*, muscle). Applied to those bivalve Molluscs (*Lamellibranchiata*) in which the shell is closed by two adductor muscles.
- DI-E'CIOUS** (Gr. *dis*, twice; *oikos*, house). Having the sexes distinct; applied to species which consist of male and female individuals.
- DIPH'Y-O-DONT** (Gr. *dis*, twice; *phuo*, I generate; *odous*, tooth). Applied to those Mammals which have two sets of teeth.
- DIPH'Y-O-ZO'OIDS**. Detached reproductive portions of adult *Calycephoridae*, an order of oceanic *Hydrozoa*.
- DIP'NOI** (Gr. *dis*, twice; *pnos*, breath). The order of Fishes represented by the *Lepidosiren*.
- DIP'TER-A** (Gr. *dis*, twice; *pteron*, wing). An order of Insects characterized by the possession of two wings.
- DISC'OID** (Gr. *diskos*, a quoit; *eidon*, form). Shaped like a round plate or quoit.
- DIS-COPH'O-RA** (Gr. *diskos*, a quoit; *phero*, I carry). This term is applied to the *Medusae*, or Jelly-fishes, from their form; and is sometimes used to designate the order of the Leeches (*Hirudinea*), from the suckorial discs which these animals possess.
- DIS-SEP'I-MENTS** (Lat. *dissepio*, I partition off). Partitions. Used in a restricted sense to designate certain imperfect transverse partitions, which grow from the septa of many corals.
- DIS'TAL**. Applied to the quickly-growing end of the hydrosoma of a *Hydrozoon*; the opposite, or "proximal," extremity growing less rapidly, and being the end by which the organism is fixed, when attached at all.
- DI-U'NAL** (Lat. *dies*, day). Applied to animals which are active during the day.
- DI-VER-TIC'U-LUM** (Lat. *diverticulum*, a by-road). A lateral tube with a blind extremity springing from the side of another tube.
- DOR'SAL** (Lat. *dorsum*, back). Connected with the back.
- DOR-SI-BRANCH-I-ATE** (Lat. *dorsum*, the back; Gr. *bragchia*, gills). Having external gills attached to the back; applied to certain *Annelides* and *Molluscs*. The term is of mongrel composition, and "notobranchiate" is more correctly employed.
- EC'DE-RON** (Gr. *ek*, out; *deros*, skin). The outer plane of growth of the external integumentary layer (viz., the ectoderm, or epidermis).

- EC'DY-SIS** (Gr. *ekdusis*, a stripping off). A shedding or moulting of the skin.
- E-CHI-NO-OCO'CI** (Gr. *echinos*, a hedgehog; *kokkos*, a berry). The larval forms (scolices) of the tapeworm of the dog (*Tenia echinococcus*), commonly known as "hydatids."
- E-CHI-NO-DER'MA-TA** (Gr. *echinos*; and *derma*, skin). A class of animals comprising the Sea-urchins, Star-fishes, and others, most of which have spiny skins.
- E-CHI-NOI'DE-A** (Gr. *echinos*; and *eidos*, form). An order of *Echinodermata*, comprising the Sea-urchins.
- E-CHIN'U-LATE**. Possessing spines.
- EC'TO-CYST** (Gr. *ektos*, outside; *kustis*, a bladder). The external investment of the coenocium of a *Polyzo'n*.
- EC'TO-DERM** (Gr. *ektos*; and *derma*, skin). The external integumentary layer of the *Cœlenterata*.
- EC'TO-SARC** (Gr. *ektos*; *sarx*, flesh). The outer transparent sarcode-layer of certain *Rhizopods*, such as the *Amœba*.
- E-DEN-TA'TA** (Lat. *e*, without; *dens*, tooth). An order of *Mammalia* often called *Bruta*.
- E-DEN-TU-LOUS**. Toothless; without any dental apparatus. Applied to the mouth of any animal, or to the hinge of the bivalve Molluscs.
- E-DRI-OPH-THAL'MA-TA** (Gr. *hedraios*, sitting; *ophthalmos*, eye). The division of *Crustacea* in which the eyes are sessile, and are not supported upon stalks.
- E-LAS-MO-BRANCH'I-I** (Gr. *elasma*, a plate; *brachia*, gills). An order of Fishes, including the Sharks and Rays.
- EL'Y-TRA** (Gr. *elutro*, a sheath). The chitinous anterior pair of wings in Beetles, which form cases for the posterior membranous wings. Also applied to the scales or plates on the back of the Sea-mouse (*Aphrodite*).
- EM'BRY-O** (Gr. *en*, in; *bruo*, I swell). The earliest stage at which the young animal is recognizable in the impregnated ovum.
- EN-CEPH'A-LON** (Gr. *egkephalos*, brain). The portion of the cerebro-spinal nervous axis contained within the cranium.
- EN-CEPH'A-LOUS** (Gr. *en*, in; *kephale*, the head). Possessing a distinct head. Usually applied to all the *Mollusca* proper, except the *Lamellibranchiata*.
- EN-CYS-TA TION** (Gr. *en*, in; *kustis*, a bag). The transformation undergone by certain of the *Protozoa*, when they become motionless, and surround themselves by a thick coating or cyst.
- EN'DE-RON** (Gr. *en*, in; *deros*, skin). The inner plane of growth of the outer integumentary layer (viz., the ectoderm, or epidermis).
- EN'DO-CYST** (Gr. *endon*, within; *kustis*, a bag). The inner membrane or integumentary layer of a *Polyzo'n*. In *Cristatella*, where there is no "ectocyst," the endocyst constitutes the entire integument.
- EN'DO-DERM** (Gr. *endon*; and *derma*, skin). The inner integumentary layer of the *Cœlenterata*.
- EN'DO'O-DITE** (Gr. *endon*; and *pous*, foot). The inner of the two secondary joints into which the typical limb of a *Crustacean* is divided.
- EN'DO-SARC** (Gr. *endon*; and *sarx*, flesh). The inner molecular layer of sarcode in the *Amœba* and other allied *Rhizopods*.
- EN'DO-SKEL'E-TON** (Gr. *endon*; and *skeletos*, dry). The internal hard structures, such as bones, which serve for the attachment of muscles, or the protection of organs, and which are not a mere hardening of the integument.
- EN'SI-FORM** (Lat. *ensis*, a sword; *forma*, shape). Sword shaped.
- EN-TO-MOPH'A-GA** (Gr. *entoma*, insects; *phago*, I eat). A section of the *Mar-supialia*.
- EN-TO-MOS'TRA-KA** (Gr. *entoma*, insects; *ostrakon*, a shell). Literally, shelled insects—applied to a division of *Crustacea*.
- EN-TO-ZO'A** (Gr. *entos*, within; *zo'n*, animal). Animals which are parasitic in the interior of other animals.
- E'O-CENE** (Gr. *eos*, dawn; *kainos*, new or recent). The lowest division of the Tertiary rocks, in which species of existing shells are to a small extent represented.

- EP-I-DER'MIS (Gr. *epi*, upon; *derma*, the true skin). The outer non-vascular layer of the skin, often called the scarf-skin or *cuticle*.
- EP-I-ME'RA (Gr. *epi*, upon; *mēron*, thigh). The lateral pieces of the dorsal arc of the somite of a *Crustacean*.
- EP-I-PO'DI-A (Gr. *epi*, upon; *pous*, the foot). Muscular lobes developed from the lateral and upper surfaces of the "foot" of some *Mollusca*.
- E-PIP'O-DITE (Gr. *epi*, upon; *pous*, foot). A process developed upon the basal joint, or "protopodite," of some of the limbs of certain *Crustacea*.
- EP-I-STER'NA (Gr. *epi*, upon; *sternon*, the breast-bone). The lateral pieces of the inferior or ventral arc of the somite of a *Crustacean*.
- EP'I-STOME (Gr. *epi*; and *stoma*, mouth). A valve-like organ which arches over the mouth in certain of the *Polyzoa*.
- EP-I-THE'CA (Gr. *epi*; and *theke*, a sheath). A continuous layer surrounding the thecae in some Corals, and being the external indications of tabulæ.
- EP-I-ZO'A (Gr. *epi*, upon; *zōon*, animal). Animals which are parasitic upon other animals. In a restricted sense, a division of *Crustacea* which are parasitic upon fishes.
- E-QUI-LAT'ER-AL (Lat. *æquus*, equal; *latus*, side). Having its sides equal. Usually applied to the shells of the *Brachiopoda*. When applied to the spiral shells of the *Foraminifera*, it means that all the convolutions of the shell lie in the same plane.
- E'QUI-VALVE (Lat. *æquus*, equal; *valvæ*, folding-doors). Applied to shells which are composed of two equal pieces or valves.
- ER-RAN'TI-A (Lat. *erro*, I wander). An order of *Annelida*, often called *Nereidea*, distinguished by their great locomotive powers.
- EU-RYP-TEE'I-DA (Gr. *eurus*, broad; *pteron*, wing). An extinct sub-order of *Crustacea*.
- EX-OP'O-DITE (Gr. *exo*, outside; *pous*, foot). The outer of the two secondary joints into which the typical limb of a *Crustacean* is divided.
- EX-O-SKEL'E-TON (Gr. *exo*, outside; *skeletos*, dry). The external skeleton, which is constituted by a hardening of the integument, and is often called a "dermoskeleton."
- FAS-CIO'U-LA-TED (Lat. *fasciculus*, a bundle). Arranged in bundles.
- FAU'NA (Lat. *Fauni*, the rural deities of the Romans). The general assemblage of the animals of any region or district.
- FE'MUR. The thigh-bone, intervening between the pelvis and the bones of the leg proper (*tibia* and *fibula*).
- FIB'U-LA (Lat. a brooch). The outermost of the two bones of the leg in the higher *Vertebrata*; corresponding to the *ulna* of the fore-arm.
- FIL'I-FORM (Lat. *filum*, a thread; *forma*, shape). Thread-shaped.
- FIS-SI-LIN'GUI-A (Lat. *findo*, I cleave; *lingua*, tongue). A division of *Lacerilia*, with bifid tongues.
- FIS'SION (Lat. *findo*, I cleave). Multiplication by means of a process of self-division.
- FIS-SIP'A-ROUS (Lat. *findo*; and *pario*, I produce). Giving origin to fresh structures by a process of fission.
- FIS-SI-ROS'TRES (Lat. *findo*, I cleave; *rostrum*, beak). A sub-order of the Perching Birds.
- F'LA-GEL'UM (Lat. for whip). The lash-like appendage exhibited by many *Infusoria*, which are therefore said to be "flagellate."
- FLO'RA (Lat. *Flora*, the goddess of flowers). The general assemblage of the plants of any region or district.
- FOOT.
- FOOT-JAWS. The limbs of *Crustacea*, which are modified to subserve mastication.
- FOOT-SE CRE'TION. The term applied by Mr. Dana to the sclerobasic corallum of certain *Actinozoa*.
- FOOT-TU'BER-CLES. The unarticulated appendages of the *Annelida*, often called parapodia.
- FO-RAM-I-NIF'E-RA (Lat. *foramen*, an aperture; *fero*, I carry). An order of

Protozoa, usually characterized by the possession of a shell perforated by numerous pseudopodial apertures.

FRU-GIV'O-ROUS (Lat. *frux*, fruit; *voro*, I devour). Living upon fruits.

FUN'NEL.

FUR'OU-LUM (Lat. dim. of *furca*, a fork). The "merry-thought" of birds, or the V-shaped bone formed by the united clavicles.

FU'SI-FORM (Lat. *fusus*, a spindle; and *forma*, shape). Spindle-shaped, or pointed at both ends.

GAL-LI-NA'CE-I (Lat. *gallina*, a fowl). Sometimes applied to the whole order of the Rasorial Birds, but properly restricted to that section of the order of which the common Fowl is a typical example.

GAN'GLI-ON (Gr. *gagglion*, a knot). A mass of nervous matter containing nerve-cells, giving origin to nerve-fibres.

GA'NOID (Gr. *ganos*, splendor, brightness). Applied to those scales or plates which are composed of an inferior layer of true bone covered by a superior layer of polished enamel.

GA-NOI'DE-A. An order of Fishes.

GAS-TE-RO-P'O-DA (Gr. *gaster*, stomach; *pous*, foot). The class of the *Mollusca* comprising the ordinary univalves, in which locomotion is usually effected by a muscular expansion of the under surface of the body (the "foot").

GEM'MÆ (Lat. *gemma*, a bud). The buds produced by any animal, whether detached or not.

GEM-MA'TION. The process of producing new structures by budding.

GEM-MIF'AR-OUS (Lat. *gemma*, a bud; *pario*, I produce). Giving origin to new structures by a process of budding.

GEM'MULES (Lat. dim. of *gemma*). The ciliated embryos of many *Celenterata*; also the seed-like reproductive bodies or "spores" of *Spongilla*.

GE-PHYR'E-A (Gr. *gephura*, a bridge). A class of the *Anarthropoda*, comprising the Spoon-worms (*Sipunculus*) and their allies.

GIZ'ZARD. A muscular division of the stomach in Birds, Insects, etc.

GLA'DI-US (Lat. for a sword). Applied to the horny endoskeleton or "pen" of certain Cuttle-fishes.

GLE'NOID (Gr. *glene*, a cavity; *eidos*, form). A shallow cavity; applied especially to the shallow articular cavity in the shoulder-blade to which the head of the humerus is jointed.

GNATH'ITES (Gr. *gnathos*, a jaw). The masticatory organs of *Crustacea*.

GON-O-BLAS-TID'I-A (Gr. *gonos*, offspring; *blastidion*, dim. of *blastos*, a bud). The processes which carry the reproductive receptacles, or "gonophores," in many of the *Hydrozoa*.

GON-O-CALYX (Gr. *gonos*; and *kalux*, cup). The swimming-bell in a medusi-form gonophore, or the same structure in a gonophore which is not detached.

GON'O-PHORE (Gr. *gonos*; and *phero*, I carry). The generative buds, or receptacles of the reproductive elements, in the *Hydrozoa*, whether these become detached or not.

GON'O-SOME (Gr. *gonos*; and *soma*, body). Applied as a collective term to the reproductive zooids of a *Hydrozoön*.

GON-O-THE'CA (Gr. *gonos*; and *theke*, a case). The chitinous receptacle within which the gonophores of certain of the *Hydrozoa* are produced.

GRAL-LA-TO'RES (Lat. *grallæ*, stilts). The order of the long-legged Wading-Birds.

GRA-NIV'O-ROUS (Lat. *granum*, a grain or seed; *voro*, I devour). Living upon grains or other seeds.

GRAP-TO-LIT'I-DÆ (Gr. *grapho*, I write; *lithos*, stone). An extinct sub-class of the *Hydrozoa*.

GREG-A-RIN'I-DA (Lat. *gregarius*, occurring in numbers together). A class of the *Protozoa*.

GUARD. The cylindrical fibrous sheath with which the internal chambered shell (phragmacone) of a *Belemnite* is protected.

GUL'LET.

GYM-NO-LÆ-MA-TA (Gr. *gymnos*, naked; *laimos*, the throat). An order of the

Polyzoa in which the mouth is devoid of the valvular structure known as the "epistome."

GYM-NO-PHI'O-NA (Gr. *gumnos*, naked; *ophis*, a snake). The order of the *Amphibia* comprising the snake-like *Ceciliæ*.

GYM-NOPH-THAL'MA-TA (Gr. *gumnos*; and *ophthalmos*, the eye). Applied by Edward Forbes to those *Medusæ* in which the eye-specks at the margin of the disc are unprotected. The division is now abandoned.

GYM-NO-SO'MA-TA (Gr. *gumnos*; and *somo*, the body). The order of *Pteropoda* in which the body is not protected by a shell.

GYN'O-PHORES (Gr. *gune*, woman; *phero*, I carry). The generative buds, or gonophores, of *Hydrozoa*, which contain ova alone, and differ in form from those which contain spermatozoa.

GY-REN-CEPH'A-LA (Gr. *guroo*, I wind about; *egkephalos*, brain). Applied by Owen to a section of the *Mammalia* in which the cerebral hemispheres are abundantly convoluted.

HE'MAL (Gr. *haima*, blood). Connected with the blood-vessels, or with the circulatory system.

HE-MA-TOC-RY-A (Gr. *haima*, blood; *kruos*, cold). Applied by Owen to the "cold-blooded" Vertebrates—viz., the Fishes, Amphibia, and Reptiles.

HE-MA-TO-THER'MA (Gr. *haima*, blood; *thermos*, warm). Applied by Owen to the "warm-blooded" Vertebrates—viz., Birds and Mammals.

HAL'LUX (Lat. *allec*, the thumb or great toe). The innermost of the five digits which normally compose the hind foot of a Vertebrate animal. In man, the great toe.

HAL-TE'RES (Gr. *halteres*, weights used by athletes to steady themselves in leaping). The rudimentary filaments or "balancers" which represent the posterior pair of wings in the *Diptera*, an order of Insects.

HAUS'TEL-LATE (Lat. *haurio*, I drink). Adapted for sucking or pumping up fluids; applied to the mouth of certain *Crustacea* and *Insecta*.

HEC-TO-COT'Y-LUS (Gr. *hekaton*, a hundred; *kotulos*, a cup). The metamorphosed reproductive arm of certain of the male Cuttle-fishes. In the *Argonaut* the arm becomes detached, and was originally described as a parasitic worm.

HEL'MIN-THOID (Gr. *helmins*, an intestinal worm). Worm-shaped, vermiform.

HE-MEL'Y-TRA (Gr. *hemi*, half; *elutron*, a sheath). The wings of certain Insects, in which the apex of the wing is membranous, while the inner portion is chitinous, and resembles the elytron of a beetle.

HEM-I-MET-A-BOL'IC (Gr. *hemi*, half; *metabole*, change). Applied to those insects which undergo an incomplete metamorphosis.

HE-MIP'TE-RA (Gr. *hemi*; and *pteron*, wing). An order of insects in which the anterior wings are sometimes "hemelytra."

HER-MAPH'RO-DITE (Gr. *Hermes*, Mercury; *Aphrodite*, Venus). Possessing the characters of both sexes combined.

HET-E-RO-CER'CAL (Gr. *heteros*, diverse; *kerkos*, tail). Applied to the tail of Fishes when it is unsymmetrical, or composed of two unequal lobes.

HET-E-RO-GE'NE-OUS.

HET-E-RO-GAN'GLI-ATE (Gr. *heteros*, diverse; *gaglion*, a knot). Possessing a nervous system in which the ganglia are scattered and unsymmetrical (as in the *Mollusca*, for example).

HET-E-RO-MOR'PHIC (Gr. *heteros*; *morphe*, form). Differing in form or shape.

HET-E-ROPH'A-GI (Gr. *heteros*, other; *phago*, I eat). Applied to Birds the young of which are born in a helpless condition, and require to be fed by the parents for a longer or shorter period.

HET-E-ROP'O DA.

HEX'A-POD (Gr. *hexa*, six; *pous*, foot). Possessing six legs; applied to the *Insecta*.

HI'LUM (Lat. *hilum*, a little thing). A small aperture (as in the gemmules of sponges), or a small depression (as in *Noctiluca*).

HIR-U-DIN'E-A (Lat. *hirudo*, a horse-leech). The order of *Annelida* comprising the Leeches.

- HIS-TOL'O-GY** (Gr. *histos*, a web; *logos*, a discourse). The study of the tissues; more especially of the minuter elements of the body.
- HOL-O-CEPH'A-LI** (Gr. *holos*, whole; *kephale*, head). A sub-order of the *Elassobranchii*, comprising the *Chimæra*.
- HOL-O-MET-A-BOL'IC** (Gr. *holos*, whole; *metabole*, change). Applied to insects which undergo a complete metamorphosis.
- HOL-O-STO'MA-TA** (Gr. *holos*, whole; *stoma*, mouth). A division of *Gasteropodous Molluscs*, in which the aperture of the shell is rounded, or "entire."
- HOL-O-THU-ROI'DE-A** (Gr. *holos*; *thura*, door; and *eidos*, form). An order of *Echinodermata* comprising the Trepangs.
- HOM-O-CER'CAL** (Gr. *homos*, same; *kerkos*, tail). Applied to the tail of Fishes when it is symmetrical, or composed of two equal lobes.
- HO-MO-GE'NE-OUS**.
- HO-MO-GAN'GLI-ATE** (Gr. *homos*, same; *gagglion*, a knot). Having a nervous system in which the ganglia are symmetrically arranged (as in the *Annullosa*, for example).
- HO-MOL'O-GOUS** (Gr. *homos*; and *logos*, a discourse). Applied to parts which are constructed upon the same fundamental plan.
- HO-MO-MOR'PHOUS** (Gr. *homos*; and *morphe*, form). Having a similar external appearance or form.
- HU'ME-RUS**. The bone of the upper arm (*brachium*) in the Vertebrates.
- HU'A-LINE** (Gr. *hualos*, crystal). Crystalline or glassy.
- HYD'A-TIDS** (Gr. *hudatis*, a vesicle). The vesicle containing the larval forms (*Echinococci*) of the tapeworm of the dog.
- HY'DRA-FORM**. Resembling the common fresh-water polype (*Hydra*) in form.
- HY'DRA**.
- HY-DRO-CAU'LUS** (Gr. *hudra*, a water-serpent; and *kaulos*, a stem). The main stem of the *cœnosarc* of a *Hydrozoön*.
- HY'DRO-CYSTS** (Gr. *hudra*; and *kustis*, a cyst). Curious processes attached to the *cœnosarc* of the *Physophoridae*, and termed "feelers" (*Fühler* and *Taster* of the Germans).
- HY-DRE'CI-UM** (Gr. *hudra*; and *oikos*, a house). The chamber into which the *cœnosarc* in many of the *Calycophoridae* can be retracted.
- HY-DROI'DA** (Gr. *hudra*; and *eidos*, form). The sub-class of the *Hydrozoa*, which comprises the animals most nearly allied to the *Hydra*.
- HY-DRO-PHYL'LI-A** (Gr. *hudra*; and *phyllon*, a leaf). Overlapping appendages or plates which protect the polypites in some of the oceanic *Hydrozoa* (*Calycophoridae* and *Physophoridae*). They are often termed "bracts," and are the *Deckstücke* of the Germans.
- HY-DRO-RHI'ZA** (Gr. *hudra*; and *rhiza*, root). The adherent base or proximal extremity of any *Hydrozoön*.
- HY-DRO-SO'MA** (Gr. *hudra*; and *soma*, body). The entire organism of any *Hydrozoön*.
- HY-DRO-THE'CA** (Gr. *hudra*; and *theke*, a case). The little chitinous cups in which the polypites of the *Sertularida* and *Campanularida* are protected.
- HY-DRO-ZO'A** (Gr. *hudra*; and *zoön*, animal). The class of the *Cœlenterata*, which comprises animals constructed after the type of the *Hydra*.
- HY-MEN-OP'TER-A** (Gr. *humen*, a membrane; *pteron*, a wing). An order of Insects (comprising Bees, Ants, etc.) characterized by the possession of four membranous wings.
- HY'OID** (Gr. *Y*; *eidos*, form). The bone which supports the tongue in Vertebrates, and derives its name from its resemblance in man to the Greek letter *Y*.
- HY'PO-STOME** (Gr. *hupo*, under; *stoma*, mouth). The upper lip, or "labrum," of certain *Crustacea* (e. g., *Trilobites*).
- HY-RA-COID'E-A** (Gr. *hurax*, a shrew; *eidos*, form). An order of the *Mammalia* constituted for the reception of the single genus *Hyrax*.
- ICH-THY-O-DOR'Y-LITE** (Gr. *ichthus*, fish; *doru*, spear; *lithos*, stone). The fossil fin-spines of Fishes.

- ICH-THY-O-MOR'PHA (Gr. *ichthus*; *morphe*, shape). An order of Amphibians, often called *Urodela*, comprising the fish-like Newts, etc.
- ICH-THY-OPH-THI'RA (Gr. *ichthus*; *phthir*, a louse). An order of *Crustacea* comprising animals which are parasitic upon Fishes.
- ICH-THY-OP'SI-DA (Gr. *ichthus*; *opsis*, appearance). The primary division of *Vertebrata*, comprising the Fishes and Amphibia. Often spoken of as the *Branchiate Vertebrata*.
- ICH-THY-OP-TER-YG'I-A (Gr. *ichthus*; *pteryx*, wing). An extinct order of Reptiles.
- ICH-THY-O-SAU'RI-A (Gr. *ichthus*; *saura*, lizard). Synonymous with *Ichthyopterygia*.
- LI'I-UM. The haunch-bone, one of the bones of the pelvic arch in the higher Vertebrates.
- I-MA'GO (Lat. for an image or apparition). The perfect insect, after it has undergone its metamorphoses.
- IM'BRI-CA-TED. Applied to scales or plates which overlap one another like tiles.
- IN-CI'SOR (Lat. *incido*, I cut). The cutting teeth fixed in the intermaxillary bones of the *Mammalia*, and the corresponding teeth in the lower jaw.
- IN-E-QUI-LAT'ER-AL. Having the two sides unequal, as in the case of the shells of the ordinary bivalves (*Lamellibranchiata*). When applied to the shells of the *Foraminifera*, it implies that the convolutions of the shell do not lie in the same plane, but are obliquely wound round an axis.
- IN-E-QUI-VALVE. Composed of two unequal pieces or valves.
- IN-FUN-DIB'U-LUM (Lat. for funnel). The tube formed by the coalescence or apposition of the epipodia in the *Cephalopoda*—commonly termed the "funnel," or "siphon."
- IN-FU-SO RI-A (Lat. *infusum*, an infusion). A class of *Protozoa*, so called because they are often developed in organic infusions.
- IN'GUIN-AL (Lat. *inguen*, groin). Connected with, or situated upon, the groin.
- IN-O-PER-CU-LA'TA (Lat. *in*, without; *operculum*, a lid). The division of pulmonate *Gasteropoda* in which there is no shelly or horny plate (operculum) by which the shell is closed when the animal is withdrawn within it.
- IN-SEC'TA (Lat. *inseco*, I cut into). The class of Articulate animals commonly known as Insects.
- IN-SEC-TIV'O-RA (Lat. *insectum*, an insect; *voro*, I devour). An order of Mammals.
- IN SEC-TIV'O-ROUS. Living upon Insects.
- IN-SES-SO'RES (Lat. *insideo*, I sit upon). The order of the Perching Birds, often called *Passeres*.
- IN-TER-AM-BU-LA'CRA (Lat. *inter*, between; *ambulacrum*, that which serves for walking). The rows of plates in an *Echinoderm* which are not perforated for the emission of the "tube-feet."
- IN-TER-MAX-IL'LE, or PRÆ-MAX-IL'LE (Lat. *inter*, between; *præ*, before; *maxilla*, the jaw). The two bones which are situated between the two superior maxillæ in *Vertebrata*. In man, and some monkeys, the præmaxillæ ankylose with the maxillæ, so as to be irreco gnizable in the adult.
- IN-TUS-SUS-CEP'TION (Lat. *intus*, within; *suscipio*, I take up). The act of taking foreign matter into a living being.
- IN-VER-TE-BRA'TA (Lat. *in*, without; *vertebra*, a bone of the back). Animals without a spinal column or backbone.
- IS'CHI-UM (Gr. *ischion*, the hip). One of the bones of the pelvic arch in Vertebrates.
- I-SOP'O-DA (Gr. *isos*, equal; *podes*, feet). An order of *Crustacea* in which the feet are like one another and equal.
- JU'GU-LAR (Lat. *jugulum*, the throat). Connected with, or placed upon, the throat. Applied to the ventral fins of fishes when they are placed beneath or in advance of the pectorals.
- KAI-NO-ZO'IC (Gr. *kainos*, recent; *zōē*, life). The Tertiary period in Geology,

comprising those formations in which the organic remains approximate more or less closely to the existing fauna and flora.

KER'A-TODE (Gr. *keras*, horn; *eidos*, form). The horny substance of which the skeleton of many sponges is made up.

KER-A-TO'SA. The division of Sponges in which the skeleton is composed of keratode.

LA'BI-UM (Lat. for lip). Restricted to the lower lip of Articulate animals.

LA'BRUM (Lat. for lip). Restricted to the upper lip of Articulate animals.

LAB-Y-RINTH-O-DON'TI-A (Gr. *laburinthos*, a labyrinth; *odous*, tooth). An extinct order of *Amphibia*, so called from the complex microscopic structure of the teeth.

LAC-ER-TIL'I-A (Lat. *lacerta*, a lizard). An order of *Reptilia* comprising the Lizards and Slow-worms.

LE-MO-DIP'O-DA (Gr. *laimos*, throat; *dis*, twice; *podes*, feet). An order of *Crustacea*, so called because they have two feet placed far forward, as it were under the throat.

LA-MEL-LI-BRANCH-I-A'TA (Lat. *lamella*, a plate; Gr. *bragchia*, gills). The class of *Mollusca*, comprising the ordinary bivalves, characterized by the possession of lamellar gills.

LA-MEL-LI-ROS'TRES (Lat. *lamella*, a plate; *rostrum*, beak). The flat-billed Swimming Birds (*Natatores*), such as Ducks, Geese, Swans, etc.

LAR'VA (Lat. for a mask). The insect in its first stage after its emergence from the egg, when it is usually very different from the adult.

LAR'YNX. The upper part of the windpipe, forming a cavity with appropriate muscles and cartilages, situated beneath the hyoid bone, and concerned in Mammals in the production of vocal sounds.

LEN-TIC'U-LAR (Lat. *lens*, a bean). Shaped like a biconvex lens.

LEP-I-DOP'TE-RA (Gr. *lepis*, a scale; *pteron*, a wing). An order of Insects, comprising Butterflies and Moths, characterized by possessing four wings which are usually covered with minute scales.

LEP-I-DO'TA (Gr. *lepidotos*, covered with scales). Formerly applied to the order *Dipnoi*, containing the Mud-fishes (*Lepidosiren*).

LEP-TO-CAR'DI-A (Gr. *leptos*, slender, small; *kardia*, heart). The name given by Müller to the order of Fishes comprising the Lancelet, now called *Pharyngobranchii*.

LIG-A-MEN'TUM NU'CHÆ (Fr. *nuque*, the nape of the neck). The band of elastic fibres by which the weight of the head in *Mammalia* is supported.

LIN'GUAL (Lat. *lingua*, the tongue). Connected with the tongue.

LIN'GU-LA (Lat. *lingula*, a little tongue). The upper flexible portion of the labium or lower lip in Insects.

LIS-SEN-CEPH'A-LA (Gr. *lissos*, smooth; *egkephalos*, brain). A primary division of *Mammalia*, according to Owen, in which the cerebral hemispheres are smooth or have few convolutions.

LITH'O-CYSTS (Gr. *lithos*, a stone; *kustis*, a cyst). The sense-organs or "marginal bodies" of the *Lucernarida* or *Steganophthalmate Medusæ*.

LON-GI-PEN-NA'TE (Lat. *longus*, long; *penna*, wing). A group of the *Natorial Birds*.

LON-GI-ROS'TRES (Lat. *longus*; *rostrum*, beak). A group of the *Wading Birds*.

LOPH'O-PHORE (Gr. *lophos*, a crest; and *phero*, I carry). The disc or stage upon which the tentacles of the *Polyzoa* are borne.

LOPH-U-ROP'O-DA (Gr. *lophouros*, having stiff hairs; and *podes*, feet). An order of *Crustacea*.

LO-RI'CA (Lat. for a breast-plate). Applied to the protective case with which certain *Infusoria* are provided.

LOB-I-CA'TA (Lat. *lorica*, a cuirass). The division of *Reptiles* comprising the *Chelonina* and *Crocodylia*, in which bony plates are developed in the skin (*derma*).

LU-CER-NAR'I-DA (Lat. *lucerna*, a lamp). An order of the *Hydrozoa*.

LUM'BAR (Lat. *lumbus*, loin). Connected with the loins.

LU'NATE (Lat. *luna*, moon). Crescentic in shape.

- LY-EN-CEPH'A-LA** (Gr. *luo*, I loose; *egkephalos*, brain). A primary divisor of Mammals, according to Owen.
- MAC-RO-DAC'TY-LI** (Gr. *makros*, long; *daktulos*, a finger). A group of the Wading Birds.
- MA-CRU'RA** (Gr. *makros*, long; *oura*, tail). A tribe of Decapod *Crustaceans* with long tails (*e.g.*, the Lobster, Shrimp, etc.).
- MAD-RE-POR'I-FORM**. Perforated with small holes, like a coral; applied to the tubercle by which the ambulacral system of the *Echinoderms* mostly communicates with the exterior.
- MAL-A-CO-DERM'A-TA**.
- MAL-A-COS'TRA-CA** (Gr. *malakos*, soft; *ostrakon*, shell). A division of *Crustacea*. Originally applied by Aristotle to the entire class *Crustacea*, because their shells were softer than those of the *Mollusca*.
- MAL-LOPH'A-GA** (Gr. *mallos*, a fleece; *phago*, I eat). An order of Insects which are mostly parasitic upon birds.
- MAM-MA'LIA** (Lat. *mamma*, the breast). The class of Vertebrate animals which suckle their young.
- MAN'DI-BLE** (Lat. *mandibulum*, a jaw). The upper pair of jaws in Insects; also applied to one of the pairs of jaws in *Crustacea* and Spiders, to the beak of Cephalopods, the lower jaw of Vertebrates, etc.
- MAN'TLE**. The external integument of most of the *Mollusca*, which is largely developed, and forms a cloak in which the viscera are protected. Technically called the "pallium."
- MA-NU'BRI-UM** (Lat. for a handle). The polypite which is suspended from the roof of the swimming-bell of a *Medusa*, or from the gonocalyx of a medusiform gonophore among the *Hydrozoa*.
- MA'NUS** (Lat. for the hand). The hand of the higher Vertebrates.
- MAR-SIP-O-BRANCH'I-I** (Gr. *marsipos*, a pouch; *bragchia*, gills). The order of Fishes comprising the Hag-fishes and Lampreys, with pouch-like gills.
- MAR-SU-PIA'LI-A** (Lat. *marsupium*, a pouch). An order of Mammals in which the females mostly have an abdominal pouch in which the young are carried.
- MAS'TAX** (Gr. for mouth). The muscular pharynx or "buccal funnel" into which the mouth opens in most of the *Rotifera*.
- MAS-TI-CA-TO-RY** (Lat. *masticio*, I chew). Applied to parts adapted for chewing.
- MAX-IL'LA** (Lat. for jaws). The inferior pair or pairs of jaws in the *Arthropoda* (Insects, *Crustacea*, etc.). The upper jaw-bones of Vertebrates.
- MAX-IL'LI-PEDES** (Lat. *maxilla*, jaws; *pes*, the foot). The limbs in *Crustacea* and *Myriapoda* which are converted into masticatory organs, and are commonly called "foot-jaws."
- ME-DUL'LA** (Lat. for marrow). Applied to the marrow of bones, or to the spinal cord, with or without the adjective "*spinalis*."
- ME-DU'S.E.** An order of *Hydrozoa*, commonly known as Jelly-fishes (*Discophora*, or *Acalphæ*), so called because of the resemblance of their tentacles to the snaky hair of the *Medusa*. Many *Medusæ* are now known to be merely the gonophores of *Hydrozoa*.
- ME-DU'SI-FORM**. Resembling a *Medusa* in shape.
- ME-DU'SOID**. Like a *Medusa*; used substantively to designate the medusiform gonophores of the *Hydrozoa*.
- MEM-BRA'NA NIC'TI-TANS** (Lat. *nicto*, I wink). The third eyelid of Birds, etc.
- MEN'TUM** (Lat. for the chin). The basal portion of the labium or lower lip in Insects.
- ME-RO-STOM'A-TA** (Gr. *mēron*, thigh; *stoma*, mouth). An order of *Crustacea* in which the appendages which are placed round the mouth, and which officiate as jaws, have their free extremities developed into walking or prehensile organs.
- MES-EN-TE'RI-ES** (Gr. *mesos*, intermediate; *enteron*, intestine). In a restricted sense, the vertical plates which divide the somatic cavity of a Sea-anemone (*Actinia*) into chambers.
- MES-O-PO'DI-UM** (Gr. *mesos*, middle; *pous*, foot). The middle portion of the "foot" of Molluscs.

- MES-O-STER'NUM** (Gr. *mesos*, intermediate; *sternon*, the breast-bone). The middle portion of the sternum, intervening between the attachment of the second pair of ribs and the xiphoid cartilage (*xiphisternum*).
- MES-O-THO'RAX** (Gr. *mesos*; and *thorax*, the chest). The middle ring of the thorax in Insects.
- MES-O-ZO'IC** (Gr. *mesos*; *zo'*, life). The Secondary period in Geology.
- MET-A-CAR'PUS** (Gr. *meta*, after; *karpus*, the wrist). The bones which form the "root of the hand," and intervene between the wrist and the fingers.
- MET-A-MOR'PHO-SIS** (Gr. *meta*, implying change; *morphe*, shape). The changes of form which certain animals undergo in passing from their younger to their fully-grown condition.
- MET-A-PO'DI-UM** (Gr. *meta*, after; *pous*, the foot). The posterior lobe of the foot in *Mollusca*; often called the "operculigerous lobe," because it develops the operculum when this structure is present.
- MET-TAS'TO MA** (Gr. *meta*, after; *stoma*, mouth). The plate which closes the mouth posteriorly in the *Crustacea*.
- MET-A-TAR'SUS** (Gr. *meta*, after; *tarsos*, the instep). The bones which intervene between the bones of the ankle (*tarsus*) and the digits in the hind-foot of the higher Vertebrates.
- MET-A-THO'RAX** (Gr. *meta*, after; *thorax*, the chest). The posterior ring of the thorax in Insects.
- MIM-ET'IC** (Gr. *mimetikos*, imitative). Applied to organs or animals which resemble each other in external appearance, but not in essential structure.
- MOL'ARS** (Lat. *mola*, a mill). The "grinders" in man, or the teeth in diphyodont Mammals which are not preceded by milk-teeth.
- MOL-LUS'CA** (Lat. *mollis*, soft). The sub-kingdom which includes the Shellfish proper, the *Polyzoa*, the *Tunicata*, and the Lamp-shells; so called from the generally soft nature of their bodies.
- MOL-LUS-CO'R'DA** (*Mollusca*; Gr. *eidos*, form). The lower division of the *Mollusca*, comprising the *Polyzoa*, *Tunicata*, and *Brachiopoda*.
- MON'ADS** (Gr. *monas*, unity). Microscopical organisms of an extremely simple character, developed in organic infusions.
- MO-NOC'U-LOUS** (Gr. *monos*, single; Lat. *oculus*, eye). Possessed of only one eye.
- MON-O-DELPH'I-A** (Gr. *monos*, single; *delphus*, womb). The division of *Mammalia* in which the uterus is single.
- MO-NOC'U-LOUS** (Gr. *monos*, single; *oikos*, house). Applied to individuals in which the sexes are united.
- MON-O-MY'A-RY** (Gr. *monos*, single; *mus*, muscle). Applied to those bivalves (*Lamellibranchiata*) in which the shell is closed by a single adductor muscle.
- MON-O-PHY'o-DONT** (Gr. *monos*; *phuo*, I generate; *odous*, tooth). Applied to those Mammals in which only a single set of teeth is ever developed.
- MON-O-THAL'A-MOUS** (Gr. *monos*; and *thalamos*, chamber). Possessing only a single chamber. Applied to the shells of *Foraminifera* and *Mollusca*.
- MON-O-TREM'A-TA** (Gr. *monos*; *trëma*, aperture). The order of Mammals comprising the Duck-mole and *Echidna*, in which the intestinal canal opens into a "cloaca" common to the ducts of the urinary and generative organs.
- MUL-TI-LOC'U-LAR** (Lat. *multi*, many; *loculus*, a little purse). Divided into many chambers.
- MUL-TI-VALVE**. Applied to shells which are composed of many pieces.
- MUL-TUN'GU-LA** (Lat. *multi*, many; *ungula*, hoof). The division of Perissodactyle Ungulates, in which each foot has more than a single hoof.
- MY'E-LON** (Gr. *myelos*, marrow). The spinal cord of Vertebrates.
- MYR-I-AP'O-DA** (Gr. *myrioi*, ten thousand; *podes*, feet). A class of *Arthropoda* comprising the Centipedes and their allies, characterized by their numerous feet.
- NA'CRE-OUS** (Fr. *nacre*, mother-of-pearl, originally Oriental). Pearly; of the texture of mother-of-pearl.
- NAT-A-TO'RES** (Lat. *nare*, to swim). The order of the Swimming Birds.
- NA'TA-TO-RY** (Lat. *nare*, to swim). Formed for swimming.

- NAU'TI-LOID.** Resembling the shell of the *Nautilus* in shape.
- NECH-O-CAL'Y-CES.**
- NECH-O-CAL'YX** (Gr. *necho*, I swim; *kalux*, cup). The swimming-bell or "disc" of a *Medusa* or Jelly-fish.
- NEM-A-TEL-MI-A** (Gr. *nema*, thread; *helmins*, a worm). The division of *Scolecida* comprising the Round-worms, Thread-worms, etc.
- NE-MAT'O-CYSTS** (Gr. *nema*, thread; *kustis*, a bag). The thread-cells of the *Celenterata*. (See *Cnidæ*.)
- NEM-A-TO'DA.**
- NEM-A-TOLD'E-A** (Gr. *nema*, thread; *eidōs*, form). An order of *Scolecida* comprising the Thread-worms, Vinegar-eels, etc.
- NE-MAT'O-PHORES** (Gr. *nema*, thread; *phero*, I carry). Cæcal processes found on the cœnosarc of certain of the *Sertularida*, containing numerous thread-cells at their extremities.
- NE-MER'TI-DA** (Gr. *Nemertes*, proper name). A division of the *Turbellarian Worms*, commonly called "Ribbon-worms."
- NERV'URES** (Lat. *nervus*, a sinew). The ribs which support the membranous wings of insects.
- NEU'RAL** (Gr. *neuron*, a nerve). Connected with the nervous system.
- NEU-RA-POPH'Y-SIS** (Gr. *neuron*, a nerve; *apophysis*, a projecting part). The "spinous process" of a vertebra, or the process formed at the point of junction of the neural arches.
- NEUR-O-PO'DI-UM** (Gr. *neuron*, a nerve; *pous*, the foot). The ventral or inferior division of the "foot tubercle" of an *Annelide*; often called the "ventral oar."
- NEU-ROP'TE-RA** (Gr. *neuron*; and *pteron*, a wing). An order of Insects characterized by four membranous wings with numerous reticulated nervures (e. g., Dragon-flies).
- NEU'TER** (Lat. for neither the one nor the other). Having no fully-developed sex.
- NID-I-FI-CA'TION** (Lat. *nidus*, a nest; *facio*, I make). The building of a nest.
- NOO-TURN'AL** (Lat. *nox*, night). Applied to animals which are active by night.
- NOR'MAL** (Lat. *norma*, a rule). Conforming to the ordinary standard.
- NO-TO-BRANCH-I-A-TA** (Gr. *notos*, the back; and *bragchia*, gills). Carrying the gills upon the back; applied to a division of the *Annelida*.
- NO'TO-CHORD** (Gr. *notos*, back; *chorde*, string). A cellular rod which is developed in the embryo of Vertebrates immediately beneath the spinal cord, and which is usually replaced in the adult by the vertebral column. Often it is spoken of as the "chorda dorsalis."
- NO-TO-PO'DI-UM** (Gr. *notos*, the back; and *pous*, the foot). The dorsal division of one of the foot-tubercles or parapodia of an *Annelide*; often called the "dorsal oar."
- NU'CLE-A-TED.** Possessing a nucleus or central particle.
- NU'CLE-O-LUS.** 1. The minute solid particle in the interior of the nucleus of some cells. 2. The minute spherical particle attached to the exterior of the "nucleus," or ovary, of certain *Infusoria*, performing the functions of a testicle.
- NU'CLE-US** (Lat. *nucleus*, a kernel). 1. The solid or vesicular body found in many cells. 2. The solid rod, or band-shaped body, found in the interior of many of the *Protozoa*, and having, in certain of them, the functions of an ovary. 3. The "madreporiform tubercle" of the *Echinodermata*. 4. The embryonic shell which is retained to form the apex of the adult shell in many of the *Mollusca*.
- NU-DI-BRANCH-I-A-TA** (Lat. *nudus*, naked; and Gr. *bragchia*, gills). An order of the *Gasteropoda* in which the gills are naked.
- NYMPHS.** The active pupæ of certain Insects.
- OC-CIP'I-TAL.** Connected with the *occiput*, or the back part of the head.
- O-CE-AN'IC.** Applied to animals which inhabit the open ocean (= pelagic).
- O-CEL'LI** (Lat. diminutive of *oculus*, eye). The simple eyes of many *Echinoderms*, *Spiders*, *Crustaceans*, *Molluscs*, etc.

- OO-TOP'O-DA (Gr. *octo*, eight; *pous*, foot). The tribe of Cuttle-fishes with eight arms attached to the head.
- O-DON-TO-CE'TI (Gr. *odous*, tooth; *kētos*, whale). The "toothed" Whales, in contradistinction to the "whalebones" Whales.
- O-DON'TOID (Gr. *odous*; *eidos*, form). The "odontoid process" is the centrum or body of the first cervical vertebra (*atlas*). It is detached from the atlas, and is usually ankylosed with the second cervical vertebra (*axis*), and it forms the pivot upon which the head rotates.
- O-DON'TO-PHORE (Gr. *odous*, tooth; *phero*, I carry). The so-called "tongue" or masticatory apparatus of *Gastropoda*, *Pteropoda*, and *Cephalopoda*.
- Œ-SOPH'A-GUS. The gullet or tube leading from the mouth to the stomach.
- OL-I-GO-CHÆ'TA (Gr. *oligoi*, few; *chaite*, hair). An order of *Annelida*, comprising the Earth-worms, in which there are few bristles.
- O-MA'SUM (Lat. for bullock's tripe). The third stomach of Ruminants, commonly called the *psalterium*, or many-plies.
- OM-NIV'O-ROUS (Lat. *omnia*, everything; *voro*, I devour). Feeding indiscriminately upon all sorts of food.
- O-PER-CU-LA'TA (Lat. *operculum*, a lid). A division of pulmonate *Gastropoda*, in which the shell is closed by an operculum.
- O-PER-CU-LUM. A horny or shelly plate developed in certain *Mollusca* upon the hinder part of the foot, and serving to close the aperture of the shell when the animal is retracted within it; also the lid of the shell of a *Balanus* or Acorn-shell; also the chain of flat bones which cover the gills in many fishes.
- O-PHID'I-A (Gr. *ophidian*, a little snake). The order of Reptiles comprising the Snakes.
- OPH-I-DO-BA-TRA'CHI-A (Gr. *ophis*, a snake; *batrachos*, a frog). Sometimes applied to the order of Snake-like Amphibians comprising the *Cæciliæ*.
- OPH-I-O-MOR'PHA (Gr. *ophis*; *morphe*, shape). The order of *Amphibia* comprising the *Cæciliæ*.
- OPH-I-U-ROID'E-A (Gr. *ophis*, a snake; *oura*, tail; *eidos*, form). An order of *Echinodermata* comprising the Brittle-stars and Sand-stars.
- O-PIS-THO-BRANCH'I-A TA (Gr. *opisthen*, behind; *brachia*, gills). A division of *Gastropoda* in which the gills are placed on the posterior part of the body.
- O-PIS-THO-CÆ'LOUS (Gr. *opisthen*, behind; *koiLOS*, hollow). Applied to vertebrae, the bodies of which are hollow or concave behind.
- O'RAL (Lat. *os*, mouth). Connected with the mouth.
- OR-NI-THO-DEL PHI-A (Gr. *ornis*, a bird; *delphus*, womb). The primary division of Mammals comprising the *Monotremata*.
- OR-THOP'TE-RA (Gr. *orthos*, straight; *pteron*, wing). An order of Insects.
- OS'CU-LA (Lat. diminutive of *os*, mouth). 1. The large apertures by which a sponge is perforated ("exhalant apertures"). 2. The suckers with which the *Tæniada* (Tape-worms and Cystic Worms) are provided.
- OS-SIC'U-LA (Lat. diminutive of *os*, bone). Literally, small bones. Often used to designate any hard structures of small size, such as the calcareous plates in the integument of the Star-fishes.
- OS-TRA-CO'DA (Gr. *ostrakon*, a shell; and *eidos*, form). An order of small Crustaceans which are enclosed in bivalve shells.
- OR'O-LITHS (Gr. *ous*, ear; and *lithos*, stone). The calcareous bodies connected with the sense of hearing, even in its most rudimentary form.
- O-VA'RI-AN VES-I-CLES or CAP'SULES. The generative buds of the *Sertularida*.
- O-VA-RY (O-VA'RI-UM). The organ by which ova are produced.
- O-VIP'A-ROUS (Lat. *ovum*, an egg; and *pario*, I bring forth). Applied to animals which bring forth eggs, in contradistinction to those which bring forth their young alive.
- O-VI-POS'I-TOR (Lat. *ovum*; and *pono*, I place). The organ possessed by some insects, by means of which the eggs are placed in a position suitable for their development.
- O'VI-SAC. The external bag or sac in which certain of the Invertebrates carry their eggs after they are extruded from the body.

- O-VO-VI-VIP'A-ROUS (Lat. *ovum*, egg; *vivus*, alive; *pario*, I produce). Applied to animals which retain their eggs within the body until they are hatched.
- O'VUM (Lat. for an egg). The germ produced within the ovary, and capable under certain conditions of being developed into a new individual.
- PACH-Y-DER'MA-TA (Gr. *pachus*, thick; *derma*, skin). An old Mammalian order constituted by Cuvier for the reception of the Rhinoceros, Hippopotamus, Elephant, etc.
- PA-LÆ-ON-TOL'O-GY (Gr. *palaïos*, ancient; *onta*, beings; and *logos*, discourse). The science of fossil remains or of extinct organized beings.
- PA-LÆ-O-ZO'IO (Gr. *palaïos*, ancient; and *zōē*, life). Applied to the oldest of the great geological epochs.
- PAL'LI-AL.
- PAL-LI-O-BRAN-CHI-A'TA (Lat. *pallium*; and Gr. *brachia*, gills). An old name for the *Brachiopoda*, founded upon the belief that the system of tubes in the mantle constituted the gills.
- PAL'LI-UM (Lat. *pallium*, a cloak). The mantle of the *Mollusca*. *Pallial*: relating to the mantle. *Pallial line* or *impression*: the line left in the dead shell by the muscular margin of the mantle. *Pallial shell*: a shell which is secreted by, or contained within, the mantle, such as the "bone" of the Cuttle fishes.
- PAL'PI (Lat. *palpo*, I touch). Processes supposed to be organs of touch, developed from certain of the oral appendages in Insects, Spiders, and Crustacea, and from the sides of the mouth in the Acephalous Molluscs.
- PA-PIL'LA (Lat. for nipple). A minute soft prominence.
- PAR-A-PO'DI-A (Gr. *para*, beside; *podes*, feet). The unarticulated lateral locomotive processes or "foot-tubercles" of many of the *Annelida*.
- PA-RI'E-TAL (Lat. *paries*, a wall). Connected with the walls of a cavity or of the body.
- PA-RI-E-TO-SPLANCH'NIC (Lat. *paries*; Gr. *splanchna*, viscera). Applied to one of the nervous ganglia of the *Mollusca*, which supplies the walls of the body and the viscera.
- PAR-THEN-O-GEN'E-SIS (Gr. *parthenos*, a virgin; and *genesis*, production). Strictly speaking, confined to the production of new individuals from virgin females by means of ova without the intervention of a male. Sometimes used also to designate a sexual reproduction by gemmation or fission.
- PAT-A-RI'UM (Lat. for the border of a dress). Applied to the expansion of the integument by which Bats, Flying Squirrels, and other animals support themselves in the air.
- PA-TEL'LA (Lat. for the knee-cap or knee-pan). A sesamoid bone developed in the tendon of insertion of the great extensor muscles of the thigh.
- PEC TI-NATE (Lat. *pecten*, a comb). Comb-like; applied to the gills of certain *Gasteropods*, hence called *Pectinibranchiata*.
- PEC TO-RAL (Lat. *pectus*, chest). Connected with, or placed upon, the chest.
- PE'DAL (Lat. *pes*, the foot). Connected with the foot of *Mollusca*.
- PED-I-CEL-LA RI-Æ (Lat. *pedicellus*, a louse). Certain singular appendages found in many *Echinoderms*, attached to the surface of the body, and resembling a little beak or forceps supported on a stalk.
- PED'I-CLE (Lat. dimin. of *pes*, the foot). A little stem.
- PED-I-PAL'PI (Lat. *pes*, foot; and *palpo*, I feel). An order of *Arachnida* comprising the Scorpions, etc.
- PE-DUN'CLE (Lat. *pedunculus*, a stem or stalk). In a restricted sense applied to the muscular process by which certain *Brachiopods* are attached, and to the stem which bears the body (capitulum) in Barnacles.
- PE-DUN'CU-LATE. Possessing a peduncle.
- PE-DUN'CU-LA-TED.
- PE-LAG'IO (Gr. *pelagos*, sea). Inhabiting the open ocean.
- PELVIS (Lat. for basin). Applied, from analogy, to the basal portion of the cup (*calyx*) of *Crinoids*. The body arch with which the hind-limbs are connected in Vertebrates.

- PER-EN-NI-BRAN-CHI-A'TA** (Lat. *pereennis*, perpetual; Gr. *bragchia*, gills). Applied to those *Amphibia* in which the gills are permanently retained throughout life.
- PER-GA-MEN-TA'CEOUS** (Lat. *pergamena*, parchment). Of the texture of parchment.
- PER-I-CAR'DI-UM** (Gr. *peri*, around; *kardia*, heart). The serous membrane in which the heart is contained.
- PER-I-DERM** (Gr. *peri*, around; and *derma*, skin). The hard cuticular layer which is developed by the coenosarc of certain of the *Hydrozoa*.
- PER-I-GAS'TRIC** (Gr. *peri*, around; and *gaster*, stomach). The perigastric space is the cavity which surrounds the stomach and other viscera, corresponding to the abdominal cavity of the higher animals.
- PER-I-OS'TRA-CUM** (Gr. *peri*; and *ostrakon*, shell). The layer of epidermis which covers the shell in most of the *Mollusca*.
- PER-I-PLAST** (Gr. *peri*; and *plasso*, I mould). The intercellular substance or matrix in which the organized structures of a tissue are embedded.
- PER-I-SOME** (Gr. *peri*; and *soma*, body). The coriaceous or calcareous integument of the *Echinodermata*.
- PER-IS-SO-DAC'TY-LA** (Gr. *perissos*, uneven; *daktulos*, finger). Applied to those Hoofed Quadrupeds (*Ungulati*) in which the feet have an uneven number of toes.
- PER-I-STOME** (Gr. *peri*; and *stoma*, mouth). The space which intervenes between the mouth and the margin of the calyx in *Vorticella*; also the space between the mouth and the tentacles in a sea-anemone (*Actinia*); also the lip or margin of the mouth of a univalve shell.
- PER-I-VIS'CE-RA-L** (Gr. *peri*; and Lat. *viscera*, the internal organs). Applied to the space surrounding the viscera.
- PET'A-LOID**. Shaped like the petal of a flower.
- PHA-LAN'GES** (Gr. *phalagx*, a row). The small bones composing the digits of the higher *Vertebrata*. Normally each digit has three phalanges.
- PHAR-YN-GO-BRAN'CHI-I** (Gr. *pharynx*, pharynx; *bragchia*, gills). The order of Fishes comprising only the Lancelet.
- PHAR'YNX**. The dilated commencement of the gullet.
- PHRAG'MA-CONE** (Gr. *phragma*, a partition; and *konos*, a cone). The chambered portion of the internal shell of a *Belemnite*.
- PHY-LAC-TO-LEM'A-TA** (Gr. *phylax*, I guard; and *laimos*, throat). The division of *Polyzoa* in which the mouth is provided with the arched valvular process known as the "epistome."
- PHYL'LO-CYSTS** (Gr. *phyllon*, leaf; and *kustis*, a cyst). The cavities in the interior of the "hydrophyllia" of certain of the Oceanic *Hydrozoa*.
- PHYL-LOP'O-DA** (Gr. *phyllon*, leaf; and *pous*, foot). An order of *Crustacea*.
- PHY-O-GEM-MA'RI-A** (Gr. *phuo*, I produce; and Lat. *gemma*, bud). The small gonoblastidia of *Veilella*, one of the *Physophoridae*.
- PHY-SO-GRA'DA** (Gr. *phusa*, bellows or air-bladder; and Lat. *gradior*, I walk). Applied formerly to the *Physophoridae*, an order of Oceanic *Hydrozoa*, in which a "float" is present.
- PHY-SO-PHOR'I-DÆ** (Gr. *phusa*, air-bladder; and *phero*, I carry). An order of Oceanic *Hydrozoa*.
- PHY'TOID** (Gr. *phuton*, a plant; and *eidōs*, form). Plant-like.
- PHY-TOPH'A-GOUS** (Gr. *phuton*, a plant; and *phago*, I eat). Plant-eating, or herbivorous.
- PIN'NÆ**.
- PIN'NATE** (Lat. *pinna*, a feather). Feather-shaped, or possessing lateral processes.
- PIN-NI-GRA'DA** (Lat. *pinna*, a feather; *gradior*, I walk). The group of *Carnivora*, comprising the Seals and Walruses, adapted for aquatic life. Often called *Pinnipedia*.
- PIN'NU-LÆ** (Lat. dim. of *pinna*.) The lateral processes of the arms of *Crinoids*.
- PIS'CES** (Lat. *piscis*, a fish). The class of Vertebrates comprising the Fishes.
- PLA-CEN'TA** (Lat. for a cake.) The "after-birth," or the organ by which a

- vascular connection is established in the higher *Mammalia* between the mother and the fetus.
- PLA-CEN'TAL. Possessing a placenta, or connected with the placenta.
- PLAC'OID (Gr. *plax*, a plate; *eidos*, form). Applied to the irregular bony plates, grains, or spines, which are found in the skin of various fishes (*Elasmobranchii*).
- PLA-GI-OS'TO-MI (Gr. *plagios*, transverse; *stoma*, mouth). The Sharks and Rays, in which the mouth is transverse, and is placed on the under surface of the head.
- PLA-NAR'I-DA (Gr. *plan*, wandering). A sub-order of the *Turbellaria*.
- PLAN-TI-GRA'DA.
- PLANT'I-GRADE (Lat. *planta*, the sole of the foot; *gradior*, I walk). Applying the sole of the foot to the ground in walking.
- PLAN'U-LA (Lat. *planus*, flat). The oval ciliated embryo of certain of the *Hydrozoa*.
- PLAS'TEON. The lower or ventral portion of the bony case of the Chelonians.
- PLAT-Y-EL'MI-A (Gr. *platus*, broad; and *helmins*, an intestinal worm). The division of *Selecida* comprising the Tape-worms, etc.
- PLAT-Y-RHI'NA (Gr. *platus*, broad; *rhines*, nostrils). A group of the *Quadrumania*.
- PLE-SI-O-SAC'RUS (Gr. *plesios*, near to; and *saurus*, lizard).
- PLEU'RA (Gr. for the side). The serous membrane covering the lung in the air-breathing Vertebrates.
- PLEU'RON (Gr. *pleuron*, a rib). The lateral extensions of the shell of *Crustacea*.
- PLU'TE-US (Lat. for a pent-house). The larval form of the *Echinoidea*.
- PNEU-MAT'IC (Gr. *pneuma*, air). Filled with air.
- PNEU-MAT'O-CYST (Gr. *pneuma*, air; and *kustis*, cyst). The air-sac or float of certain of the Oceanic *Hydrozoa* (*Physophoridae*).
- PNEU-MAT'O-PHORE (Gr. *pneuma*, air; and *phero*, I carry). The proximal dilatation of the ecnosarc in the *Physophoridae* which surrounds the pneumatocyst.
- PNEU-MO-SKEL'E-TON (Gr. *pneuma*; and *skeletos*, dry). The hard structures which are connected with the breathing organs (*e.g.*, the shell of Molluscs).
- POD-OPH-THAL'MATA (Gr. *pous*, foot; and *ophthalmos*, eye). The division of *Crustacea* in which the eyes are borne at the end of long foot-stalks.
- POD-O-SOM'A-TA (Gr. *pous*, foot; *soma*, body). An order of *Arachnida*.
- PO-EPH'A-GA (Gr. *poe*, grass; *phago*, I eat). A group of the Marsupials.
- POIS'ERS.
- POL'LEX (Lat. for the thumb). The innermost of the five normal digits of the anterior limb of the higher Vertebrates. In man, the thumb.
- POL-Y-CYS-TI'NA (Gr. *polus*, many; and *kustis*, a cyst). An order of *Protozoa*, with foraminated siliceous shells.
- PO-LYG'A-MOUS (Gr. *polus*; and *gamos*, marriage).
- POL-Y-GAS'TRI-CA (Gr. *polus*; and *gaster*, stomach). The name applied by Ehrenberg to the *Infusoria*, under the belief that they possessed many stomachs.
- POL-Y-PA-RY (Gr. *polus*; and *pario*, I produce). The hard chitinous covering secreted by many of the *Hydrozoa*.
- POLYPE (Gr. *polus*, many; *pous*, foot). Restricted to the single individual of a simple *Actinozoon*, such as a Sea-anemone, or to the separate zooids of a compound *Actinozoon*. Often applied indiscriminately to any of the *Celenterata*, or even to the *Polyzoa*.
- POL-Y-PIDE. The separate zooid of a *Polyzoön*.
- POL-Y-PID-OM. The dermal system of a colony of a *Hydrozoön*, or *Polyzoön*.
- POL-Y-PITE. The separate zooid of a *Hydrozoön*.
- POL-Y-STOME (Gr. *polus*, many; and *stoma*, mouth). Having many mouths; applied to the *Acinetæ* among the *Protozoa*.
- POL-Y-THAL'A-MOUS (Gr. *polus*; and *thalamos*, chamber). Having many chambers; applied to the shells of *Foraminifera* and *Cephalopoda*.
- POL-Y-ZO'A (Gr. *polus*; and *zoon*, animal). A division of the *Molluscoidea*, comprising compound animals, such as the Sea-mat. Sometimes called *Bryozoa*.

- POL-Y-ZO-A'RI-UM.** The dermal system of the colony of a *Polyzōon* (= Polypidom).
- POR-CEL-LA'NE-OUS.** Of the texture of porcelain.
- PO-RIF'E-RA** (Lat. *porus*, a pore; and *fero*, I carry. Sometimes used to designate the *Foraminifera*, or the *Sponges*).
- POST'A-NAL** (Lat. *post*, behind; *anus*, the fundament). Situated behind the anus.
- POST-GE-SO-PHAG'E-AL** (Gr. *oisophagos*, the gullet). Situated behind the gullet.
- POST-O'RAL** (Lat. *os*, mouth). Situated behind the mouth.
- PRÆ-MAX-IL-LÆ.** (See Internaxillæ.)
- PRÆ-MO'LARS** (Lat. *præ*, before; *molars*, the grinders). The molar teeth of Mammals which succeed the molars of the milk-set of teeth. In man, the bicuspid teeth.
- PRÆ-GE-SO-PHAG'E-AL.** Situated in front of the gullet.
- PRÆ-STER'NUM** (Gr. *sternon*, the breast). The anterior portion of the breast-bone, corresponding with the *manubrium sterni* of human anatomy, and extending as far as the point of articulation of the second rib.
- PRES-SI-ROS TRES** (Lat. *pressus*, compressed; *rostrum*, beak). A group of the Grallatorial Birds.
- PROB-OS-CID'E-A** (Lat. *prob scis*, the snout). The order of Mammals comprising the Elephants.
- PRO-BOS CIS** (Lat. or Gr. for the snout). Applied to the spiral trunk of *Lepidopterous Insects*, to the projecting mouth of certain *Crinoids*, and to the central polypite in the *Medusæ*.
- PRO-CÆ'LOUS** (Gr. *pro*, in front; *koilos*, hollow). Applied to vertebræ, the bodies of which are hollow or concave in front.
- PRO-GLOT'TIS** (Gr. for the tip of the tongue). The generative segment or joint of a Tape-worm.
- PRO'LEGS.** The false abdominal feet of Caterpillars.
- PRO-NATION** (Lat. *pronus*, lying on the face, prone). The act of turning the palm of the hand downward.
- PRO-PO'DI-UM** (Gr. *pro*, before; *pous*, foot). The anterior part of the foot in Molluscs.
- PRO-SCO'LEX** (Gr. *pro*, before; *scolex*, worm). The first embryonic stage of a Tape-worm.
- PRO-SO-BRAN-CHI-A'TA** (Gr. *proso*, in advance of; *bragchia*, gills). A division of Gasteropodous Molluscs in which the gills are situated in advance of the heart.
- PRO-SO'MA** (Gr. *pro*, before; *soma*, body). The anterior part of the body.
- PRO-THO'RAX** (Gr. *pro*; and *thorac*, chest). The anterior ring of the thorax of insects.
- PRO-TOPH'Y-TA** (Gr. *protos*, first; and *phuton*, plant). The lowest division of plants.
- PRO'TO-PLASM** (Gr. *protos*; and *plasso*, I mould). The elementary basis of organized tissues. Sometimes used synonymously for the "sarcode" of the *Protozoa*.
- PRO-TO'PO-DITE** (Gr. *protos*; and *pous*, foot). The basal segment of the typical limb of a *Crustacean*.
- PRO-TO-ZO'A** (Gr. *protos*; and *zo'n*, animal). The lowest division of the animal kingdom.
- PRO-VEN-TRIC'U-LUS** (Lat. *pro*, in front of; *ventriculus*, dim. of *venter*, belly). The cardiac portion of the stomach of Birds.
- PROX'I-MAL** (Lat. *proximus*, next). The slowly-growing, comparatively-fixed extremity of a limb or of an organism.
- PSAL-TE'RI-UM** (Lat. for a stringed instrument). The third stomach of Ruminants. (See *Omasum*.)
- PSEU-DEM'BRY-O** (Gr. *pseudes*, false; *embryon*, embryo). The larval form of an *Echinoderm*.
- PSEU-DO-BRAN'CHI-A** (Gr. *pseudes*, false; *bragchia*, gills). A supplementary gill found in certain fishes, which receives arterialized blood only, and does not, therefore, assist in respiration.

- PSEU-DO-HÆ'MAL** (Gr. *pseudes*, false; and *haima*, blood). Applied to the vascular system of *Annelida*.
- PSEU'DO-HEARTS**. Certain contractile cavities connected with the atrial system of *Brachiopoda*, and long considered to be hearts.
- PSEU-DO-NAV-I-CEL'LE** (Gr. *pseudes*, false; and *Navicula*, a genus of Diatoms). The embryonic forms of the *Gregarinidæ*, so called from their resemblance in shape to the *Navicula*.
- PSEU-DO-PO'DI-A** (Gr. *pseudes*; and *pous*, foot). The extensions of the body-substance which are put forth by the *Rhizopoda* at will, and which serve for locomotion and prehension.
- PSEU-DO'VA** (Gr. *pseudes*; (Lat. *ovum*, egg). The egg-like bodies from which the young of the viviparous *Aphis* are produced.
- PTER-OP'O-DA** (Gr. *pteron*, wing; and *pous*, foot). A class of the *Mollusca* which swim by means of fins attached near the head.
- PTER-O-SAU'RI-A** (Gr. *pteron*, wing; *saura*, lizard). An extinct order of Reptiles.
- PUBIS** (Lat. *pubes*, hair). The share-bone; one of the bones which enter into the composition of the pelvic arch of Vertebrates.
- PUL-MO-GAS-TER-OP'O-DA** (= Pulmonifera).
- PUL-MO-NA-RI-A**. A division of *Arachnida* which breathe by means of pulmonary sacs.
- PUL'MO-NA-RY**.
- PUL'MO-NATE**. Possessing lungs.
- PUL-MO-NIF'E-RA** (Lat. *pulmo*, a lung; and *fero*, I carry). The division of *Mollusca* which breathe by means of a pulmonary chamber.
- PUPA** (Lat. for a doll). The stage of an insect immediately preceding its appearance in a perfect condition. In the pupa-stage it is usually quiescent—when it is often called a “chrysalis;” but it is sometimes active—when it is often called a “nymph.”
- PY-LO'RUS** (Gr. *puloros*, a gatekeeper). The valvular aperture between the stomach and the intestines.
- PYR-I-FORM** (Lat. *pirum* or *pyrum*, a pear; and *forma*, form). Pear-shaped.
- QUAD-RU-MA'NA** (Lat. *quatuor*, four; *manus*, hand). The order of Mammals comprising the Apes, Monkeys, Baboons, Lemurs, etc.
- QUAD-RU-MA'NOUS**.
- RA-DI-A'TA** (Lat. *radius*, a ray). Formerly applied to a large number of animals which are now placed in separate sub-kingdoms (e. g., the *Cœlenterata*, the *Echinodermata*, the *Infusoria*, etc.).
- RA-DI-O-LA'RI-A** (Lat. *radius*, a ray). A division of *Protozoa*.
- RA'DI-US** (Lat. for a spoke or ray). The innermost of the two bones of the forearm of the higher Vertebrates. It carries the thumb, when present, and corresponds with the tibia of the hind-limb.
- RA'MUS** (Lat. for a branch). Applied to each half or branch of the lower jaw or mandible of Vertebrates.
- RAP-TO'RES** (Lat. *rapio*, I plunder). The order of the birds of Prey.
- RAP-TO'RI-AL**.
- RA-SO'RES** (Lat. *rado*, I scratch). The order of the Scratching Birds (Fowls, Pigeons, etc.).
- RA-TI'Æ** (Lat. *ratis*, a raft). Applied by Huxley to the Cursorial Birds, which do not fly, and have therefore a raft-like sternum without any median keel.
- REC-TUM** (Lat. *rectus*, straight). The terminal portion of the intestinal canal, opening at the surface of the body at the anus.
- REP-TIL'I-A** (Lat. *repto*, I crawl). The class of the *Vertebrata* comprising the Tortoises, Snakes, Lizards, Crocodiles, etc.
- RE-TIC-U-LA'RI-A** (Lat. *reticulum*, a net). Employed by Dr. Carpenter to designate those *Protozoa*, such as the *Foraminifera*, in which the pseudopodia run into one another and form a network.
- RE-TIC-U-LUM** (Lat. for a net). The second division of the complex stomach of Ruminants, often called the “honey-comb bag.”

- RE-VERSED'**. Applied to spiral univalves, in which the direction of the spiral is the reverse of the normal—*i. e.*, *sinistral*.
- RHI-ZOPH'A-GA** (Gr. *rhiza*, root; *phago*, I eat). A group of the Marsupials.
- RHI-ZO'P'O-DA** (Gr. *rhiza*, a root; and *pous*, foot). The division of *Protozoa* comprising all those which are capable of emitting pseudopodia.
- RHYN'CHO-LITES** (Gr. *rhugchos*, beak; and *lithos*, stone). Beak-shaped fossils, consisting of the mandibles of *Cephalopoda*.
- RO-DEN'TI-A** (Lat. *rodo*, I gnaw). An order of the Mammals; often called *Glires* (Lat. *glis*, a dormouse).
- ROS'TRUM** (Lat. *rostrum*, beak). The "beak" or suctorial organ formed by the appendages of the mouth in certain insects.
- RO-TA-TO-RI-A** (= Rotifera).
- RO-TIF'E-RA** (Lat. *rota*, wheel; and *fero*, I carry). A class of the *Scolecida* (*Annuloida*) characterized by a ciliated "trochal disc."
- RU-GO'SA** (Lat. *rugosus*, wrinkled). An extinct order of Corals.
- RU'MEN** (Lat. for the throat). The first cavity of the complex stomach of Ruminants; often called the "paunch."
- RU-MI-NAN'TI-A** (Lat. *ruminor*, I chew the cud). The group of Hoofed Quadrupeds (*Ungulata*) which "ruminates" or chew the cud.
- SA'CRUM**. The vertebrae (usually ankylosed) which unite with the haunch-bones (*ilia*) to form the pelvis.
- SAND-CA-NAL** (= Stone-CA-NAL). The tube by which water is conveyed from the exterior to the ambulacral system of the *Echinodermata*.
- SAR'CODE** (Gr. *sarx*, flesh; *eidos*, form). The jelly-like substance of which the bodies of *Protozoa* are composed. It is an albuminous body containing oil-granules, and is sometimes called "animal protoplasm."
- SAR'COIDS** (Gr. *sarx*; and *eidos*, form). The separate amœbiform particles which in the aggregate make up the "flesh" of a Sponge.
- SAU'RI-A** (Gr. *saura*, a lizard). Any lizard-like Reptile is often spoken of as a "Saurian;" but the term is sometimes restricted to the Crocodiles alone, or to the Crocodiles and Lacertilians.
- SAU-RO-BATRA'CHI-A** (Gr. *saura*; *batrachos*, frog). Sometimes applied to the order of the tailed Amphibians (*Urodela*).
- SAU-ROP'SI-DA** (Gr. *saura*; and *opsis*, appearance). The name given by Huxley to the two classes of the Birds and Reptiles collectively.
- SAU-ROP-TER-YG'I-A** (Gr. *saura*; and *pterus*, wing). An extinct order of Reptiles, called by Huxley *Plesiosauria*, from the typical genus *Plesiosaurus*.
- SAU-RU'RÆ** (Gr. *saura*; and *oura*, tail). The extinct order of Birds comprising only the *Archæopteryx*.
- SCAN-SO'RES** (Lat. *scando*, I climb). The order of the Climbing Birds (Parrots, Woodpeckers, etc.).
- SCA-PHO'G'NA-THITE** (Gr. *skapnos*, boat; and *gnathos*, jaw). The boat-shaped appendage (epipodite) of the second pair of maxillæ in the Lobster; the function of which is to spoon out the water from the branchial chamber.
- SCAP'U-LA** (Lat. for shoulder-blade). The shoulder-blade of the pectoral arch of Vertebrates; in a restricted sense, the row of plates in the cup of *Crinoids*, which give origin to the arms, and are usually called the "axillary radials."
- SCLER-EN'CHY-MA** (Gr. *skleros*, hard; and *egchuma*, tissue). The calcareous tissue of which a coral is composed.
- SCLERITES** (Gr. *skleros*). The calcareous spicules which are scattered in the soft tissues of certain *Actinozoa*.
- SCLER-O-BA'SIC** (Gr. *skleros*, hard; *basis*, pedestal). The coral which is produced by the outer surface of the integument in certain *Actinozoa* (*v. g.*, Red Coral), and forms a solid axis which is invested by the soft parts of the animal. It is called "foot-secretion" by Mr. Dana.
- SCLER-O-DE'R-MIC** (Gr. *skleros*; and *derma*, skin). Applied to the corallum which is deposited within the tissues of certain *Actinozoa*, and is called "tissue-secretion" by Mr. Dana.
- SOLE-ROT'IO** (Gr. *skleros*, hard). The outer dense fibrous coat of the eye.

- SCO-LEO'I-DA (Gr. *skolēx*, worm). A division of the *Annuloida*.
- SCO'LEX (Gr. for worm). The embryonic stage of a Tape-worm, formerly known as a "Cystic Worm."
- SCU'TA (Lat. *scutum*, a shield). Applied to any shield-like plates; especially to those which are developed in the integument of many Reptiles.
- SE-LA'CHI-A or SE-LA'CHI-I (Gr. *selachos*, a cartilaginous fish, probably a shark). The sub-order of *Elasmobranchii*, comprising the Sharks and Dog-fishes.
- SE'PI-O-STAI'RE (Lat. and Gr. *sepia*, the cuttle-fish.) The internal shell of the Cuttle-fish, commonly known as the "cuttle-bone."
- SEP'TA. Partitions.
- SER-PEN'TI-FORM. Resembling a serpent in shape.
- SER-TU-LAR'I-DA (Lat. *sertum*, a wreath). An order of *Hydrozoa*.
- SES'SILE (Lat. *sevelo*, I sit). Not supported upon a stalk or peduncle; attached by a base.
- SE'TÆ (Lat. for bristles). Bristles, or long stiff hairs.
- SE-TIF'ER-OUS. Supporting bristles.
- SE-TIG'ER-OUS (= Setiferous).
- SE'TOSE. Bristly.
- SI-LIC'E'OUS (Lat. *silex*, flint). Composed of flint.
- SIN'IS-TRAL (Lat. *sinistra*, the left hand). Left-handed; applied to the direction of the spiral in certain shells, which are said to be "reversed."
- SIN'US (Lat. *sinus*, a bay). A dilated vein or blood-receptacle.
- SIP'HON (Gr. *siphon*, a tube). Applied to the respiratory tubes in the *Mollusca*; also to other tubes of different functions.
- SI-PHON-OPH'O-RA (Gr. *siphon*; and *phero*, I carry). A division of the *Hydrozoa*, comprising the Oceanic forms (*Calycephoridae* and *Physophoridae*).
- SI-PHON-O-STOM'A-TA (Gr. *siphon*; and *stoma*, mouth). The division of *Gastropodous Molluscs*, in which the aperture of the shell is not "entire," but possesses a notch or tube for the emission of the respiratory siphon.
- SI-PHUN'CLE (Lat. *siphunculus*, a little tube). The tube which connects together the various chambers of the shell of certain *Cephalopoda* (e. g., the Pearly Nautilus).
- SI-PHUN-CU-LOI'DE-A (Lat. *siphunculus*, a little siphon). A class of *Anarthropoda* (*Annulosa*).
- SI-RE'NI-A (Gr. *seiren*, a mermaid). The order of *Mammalia* comprising the Dugongs and Manatees.
- SOL-ID-UN'GU-LA (Lat. *solidus*, solid; *ungula*, a hoof). The group of Hoofed Quadrupeds comprising the Horse, Ass, and Zebra, in which each foot has only a single solid hoof. Often called *Solipedia*.
- SO-MAT'IO (Gr. *soma*, body). Connected with the body.
- SO-MAT'O-CYST (Gr. *soma*; and *kystis*, a cyst). A peculiar cavity in the cœnosarc of the *Calycephoridae* (*Hydrozoa*).
- SO'MITE (Gr. *soma*). A single segment in the body of an Articulate animal.
- SPER-MAT'RI-UM. The organ in which spermatozoa are produced.
- SPER-MAT'O-PHORES (Gr. *sperma*, seed; *phero*, I carry). The cylindrical capsules of the *Cephalopoda*, which carry the spermatozoa; sometimes called the "moving filaments of Needham."
- SPER-MA-TO-ZO'A (Gr. *sperma*, seed; and *zo'n*, animal). The microscopic filaments which form the essential generative element of the male.
- SPI'CU-LA (Lat. *spiculum*, a point). Pointed needle-shaped bodies.
- SPIN'NER-ETS. The organs by means of which Spiders and Caterpillars spin threads.
- SPI'RA-LES (Lat. *spiro*, I breathe). The breathing-pores, or apertures of the breathing-tubes (tracheæ) of Insects. Also the single nostril of the Hag-fishes, the "blow-hole" of Cetaceans, etc.
- SPLANCH-NO-SKEL'E-TON (Gr. *splanchna*, viscera; *skeletos*, dry). The hard structures occasionally developed in connection with the internal organs or viscera.
- SPONGE-PAR'TI-CLES. (See Sarcoids).
- SPON'GI-DA (Gr. *spoggos*, a sponge). The division of *Protozoa* commonly known as sponges.

- SPORES** (Gr. *spora*, seed). Germs, usually of plants; in a restricted sense, the reproductive "gemmules" of certain Sponges.
- SPO'RO-SACS** (Gr. *spora*, seed; and *sakkos*, a bag). The simple generative buds of certain *Hydrozoa*, in which the medusoid structure is not developed.
- SQUA'MA-TA** (Lat. *squama*, a scale). The division of Reptiles comprising the *Ophidia* and *Lacertilia* in which the integument develops horny scales, but there are no dermal ossifications.
- STAT'O-BLASTS** (Gr. *statos*, stationary; *blastos*, bud). Certain reproductive buds developed in the interior of *Polyzoa*, but not liberated until the death of the parent organism.
- STEG-AN-OPH-THAL'MA-TA** (Gr. *steganos*, covered; and *ophthalmos*, the eye). Applied by Edward Forbes to certain *Medusæ*, in which the sense-organs ("marginal bodies") are protected by a sort of hood. The *Steganophthalmata* are now separated from the true *Medusidæ*, and placed in a separate division under the name *Lucernarida*.
- STEL-LE'R-I-DA** (Lat. *stella*, star). Sometimes applied to designate the order of the Star-fishes.
- STEL'LI-FORM**. Star-shaped.
- STEM'MA-TA** (Gr. *stemma*, garland). The simple eyes, or "ocelli," of certain animals, such as Insects, Spiders, and Crustacea.
- STER'NUM** (Gr. *sternon*). The breast-bone.
- STIG'MA-TA**. The breathing-pores in *Insects* and *Arachnida*.
- STO'LON** (Gr. *stolos*, a sending-forth). Off-shoots.—The connecting processes of sarcode, in *Foraminifera*; the connecting tube in the social *Ascidians*; the processes sent out by the cœnosarc of certain *Actinozoa*.
- STO-MAP'O-DA** (Gr. *stoma*, mouth; *pous*, foot). An order of *Crustacea*.
- STOM'A-TODE** (Gr. *stoma*; *eidos*, form). Possessing a mouth. The *Infusoria* are thus often called the Stomatode *Protozoa*.
- STREP-SIP'TE-RA** (Gr. *strepho*, I twist; and *pteron*, wing). An order of Insects in which the anterior wings are represented by twisted rudiments.
- STREPS-I-RHI'NA** (Gr. *strepho*, I twist; *rhînes*, nostrils). A group of the *Quadrumana*, often spoken of as *Prosimiæ*.
- STROB'I-LA** (Gr. *strobilos*, a top, or fir-cone). The adult Tape-worm with its generative segments or proglottides; also applied to one of the stages in the life history of the *Lucernarida*.
- STR'LI-FORM** (Lat. *stylus*, a pointed instrument; *forma*, form). Pointed in shape.
- SUB-CAL-CA'RE-OUS**. Somewhat calcareous.
- SUB-CEN'TRAL**. Nearly central, but not quite.
- SUB-PE-DUN'OU-LATE**. Supported upon a very short stem.
- SUB-SES'SILE**. Nearly sessile, or without a stalk.
- SUC-TO'RI-AL**.
- SU-PI-NA'TION** (Lat. *supinus*, lying with the face upward). The act of turning the hand with the palm upward.
- SU-PRA-G-E-SO-PHAG'E-AL**.
- SU'TURE** (Lat. *suo*, I sew). The line of junction of two parts which are immovably connected together. Applied to the line where the whorls of a univalve shell join one another; also to the lines made upon the exterior of the shell of a chambered *Cephalopod* by the margins of the septa.
- SWIM'MER-ETS**. The limbs of *Crustacea*, which are adapted for swimming.
- SYM'PHY-SIS** (Gr. *sumphusis*, a growing together). Union of two bones in which there is no motion, or but a very limited amount.
- SYN-AP-TIC'U-LÆ** (Gr. *synapto*, I fasten together). Transverse props sometimes found in Corals, extending across the loculi like the bars of a grate.
- SYS'TO-LE** (Gr. *sustello*, I contract). Applied to the contraction of any contractile cavity, especially the heart.

TAB'U-LÆ (Lat. *tabula*, a tablet). Horizontal plates or floors found in some Corals, extending across the cavity of the "theca," from side to side.

TAC'TILE (Lat. *tango*, I touch). Connected with the sense of touch.

- TÆ-NI'A-DA** (Gr. *tainia*, a ribbon). The division of *Scolecida* comprising the Tape-worms.
- TÆ-NI-ŌID** (Gr. *tainia*; and *eidōs*, form). Ribbon-shaped, like a Tape-worm.
- TAR-SO-MET-A-TAR'SUS**. The single bone in the leg of Birds produced by the union and anchylosis of the lower or distal portion of the tarsus with the whole of the metatarsus.
- TAR'SUS** (Gr. *tarsos*, the flat of the foot). The small bones which form the ankle (or "instep" of man), and which correspond with the wrist (*carpus*) of the anterior limb.
- TEC-TI-BRAN-CHI-A'TA** (Lat. *tectus*, covered; and Gr. *brachia*, gills). A division of *Opisthobranchiate Gasteropoda* in which the gills are protected by the mantle.
- TEG-U-MENT'AR-Y** (Lat. *tegumentum*, a covering). Connected with the integument or skin.
- TEL-E-OS'TE-I** (Gr. *telcios*, perfect; *osteon*, bone). The order of the "Bony" Fishes.
- TEL'SON** (Gr. *telson*, a limit). The last joint in the abdomen of *Crustacea*; variously regarded as a segment without appendages, or as an azygos appendage.
- TEN-U-I-ROS'TRES** (Lat. *tenuis*, slender; *rostrum*, beak). A group of the Perching Birds characterized by their slender beaks.
- TER'GUM** (Lat. for back). The dorsal arc of the somite of an Arthropod.
- TER-RES'TRI-AL**.
- TER-RIC'O-LA** (Lat. *terra*, earth; and *colo*, I inhabit). Employed occasionally to designate the Earth-worms (*Lumbricidæ*).
- TEST** (Lat. *testa*, shell). The shell of *Mollusca*, which are for this reason sometimes called "*Testacea*;" also, the calcareous case of *Echinoderms*; also, the thick, leathery, outer tunic in the *Tunicata*.
- TES-TA'CEOUS**. Provided with a shell or hard covering.
- TES'TIS** (Lat. *testis*, the testicle). The organ in the male animal which produces the generative fluid or semen.
- TET-RA-BRAN-CHI-A'TA** (Gr. *tetra*, four; *brachia*, gills). The order of *Cephalopoda*, characterized by the possession of four gills.
- THA-LAS-SI-COL'LI-DA** (Gr. *thalassa*, sea; *kolla*, glue). A division of *Protozoa*.
- THE'CA** (Gr. *theke*, a sheath). A sheath or receptacle.
- THE-CO-SOM'A-TA** (Gr. *theke*; and *soma*, body). A division of *Pteropodous Molluscs*, in which the body is protected by an external shell.
- THE-RI-O-MOR'PHA** (Gr. *therion*, beast; *morphe*, shape). Applied by Owen to the order of the Tail-less Amphibians (*Anoura*).
- THO'RAX** (Gr. for a breast-plate). The chest.
- THREAD-CELLS**. (See *Unidiv*.)
- THYS-A-NU'RA** (Gr. *thusanoi*, fringes; and *oura*, tail). An order of Apterous Insects.
- TIE'IA** (Lat. for a flute). The shin-bone, being the innermost of the two bones of the leg, and corresponding with the *radius* in the anterior extremity.
- TO-TI-PAL'MA-TÆ** (Lat. *totus*, whole; *palma*, the palm of the hand). A group of Wading Birds in which the hallux is united to the other toes by membrane, so that the feet are completely webbed.
- TRA-CHE'A** (Gr. *tracheia*, the wind-pipe). The tube which conveys air to the lungs in the air-breathing Vertebrates.
- TRA-CHE'Æ**. The breathing-tubes of insects and other articulate animals.
- TRA-CHE-A'RI-A**. The division of *Arachnida* which breathe by means of tracheæ.
- TREM-A-TO'DA** (Gr. *tréma*, a pore; *eidōs*, form). An order of *Scolecida*.
- TRICH'O-CYSTS** (Gr. *thrix*, hair; and *kystis*, a cyst). Peculiar cells found in certain *Infusoria*, and very nearly identical with the "thread-cells" of *Celenterata*.
- TRI-LOB'I-TA** (Gr. *treis*, three; *lobos*, a lobe). An extinct order of *Crustaceans*.
- TRIT-O-ZO'OID** (Gr. *tritōs*, third; *zōon*, animal; and *eidōs*, form). The zooid produced by a deuterozooid, that is to say, a zooid of the third generation.

- TRO'CHAL** (Gr. *trochos*, a wheel). Wheel-shaped; applied to the ciliated disc of the *Rotifera*.
- TRO-CHAN'TER** (Gr. *trecho*, I run). A process of the upper part of the thigh-bone (*femur*) to which are attached the muscles which rotate the limb. There may be two, or even three, trochanters present.
- TRO'CHOID** (Gr. *trochos*, a wheel; and *eidōs*, form). Conical, with a flat base: applied to the shells of *Foraminifera* and *Univalve Molluscs*.
- TRO'PHI** (Gr. *trophos*, a nourisher). The parts of the mouth in insects which are concerned in the acquisition and preparation of food. Often called "instrumenta cibaria."
- TROPH'O-SOME** (Gr. *trephe*, I nourish; and *soma*, body). Applied collectively to the assemblage of the nutritive zooids of any *Hydrozoan*.
- TRUN'CA-TED** (Lat. *trunco*, I shorten). Abruptly cut off; applied to univalve shells, the apex of which breaks off, so that the shell becomes "decolated."
- TU-BIC'O-LA** (Lat. *tuba*, a tube; and *cola*, I inhabit). The order of *Annelida* which construct a tubular case in which they protect themselves.
- TU-BIC'O-LOUS**. Inhabiting a tube.
- TU-BU-LAR'I-DA**.
- TU-NI-CA'TA** (Lat. *tunica*, a cloak). A class of *Mollusca* which are enveloped in a tough, leathery case or "test."
- TUR-BEL-LA'RI-A** (Lat. *turbo*, I disturb). An order of *Scolecida*.
- TUR-BI-NA-TED** (Lat. *turbo*, a top). Top-shaped; conical, with a round base.
- UL'NA** (Gr. *olene*, the elbow). The outermost of the two bones of the forearm, corresponding with the *fibula* of the hind-limb.
- UMBEL-LATE** (Lat. *umbella*, a parasol). Forming an umbel —i. e., a number of nearly equal *radii*, all proceeding from one point.
- UMBIL'I-CUS** (Lat. for navel). The aperture seen at the base of the axis of certain univalve shells, which are then said to be "perforated" or "umbilicated."
- UM'BO** (Lat. for the boss of a shield). The beak of a bivalve shell.
- UMBREL'LA**. The contractile disc of one of the *Lucernarida*.
- UN'CI-NATE** (Lat. *uncus*, a hook). Provided with hooks or bent spines.
- UN-GUIC'U-LATE** (Lat. *unguis*, nail). Furnished with claws.
- UN-GU-LA'TA** (Lat. *ungula*, hoof). The order of *Mammals* comprising the Hoofed Quadrupeds.
- UN'GU-LATE**. Furnished with expanded nails constituting hoofs.
- U-NI-LOC'U-LAR** (Lat. *unus*, one; and *loculus*, a little purse). Possessing a single cavity or chamber. Applied to the shells of *Foraminifera* and *Mollusca*.
- U'NI-VALVE** (Lat. *unus*, one; *valvæ*, folding-doors). A shell composed of a single piece or valve.
- URO-DE'LA** (Gr. *oura*, tail; *delos*, visible). The order of the tailed Amphibians (Newts, etc.).
- UR'TI-CA-TING CELLS** (Lat. *urtica*, a nettle). (See *Cnidæ*.)
- VAC'U-LES** (Lat. *vacuus*, empty). The little cavities formed in the interior of many of the *Protozoa* by the presence of little particles of food, usually surrounded by a little water. These are properly called "food-vacuoles," and were supposed to be stomachs by Ehrenberg. Also the clear spaces which are often seen in the tissues of many *Cœlenterata*.
- VARI-CES** (Lat. *varix*, a dilated vein). The ridges or spinose lines which mark the former position of the mouth in certain univalve shells.
- VAS'CU-LAR** (Lat. *vas*, a vessel). Connected with the circulatory system.
- VE'LUM** (Lat. for a sail). The membrane which surrounds and partially closes the mouth of the "disc" of *Medusæ*, or medusiform gonophores.
- VENTRAL** (Lat. *venter*, the stomach). Relating to the inferior surface of the body.
- VENTRI-CLE** (Lat. dim. of *venter*, stomach). Applied to one of the cavities of the heart, which receives blood from the auricle.

- VER'MES** (Lat. *vermis*, a worm). Sometimes employed at the present day in the same, or very nearly the same, sense as *Annuloida*, or as *Annuloida* plus the *Anarthropoda*.
- VER'MI-FORM** (Lat. *vermis*, worm; and *forma*, form). Worm-like.
- VER'TE-BRA** (Lat. *verto*, I turn). One of the bony segments of the vertebral column or back-bone.
- VER-TE-BRA'TA**. (Lat. *vertebra*, a bone of the back, from *vertere*, to turn). The division of the Animal Kingdom roughly characterized by the possession of a back-bone.
- VES'I-CLE** (Lat. *vesica*, a bladder). A little sac or cyst.
- VI-BRAC'U-LA** (Lat. *vibro*, I shake). Long filamentous appendages found in many *Polyzoa*.
- VIB-RI-O'NES** (Lat. *vibro*, I shake). The little moving filaments developed in organic infusions.
- VIP-E-RI'NA** (Lat. *vipera*, a viper). A group of the Snakes.
- VIS'CE-RA**.
- VI-VIP'A-ROUS** (Lat. *vivus*, alive; and *pario*, I bring forth). Bringing forth young alive.
- WHORL**. The spiral turn of a univalve shell.
- XIPH-I-STER'NUM** (Gr. *xiphos*, sword; *sternon*, breast-bone). The inferior or posterior segment of the sternum, corresponding with the "xiphoid cartilage" of human anatomy.
- XIPH-O-SU'RA** (Gr. *xiphos*, a sword; and *oura*, tail). An order of *Crustacea*, comprising the *Limuli* or King-Crabs, characterized by their long sword-like tails.
- XY-LOPH'A-GOUS** (Gr. *xulon*, wood; and *phago*, I eat). Eating wood; applied to certain *Mollusca*.
- ZO'ÖID** (Gr. *zoön*, animal; and *eidos*, form). The more or less completely independent organisms, produced by gemmation or fission, whether these remain attached to one another or are detached and set free.
- ZO'O-PHYTE** (Gr. *zoön*, animal; *phuton*, plant). Loosely applied to many plant-like animals, such as Sponges, Corals, Sea-anemones, Sea-mats, etc.
- ZO'O-SPORES** (Gr. *zoön*, animal; and *spora*, seed). The ciliated locomotive germs of some of the lowest forms of plants (*Protophyta*).

INDEX.

 Musk-ox, 340.
Musquash, 351.
Mustelidæ, 347.
Mya, 197, 201.
Mycetes, 357.
Myoxidæ, 351.
Myriapoda, 113; general characters of, 157.
Myrmecophaga, 326.
Myrmeleo, 173.
Myxine, 239.
Myxinidæ, 239.
 Myxinoids, 236, 240.
Naididæ, 131.
Naja, 264, 268.
 Narwhal, 330.
Nasua, 347.
Natatores, 293; general characters of, 293, *et seq.*
 Nautiloid shells (*Foraminifera*), 32.
Nautilus, Pearly, 208, 209, 210, 212, 215; Paper, 2, 8, 209, 211, 212.
 Nectocalyces, 72, 75.
Nematelmia, 113, 121.
Nematodea, 114; general characters of, 122.
Nemertidæ, 121.
Nereis, 135.
 Nervures, 160.
Neuroptera, 173.
 Newt, 251, 253.
Nodosaria, 30, 31.
 Nucleolus of *Paramæcium*, 40.
 Nucleus of *Paramæcium*, 40.
Nudibranchiata, 204.
Numenius, 296.
Numida, 299.
 Nannulites, 33.
 Nannulitic Limestone, 33.
Nycticebidæ, 356.
Nymphon, 153.
 OCEANIC Hydrozoa, 72, *et seq.*
Octopoda, 212, *et seq.*
Octopus, 212.
Odontoceti, 330.
Odontolceæ, 306.
 Odontophore of *Gasteropoda*, 2C1.
Odontornithes, 290, 306.
Odontotormæ, 307.
Oligochæta, 131; general characters of, 131.
Omnivora (*Ungulata*), 333.
Oniscus, 143.
Onychophora, 153.
 Operculum (of *Molluscs*), 201.
Ophidia, 253, 260; general characters of, 264, *et seq.*
Ophiocoma, 105.
Ophioglypha, 105.
Ophiomorpha, 253.
Ophisaurus, 271.
Ophiotrix, 105.
Ophiura, 105.
Ophuroidea, 99, 105; general characters of, 105.
 Opossum, 322, 323.
 Orang-outang, 359.
 Organ-pipe Coral, 92.
 Organs of the mouth of Insects, 161.
Ornithorhynchus, 319, 320, 321.
Orthoceras, 216.
Orthoptera, 171, 172.
Ortyx, 298.
Orycteropus, 326.
 Oscula of Sponges, 43, 46.
Ostraciontidae, 243.
Ostracoda, 147.
 Ostrich, 279, 281, 283, 284, 286, 288, 290, 291.
Otidæ, 297.
 Otter, 347.
 Ovarian vesicles of *Sertularida*, 67.
Ovibos, 340.
Ovidæ, 339.
 Ovipositor, 161.
Ovis, 339.

General Science.

Doerner's Treasury of Knowledge.

By CELIA DOERNER. } Part I. \$0.50.
 } Part II.65.

This book is designed to fill a gap in the ordinary course of instruction, and furnishes in a small compass much useful and important information. Since it combines entertainment with instruction, it will be found especially useful to parents as an addition to the child's home library.

Hooker's Child's Book of Nature. (COMPLETE.)

By WORTHINGTON HOOKER, M. D., \$1.00.

Three parts in one: Part I. Plants; Part II. Animals; Part III. Air, Water, Heat, Light, etc. Designed to aid mothers and teachers in training children in the observation of Nature. It presents a general survey of the kingdom of Nature in a manner calculated to attract the attention of the child, and at the same time to furnish him with accurate and important scientific information.

Monteith's Easy Lessons in Popular Science.

By JAMES MONTEITH. \$0.75.

This book combines the conversational, catechetical, blackboard, and object plans, with maps, illustrations, and lessons in drawing, spelling, and composition. The subjects are presented in a simple and effective style, such as would be adopted by a good teacher on an excursion with a class.

Monteith's Popular Science Reader.

By JAMES MONTEITH. \$0.75.

This contains lessons and selections in Natural Philosophy, Botany, and Natural History, with blackboard, drawing, and written exercises. It is illustrated with many fine cuts, and brief notes at the foot of each page add greatly to its value.

Steele's Manual. (KEY TO FOURTEEN WEEKS' COURSE.)

By J. DORMAN STEELE, Ph. D. \$1.00.

This is a manual of science for teachers, containing answers to the practical questions and problems in the author's scientific text-books. It also contains many valuable hints to teachers, minor tables, etc.

Wells's Science of Common Things.

By DAVID A. WELLS, A. M. \$0.85.

This is a familiar explanation of the first principles of physical science for schools, families, and young students. Illustrated with numerous engravings. It is designed to furnish for the use of schools and young students an elementary text-book on the first principles of science.

Copies mailed, post-paid, on receipt of price. Full price-list sent on application.

Geology.

Andrews's Elementary Geology.

By E. B. ANDREWS, LL. D. \$1.00.

This book is designed for students and readers of the Interior States, and therefore has its chief references to home geology. The scope is limited, to adapt it to beginners.

Dana's Geological Story Briefly Told.

By JAMES D. DANA, LL. D. \$1.15.

With numerous illustrations. An introduction to geology for the general reader, and for beginners in the science. It contains a complete alphabetical index of subjects.

Dana's Manual of Geology.

By JAMES D. DANA, LL. D. \$3.84.

This is a treatise on the principles of the science adapted to the wants of the American student, with special reference to American geological history. The illustrations are numerous, accurate, and well executed.

Dana's New Text-Book of Geology.

By JAMES D. DANA, LL. D. \$2.00.

On the plan of the Manual, designed for schools and academies. The explanations are simple, and at the same time complete.

Le Conte's Compend of Geology.

By JOSEPH LE CONTE. \$1.20.

A book designed to interest the pupil, and to convey real scientific knowledge. It cultivates the habit of observation by directing the attention of the pupil to scientific phenomena.

Nicholson's Text-Book of Geology.

By H. A. NICHOLSON. \$1.05.

This presents the leading principles and facts of geological science within as brief a compass as is compatible with clearness and accuracy.

Steele's Fourteen Weeks in Geology.

By J. DORMAN STEELE, Ph. D. \$1.00.

Designed to make science interesting by omitting those details which are valuable only to the scientific man, and by presenting only those points of general importance with which every well-informed person wishes to be acquainted.

Williams's Applied Geology.

By S. G. WILLIAMS. \$1.20.

A treatise on the industrial relations of geological structure, and on the nature, occurrence, and uses of substances derived from geological sources. It gives a connected and systematic view of the applications of geology to the various uses of mankind.

Copies mailed, post-paid, on receipt of price. Full price-list sent on application.
