Volume Tables and Point-Sampling Factors

for Lodgepole Pine

in Colorado and Wyoming

by

Clifford A. Myers

INTRODUCTION

The tables presented here give values needed to determine the volumes of lodgepole pines (*Pinus contorta* Dougl.) in Colorado and Wyoming. They provide timber cruisers and growth estimators with the following:

1. Gross volumes in total and merchantable cubic feet,
2. Gross volumes in board feet, International 1/4-inch and Scribner log rules,
3. Point-sampling factors for merchantable cubic feet and board feet, and
4. Distribution of board-foot volume among the logs of a tree.

Volume on an area may be determined from:

1. Measurements of tree diameters and heights,
2. Measurements of diameters and of sufficient heights to convert the appropriate volume tables to local volume tables (Chapman and Meyer, 1949),² or
3. Tree counts obtained by point-sampling.

² Names and dates in parentheses refer to Literature Cited, p. 4.

Sample trees were measured in all major areas of commercial lodgepole pine in Colorado and Wyoming.

DEFINITIONS AND STANDARDS

Definitions of variables used in the tables, and of standards followed in field measurement and computations, are as follows:

Diameter breast high (d.b.h.).--Measured to 0.1 inch outside bark 4.5 feet above average ground level. In the tables, full-inch diameter classes, with class midpoints at the half-inch marks, were used (12.5, 13.5, etc.).

Scaling diameter of logs.--Average diameter inside bark to 0.1 inch, measured at the upper (small) end of logs or half-logs. Saw-log diameter classes followed conventional scaling practice, with the class midpoints at whole inches (8.0, 9.0, etc.).

Minimum top diameter of sawtimber trees.--Diameter inside bark, 8 inches. Logs with a scaling diameter less than 7.6 inches (8-inch class) usually were not included in saw-log volume. A few logs with a scaling diameter of 7 inches were included to satisfy requirements of the 4-foot rule described with the

definition of height in logs, below. This also conforms to local practice.

Total height.--Measured to the nearest foot from average ground level at the tree base upward to the tip. Forked, stag-topped, or other deformed trees were not included in the sample. Midpoints of the total height classes used in the tables were multiples of 10.0 feet, as 10.0, 20.0, etc.

Height in logs.--Measured from the top of a stump 1.0 foot high upward to the limit of saw-log utilization. Each tree was divided into as many standard 16.3-foot-long logs as possible. An additional half-log, if present, was taken from the uppermost part of the merchantable length. Portions of the bole above the height of minimum top saw-log diameter were included in the uppermost saw log if the standard length of the log or half-log ended within 4.0 feet above this height. This "4-foot rule" was used to avoid biased negative error in volume (Chapman and Meyer, 1949).

EXPLANATION OF TABLES

The general definitions and standards given apply to all tables. Explanation of each type of table and suggestions for use are presented here.

Volume Tables

Headings and footnotes with each volume table (tables 1, 2, 4, 6, 8, 10) give the volume unit, type of height measurement, utilization standards, and volume equations used in its compilation. Ten-foot or half-log height classes and full-inch diameter classes were used in all tables.

The volume tables were derived from linear regressions in V and $D^2 H$, of the form:

$$V = a + b D^2 H$$

where

V = gross volume in the appropriate unit

D = diameter breast high outside bark

H = total height in feet or in standard logs and half-logs

a, b = regression constants

Two equations were used to derive each table; the relationship between V and $D^2 H$ could not be expressed by a single linear regression over the full range of the basic data. Correlation coefficients (r) of the 12 volume equations ranged from 0.908 (board feet with total height) to 0.990 (total cubic feet).

The number of logs in a tree shown in the tables is not necessarily the number that will actually be cut from it. Instead, it is the number of logs between the stump and the height where minimum top diameter is reached. To locate the minimum top, the 4-foot rule previously explained under "Height in logs" should be used.

Volume of nonmerchantable logs below the height of minimum top diameter should be deducted by estimation of scaling diameters, use of taper tables, or according to the percentages in table 13. Volume must not be reduced by tallying fewer logs in the tree. For example, assume that a sound tree 18 inches in diameter has a bole length of 65.2 feet (4 logs) between the stump and the height where diameter inside bark is 8 inches. The tree has a gross volume of 364 board feet Scribner rule (table 6). The top log is too limby to send to the sawmill. This log contains 8 percent of the board feet in the tree (table 13) and the other logs contain 92 percent. When 8 percent or 29 board feet is deducted, the tree contains 335 board feet. If the tree were tallied as an 18-inch, 3-log tree, it would be incorrectly credited with a volume of 275 board feet. Alternatively, the top log has a scaling diameter of 8 inches, thus 32 board feet (Scribner log rule) could be deducted from the volume of an 18-inch, 4-log tree.

POINT-SAMPLING FACTORS

The first five tables of point-sampling factors (tables 3, 5, 7, 9, 11) give the factors for each of numerous combinations of tree diameter and height. Volumes per square foot of basal area were obtained from the equations in the table footnotes. These equations resulted from the division of each volume equation (tables 2, 4, 6, 8, 10) by $0.005454 D^2$, a formula for basal area (B).

Table 12 was derived from the other tables of point-sampling factors. The factor for each height class is the weighted average of the factors in that class given in table 2, 4, 6, 8, or 10. Weights were obtained from random samples of heights and diameters in stands of commercial lodgepole pine in Colorado and Wyoming.

Point-sample cruising for volume can be done in several ways:

1. Diameters and heights of trees counted through the prism or relascope may be measured,
2. Diameters may be estimated and heights measured, or
3. Heights of the counted trees may be measured and no record made of tree diameters.

The procedure selected will depend on the accuracy desired (relative accuracy usually in the order listed above) and the time and personnel available for the job. Point-sampling factors are provided for each alternative.

The diameter and height of each counted tree may be measured and a volume conversion factor selected for each combination of diameter and height (tables 3, 5, 7, 9, 11). Volume per acre is computed as follows:

1. Multiply the number of counted trees in each diameter-height class by the point-sampling factor for the class.
2. Total the products of step one.
3. Multiply this total by the basal area factor of the prism or other angle gage used.
4. Divide the product of step three by the number of points sampled on the tract.

Time can often be saved if the heights of the counted trees are measured while diameters are estimated and tallied by broad diameter classes. Inspection of the tables shows that volumes per square foot of basal area often do not differ greatly among trees of a single height class. For example, the merchantable volumes of trees 70 feet tall vary from 29.6 to 33.8 cubic feet per square foot over a range in diameter of 5 to 24 inches (table 3). Board feet per square foot of basal area changes little with diameter when tree

heights are measured in logs (tables 7, 11). Therefore, the increased time spent measuring diameters may not result in any material increase in accuracy.

Measurement of heights with no record made of diameters is recommended when there is little change in volumes per square foot within a height class. Point-sampling factors in table 12, based on height only, will be most useful where the distributions of diameters within height classes approximate those used in preparation of the tables. Differences in the relationship between height and diameter due to differences in site quality or stand density may change the factor for each height class. These changes may be accounted for by computing new factors for each height class, using table 3, 5, 7, 9, or 11 and almost the same procedure used to derive a local volume table from a standard table (Chapman and Meyer, 1949). Diameters are plotted over heights since height will be retained as the measured variable.

The techniques of point sampling have been described in numerous publications. A good discussion of the method was presented by Bonnett (1959). A simple procedure for determination of the number of sampling points (Allen and Mogren, 1960) and precautions on the use of point-sampling on small tracts (Afanasiev, 1958) have been published. Basic American references were prepared by Grosenbaugh (1952, 1955, 1958).

Percentage of Tree Board-Foot Volume in Each Log

The board-foot volume in each log-quality class or the volume in cull logs can be determined with the percentages from table 13. Each line in the body of the table gives the distribution of volume among the logs of a tree of specified diameter and merchantable length. For example, in 18-inch, 3-log trees, the butt log contains 55 percent of the board feet, the middle log contains 33 percent, and the top log 12 percent.

Percentages for diameters that are not included in table 13 can be obtained by interpolation.
