ABSTRACT

This study has as its final product a bathymetric chart of Carmel Bay, California, which is improved over any other previously existing chart. The unique problems of applying the echo-sounding corrections necessary to create accurate bathymetric charts of areas with steep bottom slopes are discussed.

ACKNOWLEDGEMENTS

The author wishes to express his gratitude to Professor R.S. Andrews for his patience and encouragement throughout the course of this project. Thanks are also due to CDR. W.C. Knodle, USN, for his advice on conducting hydrographic surveys, to Mr. L.G. Nolan, Jr., for his help in surveying, to Mr. Don Rich for having the kelp cut performed off Carmel River Beach, and to LT. J.P. Simpson, USN, and LT. L.S. Carter, USN, for their assistance in manning the research vessel during the survey. Mr. Frederick A. Meyer of the California Department of Parks and Recreation, Mr. Earl Smith of the Monterey County Park Department, and Mr. Thompson J. Hudson provided land access for the navigation transponder locations.

Partial funding for this study was provided to Dr. Andrews by the Naval Postgraduate School Research Foundation under an Office of Naval Research grant. Funds for the leasing of the hydrographic research vessel were provided by the Naval Postgraduate School Department of Oceanography.

Further sincere appreciation is given to my mother, Mrs. A.P. Zardeskas, who forced me to study as a youth and whom I have never thanked. Thank You.

I. INTRODUCTION

This paper presents the results of a hydrographic survey of Carmel Bay, California, performed using a 12-kHz fathometer and a 3.5-kHz high resolution reflection profiler. Navigation was accomplished with a two-station range-range positioning system.

The survey was conducted on March 10-12, 1971, from a 52-ft chartered oceanographic survey boat, R/V DAWN STAR, owned and operated by General Oceanographics, Inc., of Newport Beach, California.

A. OBJECTIVE

The objective of this study was to create a bathymetric chart of Carmel Bay, California, which accurately represented the bottom topography. This completed chart, far more detailed than a standard navigational chart, provides a valuable tool to those interested in studying Carmel Bay.

The hydrographic survey was conducted using the best positioning and echo-sounding systems economically available. Corrections were applied to the bathymetric data so as to reproduce faithfully the topographic features of the bottom. During the course of reducing the bathymetric data, equations were derived to handle corrections for the steep bottom slopes encountered in the bay.

The contours on the final chart will not necessarily be the depths that a ship using a standard fathometer would find. The depth corrections were in places very large due to the steep-walled submarine canyon and would cause a vessel to read considerably shallower depths than those indicated on the chart (the depths on the chart being the actual depths).

B. DESCRIPTION OF AREA

Carmel Bay, situated on the central California coast (Fig. 1), is an embayment cut by Carmel Submarine Canyon (a principle tributary of Monterey Submarine Canyon to the north). The head of Carmel Canyon is located close to the beach in the southeastern sector of the bay.

Carmel Bay is protected to the north and south by Cypress Point and Point Lobos, both of which are composed of Cretaceous Santa Lucia granodiorite. Granite Point, Pescadero Point, and the southern half of Abalone Point are also made up of granodiorite. Arrowhead Point and the northern side of Abalone Point are made up of Miocene volcanics.

Carmel Beach, Pebble Beach, Stillwater Cove, and Whaler's Cove have been formed by the weathering of Paleocene Carmelo pebble conglomerate. Dune sands can be found at the north end of Carmel Beach.

Carmel Submarine Canyon is formed by subaerial erosion in solid rock along a possible fault trace (Martin, 1964, p. 54). The major sources of sediment into Carmel Bay

Figure 1. Location Map of Carmel Bay (from C&GS 5476).

are the Carmel River and San Jose Creek, plus some shoreline erosion.

C. PREVIOUS INVESTIGATIONS

Prior to this study, a hydrographic survey of Carmel Bay had been conducted in 1933 by the U.S. Coast and Geodetic Survey (C&GS) (1933). Also, the head of Carmel Canyon had been charted in 1934 by Shepard and Emery (1941). These surveys were conducted using lead line soundings and horizontal sextant angles for positioning. The 1933 survey of C&GS serves as the basis for the present navigation chart of Carmel Bay (C&GS 5476).

The sounding line spacing of the C&GS 1933 survey was 600 ft for depths greater than approximately 20 fm and 300 ft for depths less than 20 fm. Soundings were taken along the lines about every 400 ft in the deeper water and every 200 ft in the shallows. As no more detail than necessary for safe navigation was desired, the deeper areas of the bay lack definition.

The sounding line spacing for the Shepard and Emery survey of the canyon head was 200 ft with soundings taken every 50 ft. This survey was very accurate when accomplished, but this area is subject to variation in depth due to slumping of sediment down the steep canyon walls. It is safe to assume that some bathymetric changes have occurred since 1934.

Lead line soundings give true depths and need only be corrected for tide and wire angles, but suffer from a lack

of continuity. Because lead-line soundings are non-continuous, small-scale features such as rock pinnacles and small channels are difficult to correlate with the overall bottom topography. In addition, wire line soundings cannot be precisely contoured as the depth intervals cannot be accurately interpolated between obtained soundings for areas of rugged and highly variable bathymetry.

II. PROCUREMENT OF DATA

A. SOUNDING LINES

1. Echo-Sounding Equipment

As the ship tracked, 12-kHz fathometer and 3.5-kHz reflection profiling data were taken simultaneously. Both systems utilized 30° transducer cones.

a. Fathometer

A standard hull-mounted Raytheon 12-kHz ship fathometer was used, the data being recorded on standard 7-inch fathometer recorder paper.

b. 3.5-kHz High Resolution Reflection Profiler

Utilizing a towed streamlined transducer 'fish,' the 3.5-kHz profiling system provided the best bathymetric records of the survey. The record was maintained on a modified Giffit GDR precision depth recorder using 18-inch wide wet paper.

2. Sounding Line Spacing

Optimumly when conducting hydrographic surveys using echo sounders, the incident sound cones of the transducers for parallel adjacent sounding lines should be tangent at the ocean bottom so as to provide 100% coverage of the bottom (Fig. 2). Closer spacing of sounding lines is necessary to obtain this coverage in shallow water due to truncation of the sound cone by the bottom. Some representative sound-line spacings for a 30° cone are shown in Table I.

α = angle of transducer sound cone

$\alpha/2$ = half angle of transducer sound cone

d_i = depth

x_i = sounding line spacing for 100% coverage

$x_i = 2d_i \tan(\alpha/2)$

Note: $x_1 < x_2$ for $d_1 < d_2$

Figure 2. Definition of 100% Coverage.

TABLE I
SOUNDING LINE SPACING FOR 100% COVERAGE

<u>Depth fm</u>	<u>Sounding Line Spacing for 100% Coverage, ft</u>
10	32.4
50	161.6
80	258.0
100	323.6
200	649.2

It is estimated that for a hydrographic survey of Carmel Bay to be accomplished with 100% coverage, over 250 n miles of sounding lines would be necessary. This is a large amount considering that Carmel Bay covers less than 6 square miles. The large amount of track is necessary because the northern half of the bay is relatively shallow, requiring a high track density. In addition, the bathymetry of Carmel Bay is very complex, including many rugged rock outcrops on the bottom and a submarine canyon.

Originally proposed sounding line spacings were 250 ft for expected depths less than 80 fm and 500 ft for expected depths greater than 80 fm. These spacings were determined as a compromise between available resources (ship time, navigation net, and acoustic equipment) and desirable track density.

3. Sounding Line Layout

When planning the sounding lines to be steamed in performing a hydrographic survey, the following items were considered:

- Make each line as long as possible to cut down on non-productive time in turns and to provide continuity in the bathymetric records.
- Wider sounding line spacing can be used in deep water without a loss in coverage because the incident sound cone is wider.
- Check-lines should be provided to run at right angles to the tracks to ensure that the depth measurements agree at track intersections.
- Plan sounding lines to run normal to major slope contours so as to avoid cross slope error (discussed in a later section).

The north-south sounding lines of this survey (Fig. 3) were used because they were generally parallel to the major bottom slopes and were the longest tracks possible. These lines were spaced 250 ft apart, with every other north-south sounding line terminated when the expected depth exceeded 80 fm. East-west cross lines were included to check these tracks.

Segmented sounding lines were used around Point Lobos so as to get the maximum resolution of what was known to be an extremely irregular bottom made up primarily of jointed massive igneous rock. The Point Lobos sounding lines were checked with the north-south sounding lines.

4. Sounding Lines Accomplished

The originally planned sounding lines totaled 137 n miles. Due to equipment failure and severe weather limiting the survey to 2½ days of daylight operations, 85 n miles were actually steamed. It is anticipated that the sounding lines not completed will be done at some future date. Figure 3 shows the sounding lines that were steamed and those planned but not completed.

B. NAVIGATION

1. Navigation Equipment

Navigation was accomplished by use of a HIREX positioning system owned and operated by Offshore Navigation, Inc. (ONI), New Orleans, La. Stated accuracy was 5 to 10 ft at ranges of less than 3 miles from the shore stations

Figure 3. Sounding Lines Steamed and Sounding Lines Not Completed.

(J.W. Vernon, General Oceanographics, Inc., personal communication).

HIREX operates in the X-band frequency range and consists of two land-situated transponders powered by batteries and two shipboard receivers.

2. Transponder Positioning Requirements

It was required that the land-situated transponders be placed within line-of-sight to as much of Carmel Bay as possible and that a base line between the two transponders be offset from the bay. In addition, the positions of the transponders had to be accurately known.

Line-of-sight positioning was necessary because the X-band signal transmitted by the transponders is readily interrupted by obstructions such as trees.

The line between the transponders had to be offset because the accuracy of the system is degraded when the area of operation approaches the base line connecting the two transponders.

The position of the transponders had to be precisely known so that the track preplots and post-plots of fixes taken could be accurately made.

3. Transponder Positioning

For the Carmel Bay survey, the northern transponder was placed on C&GS Horizontal Control Point Loma Alta (Table II). The southern transponder was placed on an offset control point, subsequently named Corona, which was surveyed in by the author by land transit triangulation

TABLE II
CONTROL POINT DATA

Horizontal Control Point	Latitude & Longitude	Elevation*	Order of Survey
Corona	36° 30' 51.593" N 121° 55' 21.626" W	710 ft	Surveyed by triangulation from stations Fox and Loma Alta by author.
Fox	36° 33' 40.806" N 121° 57' 09.671" W	40 ft	Third order triangulation**
Loma Alta	36° 33' 40.169" N 121° 52' 37.586" W	1200 ft	Second order triangulation**

*Taken from U.S. Department of Interior Geological Survey, SW/4 Monterey, 15' Quadrangle, N 3630-W 12152.5/8.75X7.5 1947.

**From U.S. Department of Commerce Coast and Geodetic Survey Horizontal Control Data, 1970. (Unpublished data)

from C&GS Horizontal Control Points Fox and Loma Alta (Fig. 4).

4. Fixes

Fixes were obtained by simultaneously receiving the omni-directional range signals from the two transponders and recording them for post-plotting. Fixes were taken at the start and finish of each sounding line and at 3-min intervals along the lines. Since the ship averaged a speed of 5 knots, the 3-min fixes were about 500 ft apart. Each time a fix was taken, the fathometer and 3.5-kHz profiler records were marked and annotated to coincide with the fix number.

C. TRACK MAINTENANCE

The contracted navigation firm (ONI) was provided before the survey with the desired tracks to be steamed. Given these tracks and the fix spacing, the ranges from the two land-based transponders for each anticipated fix were computed. Plotting the ranges from each point on the sounding line to the Station Corona transponder as the abscissa and the ranges to the Station Loma Alta transponder as the ordinate gave a hyperbola segment (Fig. 4).

In this manner, ONI fabricated computerized track pre-plots consisting of segments of hyperbolas with the proposed 3-min fixes along each line indicated. The preplotted track hyperbola for a given line was placed in an X-Y recorder on the ship's bridge prior to steaming the line. The helmsman maintained track by keeping the recorder stylus, driven by

Figure 4. Construction of Track Preplot.

the navigation system, on the preplotted hyperbolas; the stylus represented the ship's position.

The actual fixes were made by hand recording the ranges from the transponder read-outs at 3-min intervals (approximately at the preplotted fixes). A post-plot of the fixes taken along each line with their assigned fix numbers was provided by the contractor. The preplot and post-plot fixes were corrected for transponder elevation because the recorded ranges were actually slant distances from the ship to the transponders.

Figure 5 is a sample preplot showing the ship's actual track superimposed over the precalculated hyperbola.

D. AREA OF SURVEY COVERAGE

The factors limiting the areas covered by this survey were shallows, kelp beds, and equipment limitations.

1. Shallows

Although the relatively small size of the vessel used (52 ft in length) allowed for work in shallow water, it was often necessary to stand well off shore due to shoaling waves and/or the presence of submerged rocks because the 3.5-kHz transducer was towed at a depth of 20 ft.

2. Kelp Beds

In Carmel Bay, large dense beds of kelp (Macrocystis pyrifera) extend for a considerable distance off shore and occasionally caused the premature termination of, or departure from, the planned sounding lines. The kelp beds were

Figure 5. Track Preplot and Ship's Actual Track.

not crossed because the towed instrumentation became fouled and the quality of data obtained deteriorated.

Under the auspices of Mr. Don Rich, Ranger of Point Lobos State Reserve, a kelp cut was held by diving clubs in the area around Carmel River Beach. The elimination of kelp in this area allowed for near shore work in the area of the sewage outfall under construction and at the head of a tributary to Carmel Canyon. Data collected in these areas will be used for baseline studies to show future changes in the bathymetry due to sand deposition from the Carmel River and sediment slumping down the canyon.

3. Equipment Limitations

As mentioned previously, it was necessary for the navigation transponders to be placed on horizontal control points with a clear line of sight to most of Carmel Bay. The sites selected were thought to meet these requirements. However, some blanking of stations did occur in the northernmost part of the bay forcing premature track line cut-off. The blanking was attributed to the tall trees close to Carmel Beach interrupting the X-band signal of the HIREX transponders.

E. DATA COLLECTION

Fathometer and 3.5-kHz transducer data were collected simultaneously as the ship tracked. Both records were marked and annotated at the start and finish of each line and at 3-min intervals coinciding with the navigation system fixes. In addition, a cruise log was kept noting the line number,

the time of start and finish of each line, depth of the towed transducer 'fish', sweep rate of the recorders, firing rate of the 3.5-kHz system, sea state, course, speed, and general remarks.

III. CORRECTIONS APPLIED

Several corrections should be applied to bathymetric data obtained using echo-sounders in order to reproduce an accurate chart of true depths. The errors considered and the corrections to be made are discussed in this section. The actual application of the corrections to the bathymetric records is discussed in the section on data resolution.

A. TRANSDUCER DEPTH

The scales automatically marked on bathymetric records are referenced to the transducer. Since hull-mounted transducers are never at the waterline of the survey vessel, a correction to account for the distance below the waterline must be determined and applied. Towed transducers must have their depths recorded for each line steamed so that the proper correction can be made. The fathometer transducer depth was determined and the towed transducer depth was measured for each line.

B. TIDE CORRECTION

Corrections for tidal variations can be obtained either from a tide gage or from tide tables. The tide gage is the most accurate as it will reflect tidal fluctuations due to meteorological disturbances and swell, whereas tide tables will not.

Tide records were obtained from the tide gage maintained by the Naval Postgraduate School at Monterey Harbor in Monterey Bay. It has been found from experience that these tide records seldom vary by more than 0.5 ft from tides in Carmel Bay (Dr. W.C. Thompson, personal communication).

C. INSTRUMENT ERROR

Instrument error does not vary with depth. That is, a fathometer with an error of 2 ft in 1 fm of water will have the same error in 200 fm of water. To calibrate the fathometer and 3.5-kHz profiling equipments, lead line soundings were made during operation of the acoustic equipment. The errors found on the lead line casts are shown in Table III.

D. SOUND VELOCITY CORRECTIONS

Depth sounding recorders are calibrated to give accurate readings when the transmitted and reflected sound pulses travel through sea water with a speed of 800 fm/sec. Deviations of the mean vertical sounding speed (MVSS) from this value will result in the recorder scale giving incorrect readings.

For depths encountered, the MVSS is chiefly dependent on the thermal structure. In order to determine the thermal structure of Carmel Bay, expendable bathythermograph data was collected.

TABLE III
INSTRUMENT ERRORS

Test	Fathometer ft	3.5 kHz Seismic ft
1	+2	+2
2	+4	+2
3	+4	+2

1. Computation of Mean Vertical Sounding Speed

Temperatures were taken off the bathythermograph at 10-m (32.8-ft) intervals and the mean temperature at each depth was found by averaging the temperature at that depth with the shallower temperatures. Using tables of sound velocity in sea water prepared by the U.S. Naval Oceanographic Office (1962), a MVSS was found at each depth. A nearly constant MVSS of 1,487 m/sec (812.9 fm/sec) was found to exist in Carmel Bay for the period of this survey.

2. Computation of Sound Speed Error

True depth relates to fathometer depth by the expression:

$$\text{true depth} = \frac{\text{MVSS} \times \text{fathometer depth}}{\text{fathometer calibrated sounding speed}}$$

for: MVSS = 1487 m/sec, and

fathometer calibration = 1,463 m/sec

true depth = 1.01640 x fathometer recorder depth.

Therefore, the fathometer was reading shallow by a factor of 1.64%.

This error was compensated for by manufacturing acetate overlays of depth scales compressed 1.64% to be used instead of the existing scales automatically marked on the bathymetric records.

E. SLOPE CORRECTIONS

1. Statement of the Problem

The sound wave front of a transducer spreads spherically. The ship will receive an echo from any part

of the sea floor that is intercepted by the spherical wave front as long as the reflection occurs within the sound cone of the transducer and any projection above the sea floor will give a hyperbolic echo trace.

Where the sea floor is sloping at an angle less than half of the transducer cone angle, the first reflection will not be detected from vertically beneath the ship, but will return from the part of the slope which is perpendicular to the ray (Fig. 6).

If the angle of sea floor slope is greater than half the transducer cone angle, the first reflection will return from the half angle of the transducer cone (Fig. 7).

2. Corrections for Slope Angles Less Than 15°

Krause (1962) has shown that the relationship between the echo slope angle (ϕ) and true bottom slope angle (θ) is:

$$\sin \theta = \tan \phi.$$

In addition, the relationship between true depth (Z) and echo depth (R) is:

$$Z = \frac{R}{\cos \theta}.$$

Tabulated values of the true depth for true bottom slope angles from 0° to 15° and echo depths from 0 to 300 fm are given in Appendix B.

3. Corrections for Slope Angles Greater Than 15°

The equations given by Krause fail at echo slope angles greater than 15° when using a transducer with a 30°

R = echo trace depth

Z = true depth

ϕ = echo trace slope angle

θ = true bottom slope angle

From Krause (1962):

$$\sin \theta = \tan \phi$$

$$Z = R / \cos \theta$$

Figure 6. Slope Correction for Slope Angles Less than 15° .

$$\tan \phi = (R_1 - R_2)/H$$

$$\tan \theta = (Z_1 - Z_2)/H$$

$$\tan \theta = \tan \phi [(Z_1 - Z_2)/(R_1 - R_2)]$$

$$Z_1/[\sin (75^\circ + \theta)] = R_1/[\sin (90^\circ - \theta)] = R_1/\cos \theta \quad ; \quad Z_1 = R_1 \sin(75^\circ + \theta)/\cos \theta$$

$$Z_2/[\sin (75^\circ + \theta)] = R_2/[\sin (90^\circ - \theta)] = R_2/\cos \theta \quad ; \quad Z_2 = R_2 \sin(75^\circ + \theta)/\cos \theta$$

$$\therefore \sin \theta = \tan \phi \sin (75^\circ + \theta)$$

$$Z = R (\cos 15^\circ + \sin 15^\circ \tan \theta)$$

Figure 7. Slope Correction for Slope Angles Greater than 15°.

sound cone. This is because his work was intended for use only in the deep sea where steep slopes are rarely encountered.

It may be seen from Fig. 7 that the relationship between the echo slope angle (ϕ) and the true bottom slope angle (θ) for echo slope angles over 15° is:

$$\sin \theta = \tan \phi \sin (75^\circ + \theta).$$

The solutions of this transcendental equation for echo slope angles of 15° up to 45° are shown in Appendix A. The solutions given in Appendix A were obtained by iterating θ so that left and right hand sides of the above equation agreed to within ± 0.00005 .

It may also be seen from Fig. 7 that the relationship between the true depth (Z) and echo depth (R) is:

$$Z = R (\cos 15^\circ + \sin 15^\circ \tan \theta).$$

Tabulated values of the true depths for true bottom slope angles from 15° to 50° and echo depths from 0 to 300 fm are given in Appendix C.

F. CROSS SLOPE CORRECTION

1. Statement of the Problem

The slope corrections previously discussed assume that the ship's track is parallel to the maximum bottom slope. If the ship's track is not parallel to the slope, the track of the point of reflection across the slope does not correspond with the vertical projection of the ship's

track on the sea floor, but lies upslope of the projection of the ship's track (Fig. 8).

2. Correction for Cross Slope

Krause (1962) has shown that the relationship between the true bottom slope angle (θ), the apparent bottom slope angle (θ_a), and the angle between the ship's track and a line parallel to the bottom contour (β) to be:

$$\tan \theta = \frac{\tan \theta_a}{\sin \beta}.$$

This relationship is good for all values of apparent bottom slope.

θ_a = apparent bottom slope angle

θ = true bottom slope angle

β = angle between ship track and line parallel to bottom contours

From Krause (1962):

$$\tan \theta = \tan \theta_a / \sin \beta$$

Figure 8. Cross Slope Correction.

IV. RESOLUTION OF BATHYMETRIC DATA

The 3.5-kHz profiler records were used to make the Carmel Bay chart rather than the fathometer bathymetry because:

- the 3.5-kHz records had better resolution than the fathometer records,
- the wide precision depth recorder paper was easier to work on, and
- the 3.5-kHz records were better on the steep slopes of the canyon walls.

The fathometer records were used to validate the 3.5-kHz profiler records so that if any penetration of the bottom sediments had occurred, the true bottom could still be determined.

A. DATA REDUCTION

1. Calculation of the Mean Lower Low Water Datum

The datum plane from which depths are recorded on hydrographic charts for the West Coast of North America is mean lower low water (MLLW). It is necessary to locate the MLLW datum on the bathymetric records so as to use it as the zero level for subsequent depth determinations. Considered in the determination of MLLW datum are transducer depth, instrument error, and the height of the tide above MLLW.

In the cruise logbook were noted the date and time that each sounding line was steamed, the instrument error determined from the most recent lead line test and the transducer

depths. The height of the tide from the MLLW datum is obtained from the tide gage records using the date and time that the line was run.

A typical calculation of the MLLW for the tide 3.0 ft above MLLW, a 3.5-kHz profiling system reading too deep by 2.0 ft, and a 3.5-kHz transducer towed 20.0 ft below the surface would total 15.0 ft $(-3.0 - 2.0 + 20.0)$. The MLLW datum is therefore located 2.5 fm above the zero scale line marked on the 3.5-kHz profiler records.

2. Preliminary Annotation of Bathymetric Records

Acetate scales (corrected for deviations of MVSS from the calibrated fathometer sounding speed) were fabricated and used to mark depth intervals on the bathymetric records. The depths should be marked at the contour line interval to be used on the completed chart. As the overlay is moved across the record, the zero line of the acetate scale must be held on the calculated zero line on the record. This is to assure that the marked depths will be taken from the MLLW datum.

Major pinnacles and troughs should be marked by some consistent convention. The pinnacles and troughs of the small scale bottom structure may or may not be annotated depending upon the intended use for the finished chart.

3. Application of Slope Corrections

The depths now on the record are corrected for tide, instrument, and sounding speed errors. The depths marked on approximately level portions of the echo trace are correct

and need no more work. Corrections still need to be applied to the depths marked on the slopes.

a. Calculation of Apparent Echo Slope Angle

The apparent echo slope angle (ϕ_a) is expressed by the relationship:

$$\tan \phi_a = \frac{\text{change in depth (ft)}}{\text{distance traveled (ft)}}.$$

The change in depth is that change which occurs between any two fixes on the same slope. The distance traveled is obtained from the track post-plot by measuring the distance between the fixes used to get the change in depth.

b. Calculation of Apparent Bottom Slope Angle

(1) Echo Slope Angles Less Than 15°. The relationship between the apparent bottom slope angle (θ_a) and the apparent echo slope angle (ϕ_a) for echo slope angles less than 15° is:

$$\sin \theta_a = \tan \phi_a.$$

Since ϕ_a is already known, it is only necessary to find the angle whose sine equals the tangent of ϕ_a to find θ_a .

(2) Echo Slope Angles Greater Than 15°. For apparent echo slope angles greater than 15°, θ_a may be obtained directly from Appendix A.

c. Calculation of True Bottom Slope

The relationship between true bottom slope angle (θ), apparent bottom slope angle (θ_a), and the angle between the ship's track and a line parallel to the bottom contour (β) is:

$$\tan \theta = \frac{\tan \theta_a}{\sin \beta}.$$

The angle β need not be exact. For the Carmel Bay survey, β was obtained from previously existing hydrographic charts.

d. Final Annotation of Bathymetric Records

With the true bottom slope angle known, the true depth may be obtained for every echo depth (up to 300 fm) from Appendix B ($\theta \leq 15^\circ$) or Appendix C ($\theta \geq 15^\circ$).

If the corrected depths are plotted below every echo depth on the records and connected, the profile of the true bottom will be seen. Again, using the acetate scales, even depth intervals can be marked on the true bottom.

e. Ambiguity of 'V' Shaped Depressions

Extending the true bottom profiles of both sides of a 'V' shaped depression until they intersect will give a very rough approximation of the bottom of the depression. An ambiguity exists as to the actual shape of the bottom since the echo trace would appear the same for a variety of depression cross sections (Fig. 9). This ambiguity causes the Carmel Bay chart to be inaccurate along the canyon axis.

Shepard and Emery (1941, p. 76), using lead lines, found that the Carmel Canyon head had a narrow, comparatively flat base. The wide (30°) transducer sound cones employed on the echo sounding equipments of this survey would completely mask this feature of the canyon profile.

Note the identical echo traces (first reflection) for both troughs.

Figure 9. Ambiguity of 'V' Shaped Depression.

V. CARTOGRAPHY

A. CONSTRUCTION OF THE SMOOTH SHEET

The true depths on the bathymetric records were next transposed to the post-plot of the fixes taken. Every mark on the record had a coinciding fix on the post-plot. Proportional dividers were used to locate the positions of useful contour depths on the post-plot between fixes. Pinnacles and troughs were also located.

B. CONSTRUCTION OF THE FINISHED CHART

The last step in the manufacture of a hydrographic chart is the contouring of the smooth sheet. Contouring of depths was done on tracing paper, as many erasures were often necessary.

The shoreline for the Carmel Bay chart was taken from the 1933 hydrographic survey smooth sheet made by C&GS.

VI. SUMMARY

The completed chart of Carmel Bay is enclosed as Plate I. Every precaution has been taken to insure the accuracy of the contours. Unfortunately, the 30° transducer cones did not allow for the bottom of the canyon to be properly surveyed and the chart is not exact in these areas.

Figure 10 shows the depth contours from the current navigation chart of Carmel Bay (based on the 1933 C&GS survey) as compared with the contours obtained by this survey. It may be seen that although the 1933 survey provided the general trends of the bottom topography, this study is more specific.

It is hoped that this study can be used as a guide for those interested in conducting bathymetric surveys of areas similar to Carmel Bay.

Figure 10. Comparison of 1933 and 1971 Bathymetric Surveys.

VII. FUTURE WORK

It is anticipated that the sounding lines not completed will be accomplished at some future date so that the contours in this region (Fig. 3) can be drawn with more certainty.

Carmel Submarine Canyon should be surveyed with a narrow beam profiler so as to accurately determine the cross-section profile of the entire canyon. If this profiling could be done on regular intervals, every few years or so, the slumping at the head of Carmel Canyon could be closely documented.

Work is presently under way at the Naval Postgraduate School to define the textural and mineralogical distribution and basins of the bottom sediments of Carmel Bay. Also, a careful study is being conducted of the shoreline geology of Carmel Bay.

APPENDIX A

PRECISION DEPTH RECORDER SLOPE CONVERTED
TO APPARENT BOTTOM SLOPE

THIS PROGRAM SOLVES THE EQUATION -

$$\sin(\theta) = \sin(75 + \theta) * \tan(\phi)$$

FOR EACH VALUE OF PHI FROM 15 TO 45 DEGREES
BY ITERATING THETA UNTIL THE LEFT AND RIGHT
SIDES OF THE EQUATION AGREE TO WITHIN PLUS
OR MINUS 0.00005 .

13. ABSTRACT This study has as its final product a bathymetric chart of Carmel Bay, California, which is improved over any other previously existing chart. The unique problems of applying the echo-sounding corrections necessary to create accurate bathymetric charts of areas with steep bottom slopes are discussed.
