Site Indexes for Lodgepole Pine, with Corrections for Stand Density: Instructions for Field Use

by

Robert R. Alexander

Lodgepole pine (*Pinus contorta* Dougl.) commonly grows in overly dense stands, and crowding restricts the rate of height growth. Site index must, therefore, be adjusted for stand density. Figures 1 and 2, and tables 1 through 7 have been prepared for field use in estimating site index for lodgepole pine. They are applicable to lodgepole pine stands in Colorado, Wyoming, Utah, Idaho, Montana, and eastern Washington and Oregon.² Information necessary to understand field application of the site index curves and instructions for their use are presented in this paper. Methodology used to develop the site index curves will be presented in a subsequent paper.

Stand density is expressed as Crown Competition Factor (CCF).³ CCF compares growing space available to a tree with the space represented by a vertical projection of the average crown area of an open-grown tree of the same stem diameter (Maximum Crown Area, MCA). Because space occupied by a single tree is not easily determined, the comparison is made on a stand basis. CCF may be obtained from the numbers and diameters of trees in a stand, or it may be estimated from measurements of basal area and average diameter.

² This paper is based on a cooperative study planned and undertaken jointly by the Rocky Mountain, Intermountain, and Pacific Northwest Forest and Range Experiment Stations. David Tackle (INT) and Walter G. Dahms (PNW) collected the field data in their respective areas.

³ Krajicek, John E., Brinkman, Kenneth A., and Gingrich, Samuel F. Crown competition factor, a measure of density. *Forest Sci.* 7: 35-42. 1961.

Site index is expressed as the average height of dominant trees in pure, even-aged stands at age 100 years. For stands where the CCF is 125 or less, height growth is unaffected by density. For stands where the CCF is greater than 125, height growth is reduced as density increases, and the reduction in height growth at any level of CCF above 125 becomes greater as site quality improves.

Site index can be estimated from tables 1 through 5 for all combinations of height, age, and density indicated in the Rocky Mountain and Intermountain regions, providing the average height of the trees selected for site determination is equal to or exceeds the height of the site index 30 class but does not exceed the height of the site index 100 class at the age sampled. Figure 1 can be used if the CCF is 125 or less. In the Pacific Northwest region, site index can be estimated reliably only if the "site trees" are 50 or more years old.

Field Application of Site Index Curves

Step 1.--Determine average height and age of the stand. Select four or more dominant trees (site trees) and measure heights and ages in the conventional manner.⁴ Average total age may be approximated from age at breast height by adding 9 years to the average age at breast height (fig. 1 and all tables are based on total age).

⁴ Chapman, Herman H. and Meyer, Walter H. *Forest mensuration*, Chap. 15, "The measurement of heights in standing trees," pp. 149-212 and Chap. 23, "The age of standing trees," pp. 318-323. New York: McGraw-Hill Book Co. 1949.

Step 2.--Determine the CCF of the stand in which the "site trees" developed. Two alternative methods of obtaining CCF are suggested.

A. Estimate CCF from measurements of stand diameters at breast height.

1. Establish a density plot for each "site tree." It will be a fixed-radius plot centered on the "site tree" or close enough to the "site tree" to accurately estimate the stand density in which the "site tree" developed. Plot sizes are suggested in table 6. Plots for any group of four "site trees" should be the same size. Plots may overlap, so some trees may occur in more than one plot, and may, therefore, have to be tallied more than once.
2. Measure the diameters at breast height of all trees on the density plots, and record by 1-inch classes. It is not necessary to keep the data from the four density plots separate, but care must be exercised to locate the "site trees" and density plots that make up any sampling group in a part of the stand where density is representative, and where average spacing between trees and the average diameter of those trees are similar.
3. Multiply the number of trees in each diameter class by the MCA for that diameter class (MCA constants for each diameter class for lodgepole pine are given in column 2, table 7).
4. Sum the MCA values and convert to an acre basis. The resulting value is the CCF of the stand.
5. An example of the procedure outlined in step 2A, items 3 and 4, is shown in table 7 for a typical lodgepole pine stand.

B. Estimate CCF from measurements of basal area and average diameter.

1. Determine average basal area of the stand.
 - a. Select the prism with the appropriate Basal Area Factor (BAF) for the density of the stand to be sampled.

- b. Count all trees that are "in" at each sample point. Each sample point should be sufficiently close to each "site tree" to permit a valid estimate of CCF around the "site tree."
 - c. Total the trees counted at the sample points, and average to determine the average number for the plot.
 - d. Multiply the average per plot by the appropriate BAF. The resulting value is basal area per acre.

2. Obtain an estimate of average diameter. There are many methods available for determining average diameter. The rule-of-thumb procedure described here is rapid and accurate for the purpose intended.

- a. Walk through the stand sampled, and select what appears to be a tree of average diameter.
- b. Lay out a transect line across the stand that passes close to each "site tree."
- c. Measure the first 10 trees along this line that appear to the observer to be of average diameter.
- d. Sum those diameters and obtain an arithmetical average. That value is the estimate of average diameter.

3. Determine the $BA/\bar{D}$ Factor by dividing the average basal area per acre by the average diameter.

4. Determine estimated CCF by substituting the $BA/\bar{D}$ Factor into the equation:

$$CCF = 50.58 + 5.25 (BA/\bar{D})$$

where

CCF = Crown Competition Factor
BA = Average basal area per acre
D = Average diameter

or obtain from figure 2.

Step 3.--Determine site index.

- A. Select the appropriate height-age table, based on the CCF determined in Step 2 (if CCF is 125 or less, fig. 1 may be used in place of table 1).

B. Enter the appropriate height-age table with the average dominant height and age from Step 1. Determine site index in the conventional manner; interpolate where necessary.

Specifications for Stands and Site Trees

The following specifications, upon which figures 1 and 2 and tables 1 to 7 are based, are included to provide field users with a guide to the kinds of stands and site trees to be selected for sampling.

Stands:

1. Even-aged--not more than 20 years' spread in the age of dominant trees.
2. At least 30 years old, but not more than 200 years old. (At least 50 years old in Pacific Northwest.)
3. Apparent site the same throughout the stand. Site will be considered the same if

all trees are growing on similar topography, slope, aspect, and soils.

Site Trees:

1. Located in an area in the stand where present density is uniform, and there have been no abrupt changes in past density.
2. Dominants that appear to have been dominant throughout their lives. (Dominants with a normal pattern of ring widths from pith to cambium to demonstrate that they have been free to grow throughout their lives, and no changes are likely to have occurred in their relative position in the crown canopy.
3. Reasonably free of dwarfmistletoe or other diseases or injuries that may reduce height growth.
4. Sound enough for ring counts.
5. Show no visible evidence of crown damage, or tops that are broken, forked, and so forth.

Figure 1.--Lodgepole pine site index curves for CCF 125 or less.

Table 1.--Heights of dominant trees at CCF levels of 125 or less for site index classes 30 to 100 by decadel ages 30 to 200 years
