The writer was born on July 3, 1892, in St. Louis, Missouri. His early education was received in the public schools of St. Louis. In 1914 he was graduated from Washington University, in St. Louis, receiving the degree of bachelor of arts. Since 1914 he has been a graduate student at the Johns Hopkins University, with plant physiology as the principal subject and with botany and physical chemistry as subordinate subjects. He was an assistant in the department of plant physiology in 1916, and has held a university scholarship from 1915 to 1917. During the summers of 1914 and 1915 he did work in botany in the graduate school of the University of Illinois.

TWELVE TEXT FIGURES

INTRODUCTION

For the development of higher plants the chemical elements carbon, hydrogen, oxygen, nitrogen, phosphorus, sulphur, calcium, magnesium, potassium, and iron are unquestionably necessary. Carbon mainly derived from the carbon dioxide of the air, together with hydrogen and oxygen, which enter through the roots in the form of water, make up by far the greater portion of the plant substance. But the other necessary elements must be supplied and they also enter through the roots from aqueous solution. With the exception of iron, of which but little is needed, these essential elements must be furnished in relatively large amounts.

That higher plants require nitrogen, sulphur, phosphorus, calcium, magnesium, potassium, and iron in an aqueous solution about their roots was pointed out very early by Birner and Lucanus.² These writers supplied the necessary elements in

¹ Botanical contribution from the Johns Hopkins University, No. 58.

the form of the salts monopotassium phosphate, calcium nitrate, magnesium sulphate, and ferric phosphate. Oat plants grown in solutions that lacked any of these elements were found to have much smaller dry weights than those grown in the full nutrient solution. Similar experiments by later workers with many other kinds of higher plants have given the same general results; namely, that the dry yield is much greater when all seven of these elements are present in the culture solution than when one or more of them are omitted.

Birner and Lucanus also showed that these seven are the only elements that are necessary for excellent growth of oat plants. There has been considerable discussion, however, among various writers as to whether certain other elements may not be essential for plants in general or for certain plants in particular. Nobbe and others, for example, believed that chlorine was necessary for the complete development of the buckwheat plant.³ Beyer⁴ reported that the fruiting of oats and peas was not normal in culture solutions that lacked chlorine. Also, Salm-Horstmar⁵ was of the opinion that silicon and manganese were necessary for oats. But from all the work that has been done it may be concluded that for most higher plants only the seven elements mentioned above are to be regarded as essential constituents of the nutrient solution.

There still remains, however, the problem as to whether plant growth may not be significantly accelerated in the presence of nonessential elements, and modern investigators have studied the effects of a number of such elements. Of course it is well known that many unnecessary elements act as poisons and retard plant growth when supplied in certain concentrations, and the problem thus suggested has also been taken up by many writers.

Among the generally unessential elements that have been considered by investigators, chlorine is one of the commonest, and it has attracted considerable attention among agriculturists also. This element is frequently added to the soil as potassium chloride in fertilizer practice, and it has even been maintained that addition of sodium chloride to the soil results in an increased yield of certain crops. The present study deals with the influence of chlorine upon the growth of plants in a nutrient solution that also contains the seven essential elements.

Chlorine is not required in large amounts, since plants are able to grow and mature normally without appreciable amounts of this element. Birner and Lucanus (1886) concluded that chlorine was not essential; Knop,⁶ after growing many kinds of plants, including buckwheat, also concluded that chlorine was unnecessary for normal development. Wagner⁷ obtained apparently completely developed maize plants when no chlorine was in the culture solution. Recently Priianishnikov,⁸ employing both the water-culture and the sand-culture methods, was unable to establish the necessity of this element. Shulov⁹ concluded after several years of experimentation that chlorine is not necessary for the normal development of buckwheat plants.

Other investigators have found that many plants make very good growth without a chloride in the culture solution, and in no case has the necessity for the element chlorine been demonstrated. Crone,¹⁰ using a nutrient solution without chlorine, found that rape, barley, grape, and maize made excellent growth.

Shive¹¹ found that young wheat plants made better growth in a three-salt nutrient solution, containing the same salts as employed by Birner and Lucanus, than in any chloride-containing solution that he tested. Buckwheat also matured in Shive's

three-salt solutions containing no chlorides. Apparently normal seeds were obtained repeatedly by Johnston from buckwheat plants grown in one of Shive's solutions, without any chloride.¹²

In spite of the fact that these experiments show that chlorine is not required in any considerable amount, it is probable that plants have never been grown without containing at least small amounts of chlorine. Most plants contain some chlorine and, besides typical saline plants, many contain relatively large amounts of chlorine in their ash.¹³ Since seeds probably always contain small amounts of this element, it cannot be regarded as actually proved that it is absolutely unnecessary. However, the fact that chlorine is found in the ash must not, of course, be considered proof that it is essential. Thus, sodium, silicon, aluminium, barium, strontium, manganese, zinc, arsenic, copper, boron, bromine, iodine, fluorine, cobalt, nickel, tin, and lead are all found in plant ash, and yet no experiments have shown that these are necessary to induce growth. But a very recent paper, of which I have seen only a brief review, appears to furnish evidence that very small amounts of chlorine are necessary for buckwheat. Pfeiffer and Simmermacher¹⁴ studied the significance of chlorine in fertilization experiments. Chlorine is reported as indispensable for the growth of buckwheat; but the amount of chlorine considered to be required was very small, and larger quantities of chlorine compounds were regarded as injurious.

As with many other nonessential elements, plants may be altered in their manner of growth by supplying them with chlorine, in addition to the small amount contained in the seed. Such alterations may result in accelerated or retarded growth, increase or decrease in yield, etc., and chlorides may therefore be

considered as beneficial or injurious, depending upon the desirability or undesirability of the changes produced by their use.

Tottingham¹⁵ presents a review of the literature on the effects of chlorides on plant growth, and reports experimental studies on the influence of chlorides on the growth of a number of agricultural plants. He reports that the introduction of potassium and sodium chlorides into solution cultures had little effect on wheat seedlings. Both yield of dry matter and length of roots were depressed in buckwheat grown to maturity in similar cultures. In soil cultures, radish was affected only slightly by chlorides; increased production of dry matter and sugar content resulted with carrot, while the reverse was true of parsnip. Sugar beet, in soil cultures, produced more watery roots and a greater amount of dry matter; the roots contained more glucose, but less sucrose. Similar responses followed the application of common salt alone to beets grown in the field. The potato produced increased yields of dry matter in the tuber when potassium chloride was supplied in place of potassium sulphate, in a complete fertilizer ration, to soil cultures in the greenhouse. Different varieties responded differently according to the percentage of starch. In field cultures in a dry season the application of potassium chloride in a complete fertilizer decreased the yield of dry matter in the tubers, but not the percentage of marketable tubers, of the Triumph variety. In a season that was very humid toward its close, no significant differences in composition or cooking qualities were found between tubers of the Rural New Yorker variety produced, when potassium sulphate and potassium chloride were employed separately in a complete fertilizer ration. Sodium chloride applied alone altered the composition of the tubers only slightly, but affected their quality seriously. It has, of course, been found that growth may be retarded when chlorides are supplied in very large amounts.¹⁶

¹⁶ Wheeler, H. J., and Hartwell, B. J., Conditions determining the poisonous action of chlorides, *Rhode Island Exp. Sta. Ann. Rep.* 15 (1901-1902) 287-304.

Increased growth is reported to have followed the application of sodium chloride to the soil, especially in the case of experiments carried out in the British Isles.¹⁷ From the point of view of physiology it is of course possible that under certain conditions the addition of chlorides to a nutrient solution may produce increased growth, as has been found for many salts of proved toxic action.¹⁸

Not only alterations in the amount of substance produced but also changes in the structure and physiological nature of plants have been brought about by the addition of chlorides to the nutrient medium.¹⁹ Harter²⁰ found that the addition of sodium chloride to the soil of experimental cultures might either increase or decrease the transpiration rate, and alter the structure of wheat, oat, and barley plants.

It is possible that chlorides may affect certain special metabolic processes and thus influence the plant more in one stage of its development than in another. Nobbe and his coworkers reported that chlorides were beneficial for the production of seed by buckwheat plants. He considered that this result was due to an influence exerted by chlorine upon the translocation of carbohydrate food; but Nobbe's observations have not been substantiated by more recent research.

It seems to be well established that many kinds of plants may be grown successfully in liquid media without any chloride. Nevertheless, most of the culture solutions recommended in the literature of plant physiology include a chloride. The following solutions may be mentioned as belonging to this class:

The study to be reported in the present paper was undertaken, as has been stated, to throw more light upon the problem as to what may be the physiological influence upon plants of considerable amounts of potassium chloride in a nutrient solution that also contains other salts supplying all the essential elements.

This investigation was carried out at the Laboratory of Plant Physiology of the Johns Hopkins University, under the direction of Prof. B. E. Livingston, to whom I am indebted for valuable assistance during its progress and for aid in the preparation of this paper. I am also indebted to Dr. H. E. Pulling for many suggestions.

GENERAL METHODS

The experimental work comprised four series of cultures carried out at different times. The first two of these were planned to furnish a general survey of the relations between plant growth and salt proportions with a single total concentration of the solution (osmotic value 1.60 atmospheres). The results obtained from these two series made it appear desirable to test the effects of higher partial concentrations of potassium chloride than had been originally planned, and the third series included such tests. Finally, the influence of the total concentration of the medium was studied for four selected sets of salt proportions; these tests made up the fourth series. The present section will begin with an account of the general methods employed in all four series. This will be followed by a more detailed account of the methods employed, the results obtained, and a discussion of these results for each of the series taken in order.

In the nutrient solutions of the present study the essential elements (besides iron) were supplied as monopotassium phosphate, calcium nitrate, and magnesium sulphate, and the chloride ion was added by the introduction of potassium chloride.

³¹ Birner, H., and Lucanus, B., Wasserculturversuche mit Hafer. (In der agr.-chem. Versuchsstation zu Regenwalde i. J. 1864 durchgeführt.) Landw. Versuchsst. 8 (1866) 128-177. Shive, J. W., A study of physiological balance in nutrient media, *Physiol. Res.* 1 (1915) 327-397.

³² Crone, G., Ergebnisse von Untersuchungen über die Wirkung der Phosphorsäure auf die höhere Pflanzen und eine neue Nährlösung. Sitzungsber. Niederrhein. Nat.- und Heilkunde. Bonn. (1902) 167-173.

Thus the solutions here considered are four-salt solutions, and they are similar in their general make-up to the other four-salt solutions already employed by Tottingham. It will be seen that a solution made up of monopotassium phosphate, calcium nitrate, magnesium sulphate, and potassium chloride may be derived from the proper one of Shive's three-salt series by the addition of potassium chloride. These four salts have been employed in Nobbe's solution in a single set of proportions and in the so-called Detmer's solution in another set of proportions, as pointed out above. The present study aimed primarily to employ these four salts in various proportions, the total concentration of the solution remaining the same. The effects of different total concentrations with a constant set of salt proportions was also studied to some extent.

Culture solutions.—The culture solutions, whose compositions are given among the other data of the individual experiments, were prepared from analyzed chemicals³³ and water obtained from a "Barnstead" still. Each salt was dissolved separately, and the exact concentration of the resulting solution was determined by chemical analysis (except in the case of potassium chloride). This procedure is especially necessary for solutions of calcium nitrate and of magnesium sulphate, because these salts contain amounts of water of crystallization that vary between wide limits, and because they are rather readily decomposed by heat. Upon dilution to convenient volume-molecular concentrations,³⁴ these solutions became the "stock solutions" from which the various culture media were prepared. The stock solutions were stored (never longer than one month) in cork-stoppered glass bottles.

Ferric phosphate (used as a source of iron) was prepared from a ferric nitrate solution by precipitation with a one-fourth molecular solution of monopotassium phosphate. The precipitate was obtained in a finely divided condition by using cold solutions and by constantly stirring while the potassium salt was added. After thoroughly washing the precipitate, it was shaken with sufficient water to form a suspension containing approximately 0.0022 gram of ferric phosphate, or 0.0008 gram of iron, in each cubic centimeter.

³³ The potassium chloride was the Baker and Adamson Chemical Company's "analyzed" salt; the other salts were the J. T. Baker Chemical Company's "analyzed" salts.

³⁴ By volume-molecular concentration is meant the number of gram molecules contained in each liter of solution.

For the preparation of the culture solutions, the required amount of each stock solution was drawn from a burette into a volumetric flask partially filled with distilled water, and the flask was finally filled to the mark with more water. For the cultures in series IV, in which culture solutions ranging from 0.50 to 7.00 atmospheres were employed, stock culture solutions of 7.00 atmospheres were prepared and the less-concentrated culture solutions were made by proper dilution. The culture solutions were poured from the volumetric flasks into the culture jars, and two drops of the suspension of ferric phosphate were added to each complete solution. The culture jars were wide-mouthed glass bottles of 250 cubic centimeters capacity, which had been used for several years in similar experiments.

The plants.—The wheat seeds used in these studies were supplied by the Bureau of Plant Industry of the United States Department of Agriculture. The variety was "Fulcaster," C. I. No. 1918, grown at the Arlington Experiment Farm, Arlington, Va., in 1915. The seeds were germinated in moist chambers and then transferred to a netting germinator. At the end of about five days, when the seedlings were from 8 to 10 centimeters high, they were transferred from the germinator to the culture solutions.

The internal differences between seedlings grown from the same stock of seed and exposed to practically identical external conditions constitute a source of great difficulty in work with water-cultures.³⁵ To minimize such variations, seedlings were selected that were as nearly alike as possible, this selection being made on the basis of the appearance of the seedlings. Two selections were made, the first when the sprouted seeds were transferred to the netting germinators, and the second when the plants were transferred to the culture jars.

Six seedlings were used in each culture. These were supported by cotton in holes near the margin of the cork, the seed remnants remaining below the cork. To prevent entrance of light to the roots, the jars were covered with cardboard covers.

The method of supporting the stem and leaves is important, because the rate of transpiration, and probably that of photosyn-

³⁵ This has been emphasized by Stiles. Stiles, W., On the relation between the concentration of the nutrient solution and the rate of growth of plants in water culture, *Ann. Bot.* 29 (1915) 89-96. Observations on the influence of aeration of the nutrient solution in water culture experiments, with some remarks on the water culture method, *New Phytol.* 16 (1917) 181-197.

thesis and other processes, may be greatly modified by the way in which the leaves are exposed to the air. The pointed end of a cylindrical wooden rod (a quarter-inch dowel), 6 millimeters in diameter and 30 centimeters long, was set into a hole in the center of the cork. A loop (5 centimeters in diameter) of paraffined copper wire, the lower part of which was wrapped around the rod several times, was used to hold the plant erect.³⁶ As the height of the plants increased, the loop was raised on the rod. Care was taken to support all the plants in the same way.

The same aërial conditions were secured for all the cultures in a series by rotating the cultures near the margins of the circular tables described by Shive. Each of the cultures was thus exposed to approximately the same changes in light, temperature, and humidity conditions.

The frequency with which the culture solutions are renewed is very important in experiments with solution cultures.³⁷ The solutions here used were changed every four days. Thus the period between changing is not strictly comparable with that used by Shive and by Tottingham, each of whom employed a three-day period. When the solutions were changed the decrease in volume of the solution during the previous period was measured, and the amount of solution found to have been removed was taken as an approximate measure of the amount of water absorbed and transpired during the period.

The developmental stage of the plants probably has an important bearing on their salt requirements.³⁸ The present study is concerned only with the early vegetative stage of the young wheat plants. When transferred from the germinators to the

culture solutions the plants were about five days old. They were grown in the culture solutions, renewed every four days, for twenty-four days, except in the case of series III and IV in which the growth period was extended to thirty-two days.

At the end of the growth period the plants were harvested for the determination of their dry weight. Notes were made at this time of the appearance of the tops and roots, special attention being given to apparent pathological conditions that might indicate injury from unbalanced salt nutrition. The tops and roots were harvested separately, the roots being severed from the tops at the point of attachment of the seed.³⁹ The tops and roots were dried separately for about two days, at a temperature of 102–105° C., to approximately constant weight, and the dry weights were then determined.

The experiments were conducted in one of the greenhouse rooms of the Laboratory of Plant Physiology, on the outskirts of the city of Baltimore. The evaporating power of the air for the period of each experiment was determined by means of Livingston white spherical porous-cup atmometers,⁴⁰ one of the instruments being operated on each of the rotating tables. The atmometer bottle was placed 10 centimeters from the center of the table, the top of the sphere being 40 centimeters above the table top. The atmometers were read every four days, when the solutions were changed. A record of fluctuations in temperature was obtained by means of a Richard thermograph placed in the shade near the plants.

SERIES I

METHODS OF SERIES I

Series I was continued for twenty-four days, from January 11 to February 4, 1916. During this period the highest air temperature was 29° C., on January 26, and the lowest was 10° C., on January 17. The average daily maximum temperature for the period was 25° C., and the average daily minimum 18° C. The mean daily water loss from a white spherical porous-cup atmometer, indicating the evaporating power of the air, was 17.2

³⁹ The seed-coat remnants were dried and weighed with the roots; Shive discarded them.

⁴⁰ Livingston, B. E., *Atmometry and the porous cup atmometer*, *Plant World* 18 (1915) 21–30, 51–74, 95–111, 143–149. Also reprinted, Tucson, Ariz. (1915).

cubic centimeters, and the total loss for the entire period was 415 centimeters.

The general plan of this series is similar to that employed by Tottingham. Eighty-four solutions were made from four salts: potassium chloride, monopotassium phosphate, calcium nitrate, and magnesium sulphate. In each solution the four salts were so proportioned that the total concentration of each solution corresponded to 1.6 atmospheres of osmotic pressure at 25° C., and in the different solutions the proportion of each salt was varied by 0.1 of the total osmotic concentration of all salts. The lowest concentration of any salt was thus 0.1 of the total concentration and the greatest 0.7. All of the possible different proportions were used that could be produced by these variations. Thus, there were eighty-four different solutions in this series, all of which had approximately the same total osmotic concentration, but no two of which had the same set of salt proportions. This may be stated in another way by saying that all of the solutions were planned to have the same total number of particles (ions plus molecules) per unit volume, but no two solutions the same proportions of the different kinds of particles. Besides the eighty-four solutions belonging in the series, Shive's best three-salt solution for wheat and Tottingham's best four-salt solution for wheat were employed for the sake of comparison.

If three salts had been employed instead of four, the compositions of the solutions could have been represented graphically by means of points placed in an equilateral triangle, the points being so placed that the least concentration of one salt would have been along one side of the triangle and the greatest at the opposite angle. As four salts were used, a figure representing their various proportions assumes the form of a regular tetrahedron. In this figure each face of the tetrahedron represents 0.1 concentration of one salt and the opposite apex 0.7. Since seven proportions of each salt were employed, different concentrations of the salt whose lowest concentration is represented by the base of the figure will fall in seven planes. For convenience of graphical presentation the planes representing the different concentrations of potassium chloride have been plotted separately (fig. 1). Since only one culture that had the greatest concentration of potassium chloride was used, the plane which passes through the apex is represented by a point; the

FIG. 1. Diagram for series I, showing culture numbers and osmotic proportions of the four salts.

other planes are represented by triangles. The seven triangles in fig. 1 (numbered T1 to T7) represent as many horizontal planes passed through the tetrahedron and all the points upon any one triangle denote solutions having the same partial concentration of potassium chloride. Similarly, the position of a point upon any one of the triangles indicates the osmotic proportions of the other three salts in the corresponding solution. The lines are so drawn that their intersections represent the salt proportions actually employed. It will be seen that there are twenty-eight solutions (triangle 1) that are characterized by having 0.1 of their total osmotic concentration due to potassium chloride, while there is but one solution (triangle 7) in which 0.7 is due to this salt.⁴¹ Each solution will be designated by a triple number, the first part denoting the triangle (as T2), the second the horizontal row of intersections in that triangle (as R3), and the third representing the number of the intersection in the row, counted from left to right (as C2). The solution just described is thus named T2R3C2, and the four salts contribute, respectively, the following proportions of the total concentration: potassium chloride, 0.2; monopotassium phosphate, 0.3; calcium nitrate, 0.2; and magnesium sulphate, 0.3. The triangle number gives the number of tenths due to potassium chloride, the row number gives the number of tenths due to monopotassium phosphate, and the culture number gives the number of tenths due to calcium nitrate. The number of tenths of the total concentration due to the fourth salt (magnesium sulphate) is found by subtracting from 10 the sum of the numbers appearing in the designation of the solution.

The actual chemical composition of each of the eighty-four solutions in series I is given in Table 1, in terms of the volume-molecular partial concentrations of the four salts. The first column of this table gives the culture numbers of the solutions just described, and the last three columns give the three cation-ratio values of each solution, which will be referred to later. To obtain these concentration values, it was necessary to calculate the volume-molecular partial concentrations of each salt that would produce 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, and 0.7 of 1.60 atmospheres of osmotic pressure at 25° C. The values thus obtained are given in Table 2.

⁴¹For a more detailed discussion of the interpretation of this kind of diagram, Tottingham's paper may be referred to.

0.3	0.0101	0.0103	0.0072	0.0126
0.4	0.0135	0.0138	0.0098	0.0171
0.5	0.0170	0.0173	0.0124	0.0216
0.6	0.0205	0.0208	0.0150	0.0261
0.7	0.0240	0.0243	0.0177	0.0309

The method used in these calculations may be illustrated with potassium chloride, the calculations for the other salts being made in the same way. It was first necessary to obtain certain physico-chemical data regarding each of the four salts dealt with, and these data as used for potassium chloride are given in Table 3. The numbers in the first column represent the tenths (from 0.1 to 0.7) of the total concentration of 1.60 atmospheres. Those in the second column represent the corresponding actual pressures in atmospheres. According to the van't Hoff equation, $\pi = CRT$, the osmotic value (π) of any solution may be obtained from the concentration of the particles in solution (C), the gas constant (R), and the absolute temperature (T).⁴² If the osmotic value is expressed in atmospheres, then R has the value 0.08207. The osmotic values here used are all calculated for a temperature of 25° C. (298° Abs.), so that T becomes 298, and the equation may be restated:

$$\pi = (298) (0.08207) C = 24.46 C.$$

For substances which do not dissociate or polymerize or form hydrates in solution the concentration, C , corresponds to the volume-molecular concentration, M ; and the osmotic pressure formula becomes: $\pi = 24.46 M$. But for salts, such as potassium chloride, which dissociate in solution into ions, $C = iM$;

⁴² The osmotic pressure equation here used must be understood to be only approximately true for solutions such as are dealt with in the present work. It really applies only to very *dilute solutions*. For a good discussion of osmotic pressure equations see Washburn, E. W., *Principles of Physical Chemistry*. New York (1915) 150-164. Also see Renner, O., Ueber die Berechnung des osmotischen Druckes, *Biol. Centralbl.* 32 (1912) 486-504.

in this equation i is the van't Hoff coefficient (or "mole-number"), which may be defined as the quotient of the number of particles actually present in the solution, divided by the number that would be present in an equal volume-molecular concentration of a substance that is unmodified in solution. Consequently, for salts the osmotic pressure formula becomes: $\pi = 24.46 \ iM$. For un-ionized substances i is unity, and for ionized substances such as salts i has a value greater than unity. The equation may be written in the form:

$$iM = \frac{\pi}{24.46}$$

By substituting for π in this equation each of the partial osmotic pressures from the second column of Table 3, the corresponding values of iM were obtained, and these are given in the fourth column. They represent the osmotic concentrations which are necessary to give the corresponding partial osmotic pressures given in the second column.

TABLE 3.—Data used in calculating the partial concentrations (column III) of potassium chloride required to give from 0.1 to 0.7 of the total osmotic concentration of 1.60 atmospheres, for series I.

^a The values in italics have been obtained from Noyes and Falk.

^b From Noyes and Falk.

^c This is the van't Hoff coefficient. It is obtained from the relation $i=1+(n-1) \alpha$. For non-electrolytes its value is 1.

It was next necessary to calculate the volume-molecular concentrations (M) of potassium chloride that correspond to these values of iM . To do this an indirect method is required. If

the degree of dissociation of a salt is known for a given volume-molecular concentration, M , the particulate concentration, iM , may be calculated by means of the equation:

$$iM = 1 + (n-1) \alpha M.$$

In this equation n is the number of ions formed when a molecule of the salt is dissociated, and α (given just below) is the degree of ionization, or the fraction of the whole number of molecules that dissociates at a given concentration. For potassium chloride n has a value of 2, and the equation becomes:

$$iM = (1 + \alpha) M.$$

Values for the degree of ionization α of potassium chloride were obtained from Noyes and Falk's compilation,⁴³ based upon determinations of the conductance ratio. The volume-molecular concentrations (M) and the corresponding values of α are the italicized values given in the third and fourth columns, respectively. The corresponding values of iM for this salt, calculated by means of the last-mentioned formula, are the italicized values in the sixth column. Each of these italicized values in the sixth column represents the calculated osmotic concentration (iM), corresponding to a known volume-molecular concentration (M) of potassium chloride.

As has been explained, each of the values in roman type in the sixth column represents an osmotic concentration (iM) corresponding to an unknown volume-molecular concentration (M). These unknown values have been calculated by interpolation between the italicized values in the third column, assuming a linear relationship. The formula⁴⁴ used for this interpolation was the following:

$$M_0 = M_1 + [(iM)_0 - (iM)_1] \frac{M_2 - M_1}{(iM)_2 - (iM)_1}.$$

In this equation the two given values of M are M_1 and M_2 , the two given values of iM are $(iM)_1$ and $(iM)_2$, and the values to be interpolated are M_0 and $(iM)_0$, the value for $(iM)_0$ being derived from the formula:

$$(iM)_0 = \frac{\pi}{RT}$$

as described above.

⁴³ Noyes, A. A., and Falk, K. G., The properties of salt solutions in relation to the ionic theory. III. Electrical conductance, Journ. Am. Chem. Soc. 34 (1912) 474 and 475.

⁴⁴ See Ashton, C. H., Analytic Geometry. New York (1908) 35.

The interpolated values thus obtained for M_0 are inserted in roman type in the third column of the same table, and each of these is taken as the volume-molecular concentration of potassium chloride required to produce the corresponding partial osmotic pressure given in the second column. It will be seen that only these interpolated values were actually employed in making up the solutions. These are the values given in the second column of Table 2.

Similar calculations were made for each of the other three salts. The degrees of dissociation for calcium nitrate and magnesium sulphate were taken from Noyes and Falk, while those for monopotassium phosphate were obtained from Abbott and Bray.⁴⁵ The data used in making the calculations for these three salts will not be given here, but the final interpolated values are given in the last three columns of Table 2.

Many of the solutions used in this set were subjected to freezing-point determinations by the Beckmann method, in the same way that Shive⁴⁶ tested the total concentrations of Tottingham's and his own solutions. It was found that the lowering of the freezing point (Δ) for the solutions of this series varied from about 0.11° to 0.13° . Calculating the osmotic values corresponding to these limits, it appears that these values (for 25° C.) varied from about 1.50 to about 1.70 atmospheres.⁴⁷ The error in the osmotic value here introduced may be considered as negligible in this kind of work, for it will be recalled that those solutions were calculated to have an osmotic value of 1.60 atmospheres.

RESULTS OF SERIES I

Appearance of plants.—During the early part of the twenty-four-day period of series I most of the cultures were alike in appearance, although root development was noticeably retarded in some of the cultures as early as the time of the first renewal of solution. These injured cultures were the ones in solutions

⁴⁵ Abbott, G. A., and Bray, W. C., The ionization relations of ortho- and pyrophosphoric acids and their sodium salts, *Journ. Am. Chem. Soc.* 31 (1909) 729-763.

⁴⁶ Shive, J. W., The freezing points of Tottingham's nutrient solutions, *Plant World* 17 (1914) 345-353. Also, see Shive, J. W., *Am. Journ. Bot.* 2 (1915) 157-160.

⁴⁷ The following approximate formula was used for this calculation:

$$\pi 25^\circ = \frac{298}{273} 12.06 \Delta = 13.164 \Delta.$$

having high partial concentrations of magnesium sulphate, especially cultures T1R1C1 and T2R1C1. Growth, however, did not cease in these injured cultures, for the plants continued to enlarge slowly throughout the period. The solutions containing less magnesium sulphate produced much better growth and gave the most healthy appearing plants when the series was discontinued. During the latter part of the period these better cultures were seen to have much longer lateral roots and their tops were lighter green in color and noticeably larger than in the injured cultures.

Rather pronounced differences in the color of the plants in different cultures were apparent at the time of harvesting. The color ranged from a very deep shade of green to a light yellowish green. The plants in the cultures along the left-hand margins of triangle 1 and triangle 2 (fig. 1) were darkest green, while those along the right-hand margins of triangles 4, 5, and 6, and the culture of triangle 7 were the most chlorotic. In general, the depth of green decreased in passing from left to right in the triangles and in passing in the tetrahedron from triangle 1 to triangle 7. The largest tops were intermediate in color. Another morphological difference that appeared was a drying and bleaching of the tissue between the main veins, in some cultures resulting in longitudinal stripping of the leaves. This condition was limited to the cultures in solutions with low monopotassium phosphate content, especially rows 1, 2, and 3 of triangles 1 and 2.

A very similar symptom was observed by Tottingham in several of his four-salt solutions having an osmotic concentration of 8.15 atmospheres. This symptom was found in cultures having a high content of monopotassium phosphate, a maximum content of potassium nitrate, and approximately equal contents of calcium nitrate and magnesium sulphate. A thickening of the base of the stem with branching from the same region (perhaps equivalent to the "stooling" of wheat in the field) appeared in those cultures where root injury was most pronounced. Such branching of the wheat plant occurs normally in the field when the plants are considerably older than these plants were. It is suggested that those solutions which were unfavorable to root development also brought about symptoms of an earlier maturation of the plant.

The most pronounced morphological modification of the leaves appeared to be similar to that described by Tottingham as magnesium injury; this modification was also observed by Shive.

This form of leaf injury, which appeared in a few of the plants after about twelve days in the culture solutions and in more of them at the time of harvest, was characteristic of those cultures whose solutions had high ratios of magnesium sulphate to calcium nitrate. The two degrees of this injury, described by Shive as severe and as slight, were observed in this series and their distribution on the diagram is shown in fig. 2. In recording the occurrence of these two degrees of injury, when a spiral coiling was formed or the whole leaf was affected, the injury was considered severe; when no spiral was formed and not the whole leaf was affected, the injury was considered slight. In fig. 2 the cultures marked with crosses showed severe injury, and those marked with circles slight injury. The number of leaves injured, in the entire culture of six plants, is shown by the numeral placed near the point of the diagram.

Dry weights.—Since the roots and tops were weighed separately, two dry-weight data were obtained for each culture. The sum of these two weights, of course, gives the total dry weight of the plants in the cultures, but since this sum is generally controlled in its variation by the dry weight of tops, only the separate data for tops and for roots will be considered.

These data are presented in Table 4, in which the first column gives the culture number; the second, the data for tops; and the third, the data for roots. The dry weights are expressed as relative numbers, in terms of the value for the highest actual dry weight considered as 100. The actual dry weight for this culture is given in parentheses below the value 100. The actual dry weights may be obtained by means of this value.

High yields are indicated in the table by the letter H and low by the letter L. The method of defining high and low yields is as follows: The twenty-one cultures (one-fourth of the total number) giving highest yields are marked H, and the twenty-one giving lowest values are marked L. The remaining forty-two cultures (half of the total number) are considered as medium, excepting those which are numerically the same as the lowest of the "high" group which are marked H, and those which are the same as the highest of the "low" group which are marked L. The highest yield obtained in the series is indicated by gothic type, and the lowest by italics. The average relative yields obtained with Shive's and with Tottingham's best solutions, employed as controls in this series, are given at the bottom of the table, for comparison.

FIG. 2. Diagram for series I, showing leaf injury.

TABLE 4.—Relative dry weights of tops and roots of wheat; also, water-absorption data, and the amount of water absorbed for each gram of yield of tops and of roots (water requirement), relative to the highest as 100; for series I, conducted from January 11 to February 4, 1916.

The yield data of Table 4 are presented graphically in fig. 1 (tops) and fig. 3 (roots). On these diagrams areas of high yields (H) are marked with small crosses, and those of low yields (L) are marked with small circles. The highest value in each case is shown by a large cross, and the lowest, by a large circle.

Water absorption.—The total amount of water absorbed by each culture was obtained by adding together the partial quantities recorded at the several changes of the solution. The sums thus obtained (relative to the greatest one) are shown in the fourth column of Table 4. Following the method employed for dry-weight data, the cultures giving high and low values are indicated by the letters H and L, respectively. The highest water-absorption value is indicated by gothic type and the lowest by italics.

Water requirement.—The amounts of water absorbed per unit of dry weight of tops and of roots were calculated for each culture. This ratio value is practically what has been termed the water requirement, and this term will be employed in this paper.⁴⁸ The last two columns of Table 4 present these data. The letters H and L are employed as heretofore, the highest value being again indicated by gothic type and the lowest by italics.

DISCUSSION OF SERIES I

Appearance of plants.—As has been mentioned, the plants appeared greener in color with solutions having higher partial concentrations of magnesium sulphate, which suggests a direct relation between the color and the amount of magnesium present in the cells. Furthermore, the color was more intense in the cultures having low partial concentrations of potassium chloride, or in those cultures in which the other three salts were present in relatively large amounts. The cultures with high partial concentrations of potassium chloride may be considered as those in which the plants were deprived in a large measure of the essential elements, excepting potassium.

Striping of the leaves occurred, as already described, with solutions having comparatively low potassium chloride values and very low monopotassium phosphate values.

⁴⁸ Briggs, L. J., and Shantz, H. L., The water-requirement of plants., II. A review of the literature, Bull. U. S. Dept. Agric., Bur. Pl. Ind. (1913) 285. Since practically all the water absorbed by such plants as those of the present experiments is given off by transpiration, the water-absorption data represent total transpiration.

FIG. 3. Diagram for series I, showing relative dry weights of wheat roots.

Severe magnesium injury, pronounced root modifications, and the phenomenon resembling "stooling" were all clearly confined to solutions in which the ratio of magnesium to calcium lay between the limits 1.65 and 13.43; that is, in which the amount of magnesium sulphate was relatively high as compared with the amount of calcium nitrate. Of the remaining solutions, those in which the Mg/Ca-ratio value lay between the limits 0.81 and 3.64 showed slight magnesium injury. This form of injury in general was confined to the range of the ratio values from 0.81 to 13.43, and entire freedom from injury was shown in the cultures which had ratio values within the very narrow range from 0.21 to 0.81.

Shive found that when his three-salt solution had an osmotic value of 1.75 atmospheres the plants were free from magnesium injury with Mg/Ca-values of less than 1.5; and when the osmotic value was 4.00 atmospheres this limit occurred with the ratio value 2.2. From Tottingham's data it appears that no injury occurred with ratio values below 0.40, when the total osmotic value was 2.50 atmospheres; or below 0.28, when that value was approximately 8.00 atmospheres. This limiting value of the ratio Mg/Ca is thus seen to vary considerably according to the kinds of salts used, the salt proportions, and the total concentration of the solution. It may be added, however, that no case has been observed in the experimental studies here considered in which freedom from magnesium injury occurred with a ratio having a higher value than 2.90, except with solutions of very low total concentration where, Shive and Tottingham agree, none of this injury occurs at all with any value of this ratio.

Dry weights.—Inspection of the tetrahedral diagram of fig. 1 shows that the highest dry yield of tops was obtained in culture T2R4C2, having volume-molecular partial concentrations of the four salts as follows: 0.0067 M potassium chloride, 0.0138 M monopotassium phosphate, 0.0047 M calcium nitrate, and 0.0081 M magnesium sulphate. Lowest dry yield of tops (60 per cent of the highest) occurred in culture T1R1C1, having volume-molecular partial concentrations of the salts as follows: 0.0033 M potassium chloride; 0.0033 M monopotassium phosphate; 0.0023 M calcium nitrate; and 0.0309 M magnesium sulphate. The areas of low yields of tops occur in all triangles along the left-hand margins, corresponding to regions charac-

terized by low partial concentrations of calcium nitrate and high partial concentrations of magnesium sulphate.

The highest actual dry weights of tops obtained from these twenty-four-day cultures was 0.761 gram, and the lowest was 0.457 gram. The average dry yields of tops from three cultures each of Shive's and Tottingham's best solutions for wheat were 0.684 and 0.714 gram, respectively. It, therefore, appears that all three of these best solutions may be expected to give about the same yield of tops for wheat plants of this variety grown for twenty-four days under the general aërial conditions met with in the present series.

A few other points bearing on the top yields of this series will be mentioned in the discussion of series II.

With reference to root yields, the maximum dry weight was obtained in culture T3R3C3. In a general way, the areas of high and low root yields on the diagram (fig. 3) agree with the corresponding areas for top yields (fig. 1). The general truth of this statement is especially worthy of emphasis, because its opposite was true for the series of Shive and of Tottingham. It is possible that the addition of potassium chloride to the Shive three-salt solution resulted in altering in a fundamental way the relation between top yields and root yields.

Water absorption.—Greatest water absorption occurred with two cultures, T2R4C2, which also gave highest top yields, and culture T3R3C3, the latter culture having the following partial concentrations: 0.0101 M potassium chloride, 0.0103 M monopotassium phosphate, 0.0072 M calcium nitrate, and 0.0038 M magnesium sulphate. The lowest amount of water absorption occurred in culture T1R1C1, which also gave the lowest top yield and very low root yields. This very small water absorption appears undoubtedly related to the stunted tops and poor root development previously mentioned.

Triangular diagrams for water absorption (which is practically a measure of transpiration) have been omitted in the publication of this paper. But a comparison of such diagrams with those of figs. 1 and 3 (dry weights of tops and of roots, respectively) has shown that, in a very general way, the regions for high absorption correspond to those for high top and high root yields, all three occupying the areas of the triangles characterized by medium proportions of calcium and magnesium, and medium and low proportions of potassium chloride. This comparison has also shown that the areas of low water absorption generally correspond to areas of low top and root yields.

these low areas lying in the lower left-hand corners of the triangles, denoting solutions having high proportions of magnesium sulphate, and low proportions of calcium nitrate and monopotassium phosphate. The general proportionality between the transpiration and the dry yield reported by other workers was thus observed in these experiments. This relation is of course to be expected, since the ability of a particular set of plants to transpire depends principally upon the leaf surface of the plants; this is measured approximately by their dry weight, and the amount of water absorbed is a measure of their transpiration.⁴⁹

Water requirement.—The highest water requirement for tops (Table 4) was found to be that for culture T6R1C1, having 0.6 of its total osmotic concentration due to potassium chloride. Three quite different cultures showed the lowest water requirement for tops. These were cultures T1R5C2, T2R2C2, and T2R4C3. There is very little in common between these cultures, as regards the proportions of the salts. Triangular diagrams, omitted in this publication, have shown that areas of high water requirements for tops occur in all of the triangles; that is, with all proportions of potassium chloride tested. These areas lie in almost all cases along the lower margins of the triangles, and are thus restricted to cultures having very low partial concentrations of monopotassium phosphate. On the other hand, low water requirements are in general associated with high relative proportions of monopotassium phosphate. In a very general way, solutions which gave high water requirements of tops also gave high top yields and, conversely, those which gave low water requirements gave low top yields. No relation is apparent between high water requirement of tops and either water absorption or root yields.

Turning now to water requirement of roots, it is seen that culture T2R1C3 showed the highest value, while culture T1R1C1 showed the lowest value. High values were not found in this series for solutions having more than 0.4 of their total concentration due to potassium chloride. There is no evident general correlation between either high or low values and the proportions of the various nutrient salts. A comparison of the triangular diagrams, representing water requirement of roots, with fig. 3 has shown that there is a suggestion of an inverse relationship

⁴⁹ Livingston, B. E., Relation of transpiration to growth in wheat, Bot. Gaz. 40 (1905) 178-195.

between the water requirement of roots and the dry weight of roots. Likewise, there is, in the present results, a tendency for the water requirement of roots to be inversely related to water absorption. There appears to be little or no relationship between the water requirement of roots and either the dry weight or the water requirement of tops.

SERIES II

METHODS OF SERIES II

This series was conducted for twenty-four days, from February 12 to March 7, 1916. The highest temperature recorded during this period was 28° C. (February 14, 22, 28) and the lowest was 10° C. (February 13). The average daily maximum temperature for the period was 25°, and the average daily minimum was 16° C. The corrected water loss from the spherical porous-cup atmometer showed a daily mean of 17.5 cubic centimeters and a total loss of 241 cubic centimeters for the entire period. This series was carried out in duplicate, so that there were two simultaneous cultures of six plants each for each of the sets of salt proportions tested.

The plan of this series was similar to that followed for series I. The same four salts were employed and the solutions also had the same total osmotic concentration (1.60 atmospheres) as before. In series II it was planned to cover the range of salt proportions used in series I without repeating all of the cultures. Forty selected solutions were used. Their composition may be represented by the same kind of diagrams as were used for series I. The numbers and positions upon the diagram of these selected solutions are shown in fig. 4, the culture solutions here used being represented by dots. It will be seen that solutions from all of the triangles are included. The method of designation is the same as in series I, but fractional numbers must be used to designate solutions which do not fall upon the points of intersection of the lines. In solution T2R4 $\frac{2}{3}$ C1 $\frac{1}{3}$, for example, the four salts contribute the following portions of the total osmotic concentration: Potassium chloride, 0.2; monopotassium phosphate, 0.4 $\frac{2}{3}$; calcium nitrate, 0.1 $\frac{1}{3}$; and magnesium sulphate, 0.1 $\frac{1}{3}$. For comparison, Shive's best three-salt solution for wheat and Tottingham's best four-salt solution were again used.

TABLE 5.—Partial concentrations of potassium chloride, monopotassium phosphate, calcium nitrate, and magnesium sulphate in each of the solutions employed in series II; also, the values of the three cation ratios; total osmotic value of each solution, 1.60 atmospheres.

The chemical composition of each of the forty solutions in series II is shown in Table 5, which corresponds in arrangement to Table 1. The calculation for this series followed the general method employed in series I and resulted in the partial molecular concentrations given in Table 6, which were used directly in the preparation of Table 5.

RESULTS OF SERIES II

Appearance of plants.—Root and top development took place in a way very similar to that described for the preceding series. The various differences in the appearance of the plants described as occurring in series I were observed in the present series to about the same degree with reference to the range of salt proportions. The distribution of the two forms of magnesium injury in this series is shown by the diagrams of fig. 5, which is to be interpreted like fig. 2.

Dry weights.—The dry weight data for this series are shown in Table 7, in which the various items are arranged as in Table 4, excepting that in the present case the actual values corresponding to the two duplicate cultures are given, followed by the relative average. Thus these relative average weights correspond to the relative weights given in Table 4. The letters H and L are used in the same way as in the preceding series, but it will of course be noted that the "high" and the "low"

FIG. 4. Diagram for series II, showing culture numbers and osmotic proportions of the four salts.

FIG. 5. Diagram for series II, showing leaf injury.

FIG. 6. Diagram for series II, showing relative dry weights of wheat roots.

groups here primarily include ten cultures each, instead of twenty-one as in the other case. The relative average yields simultaneously obtained with Shive's and with Tottingham's best solutions are again given at the bottom of the table. The data of Table 7 are shown diagrammatically in fig. 4 (tops) and fig. 6 (roots), in which the method of plotting is the same as that for series I (figs. 1 and 3.)

Water absorption.—The data of the total water absorption for each of the cultures in this series are shown in Table 8, where arrangement and notation are the same as heretofore followed.

Water requirement.—The relative average values for the amounts of water absorbed per unit of dry weight of tops and of roots are also presented in Table 8.

DISCUSSION OF SERIES II

Appearance of plants.—The appearance of the plants and the occurrence of magnesium injury were practically the same as in series I, and these features need not be discussed in detail.

Dry weights.—The distribution of the high and low values of top yields on the diagram for this series (fig. 4) agrees in general with the distribution of these values for series I (fig. 1). The highest yields of tops for series II was 0.804 gram for culture T2R4 $\frac{2}{3}$ C1 $\frac{2}{3}$, which had virtually the same salt proportions as the one giving the highest yield in series I (T2R4C2). Culture T1R1C1 gave the lowest top yield in series I and in both the duplicates of series II. The lowest yields for the two duplicates of series II were 0.573 and 0.529 gram (an average of 69 per cent of the highest), while the corresponding lowest yield for series I (carried out earlier in the winter) was 0.457 gram. In a similar way, the two duplicates giving the highest yield in series II (culture T2R4 $\frac{2}{3}$ C1 $\frac{2}{3}$) were 0.804 and 0.803 gram, while the highest yield from series I (culture T2R4C2) was 0.761 gram. This suggests that the aerial conditions for the two series were such as to give a somewhat higher yield of tops in the second series. The average top yield for four parallel cultures of Shive's best solution was 0.801 gram, practically the same as the best yield from the series with chloride. This value was also markedly higher than the corresponding value (0.684 gram) for the Shive solution in series I. A similar, though less pronounced, difference between the average top yields for Tottingham's solution in series I (0.714 gram) and in series II (0.751 gram) may be noticed. As far as these

data go, it appears that Tottingham's best solution gave a somewhat higher top yield than did Shive's in series I, while this relation was reversed in series II. On the whole, however, the best three salt proportions seem to be about the same in their ability to produce dry top yields under the aërial conditions of both these series.

As has been said, the salts used in the present study are the same as those of the solution that has come to be known as Detmer's solution.⁵⁰ This contains the four salts in the following proportions: 0.0130 M calcium nitrate, 0.0039 M monopotassium phosphate, 0.0044 M magnesium sulphate, and 0.0072 M potassium chloride. These exact proportions were not tested in the present work, but there were two solutions, in both series I and series II, the proportions of which closely resembled those used by Detmer. These were T2R1C6 and T3R1C5. These two solutions resembling Detmer's gave only 81 and 85 per cent of the top yield obtained with the best proportions in series I (solution T2R4C2); and these same solutions gave only 77 and 81 per cent of the top yields obtained with the best proportions in series II (solution T2R4 $\frac{2}{3}$ C1 $\frac{2}{3}$). In series I, at least thirty of the eighty-four solutions tested gave higher yields of tops than were obtained with the solutions closely resembling Detmer's in salt proportions. An even more marked improvement over the growth obtained with Detmer's exact proportions is reported by Shive for his best three-salt solution which, as has been mentioned, gave practically the same yield as did the best four-salt solution used in this study.

Regarding the production of root yields, the same generalizations appear to hold for series II as were stated for series I; and the general correspondence between high and low root areas, on the one hand, and between high and low top areas, on the other hand, seems to be more definite in the latter series. The salt proportions giving the lowest root yields were the same in both series (T1R1C1), and these same proportions also gave lowest top yields in both. In series II the highest root yield occurred in culture T2R3 $\frac{1}{2}$ C3 $\frac{1}{2}$, which had nearly the same salt proportions as the culture giving highest root yields in series I (T3R3C3).

From the dry-weight data of both series I and series II it appears that for a given total concentration these plants were not very sensitive to small differences in the salt proportions. A relatively large number of salt combinations in both series I and series II gave approximately equal growth, with apparently identical conditions other than those in the nutrient solution. Thus in series I eleven other solutions gave at least nine-tenths as high dry yields of tops as did the best solution; and in series II twelve other solutions gave at least nine-tenths of the yield of tops obtained in the best solution. The individual differences between the different plants in a culture is probably the greatest factor in determining just which set of a number of very favorable sets of salt proportions will give the very highest yield.

The relation between the cation-ratio values and the yields of wheat tops for series I and II are shown in Table 9. It will be seen that for low yields of tops the Mg/Ca-ratio values cover practically the whole range of these values for the entire series. There is thus no relation between the value of the Mg/Ca-ratio and the low yield of tops. The same thing is also true of the values of the Mg/K- and Ca/K-ratios, since all tested values of these ratios give low yields in some cultures.

TABLE 9.—Cation-ratio values for solutions of series I and II; for the entire series, and for solutions giving high and low and highest and lowest top yields.

	Mg/Ca.		Mg/K.		Ca/K.	
	Series I.	Series II.	Series I.	Series II.	Series I.	Series II.
Entire series:						
Minima	0.21	0.21	0.14	0.14	0.08	0.08
Maxima	13.43	13.43	4.68	4.68	2.63	2.68
Range	13.22	13.22	4.54	4.54	2.60	2.60
Low yields:						
Minima	0.54	0.21	0.14	0.14	0.08	0.08
Maxima	13.43	13.43	4.68	4.68	2.27	2.68
Range	12.89	13.22	4.54	4.54	2.19	2.60
High yields:						
Minima	0.53	0.53	0.14	0.14	0.08	0.08
Maxima	3.52	1.73	0.93	0.70	0.73	0.45
Range	2.99	1.20	0.79	0.66	0.65	0.37
Highest yields	1.72	1.72	0.40	0.29	0.23	0.17
Lowest yields	13.43	13.43	4.68	4.68	0.35	0.35
Do		11.35		2.61		0.23

For high yields of tops, however, there does appear to be a certain relation between cation-ratio values and yield. High

yields of tops were restricted to cultures having values of the Mg/Ca-ratio ranging from 0.53 to 3.52 for series I, and from 0.53 to 1.73 for series II, while the total range for each of these entire series was from 0.21 to 13.43. Thus high yields of tops were never obtained when the Mg/Ca-ratio value was above 3.52, no matter what the proportions of the other ions. High yields of tops were obtained when the Mg/K-ratio had the lowest value tested (0.14), and were restricted to relatively low values of this ratio. The highest value of the Mg/K-ratio that gave high yields was 0.93, while the highest value tested was 4.64. High yields of tops were also restricted to low values of the Ca/K-ratio, never being obtained when this was higher than 0.73, while the highest value for the entire series was 2.68. The very lowest value (0.08) of the Ca/K-ratio also produced high yields of tops. The data presented in this table may be summarized by stating that low yields were obtained with practically all ratio values tested; but that high yields were never obtained when the Mg/Ca-ratio was higher than 3.52, nor when the Mg/K-value was above 0.93, nor when the Ca/K-value was above 0.73.

Culture T1R1C1, which gave the lowest yields of tops in series I and II, had the following ratio values: Mg/Ca, 13.43; Mg/K, 4.68; Ca/K, 0.35. The other culture in series II giving a yield as low as T1R1C1 (namely culture T2R1C1) had the following values: Mg/Ca, 11.35; Mg/K, 2.61; and Ca/K, 0.23. The highest yields of tops were obtained, in series I, with culture T2R4C2 having the following ratio values: Mg/Ca, 1.72; Mg/K, 0.40; Ca/K, 0.23; and in series II, with culture T2R4 $\frac{2}{3}$ C1 $\frac{2}{3}$ having the ratio values: Mg/Ca, 1.72; Mg/K, 0.29; Ca/K, 0.17. These two solutions are characterized by equal Mg/Ca-ratios; but the other two ratios are different for the two solutions.

The relations between cation-ratio values and root yields for series I and II are shown in Table 10. Considering the results of the two series together, it is apparent that there is little or no relation between low root yield and the value of any one of the three cation ratios. This agrees with what was found for top yields. However, as in the case of top yields, there was an apparent relation between high yields and cation-ratio values. Thus, high root yields were obtained only when the Mg/Ca-ratio had values from 0.21 to 5.48, while the total range for the series was from 0.21 to 13.43. In a similar way high root yields were restricted to low values of the Mg/K-ratio, from 0.14 to 0.80, and never occurred with ratio values between 0.80 and 4.68. On the other hand, there was no relation between high

root yields and the Ca/K-ratio values, high yields being obtained with the whole range of these values tested.

The general conclusion which must be reached from these experiments is similar to that already stated by Gile,⁵¹ by Tottingham, and by Shive. The effect of a certain ratio between any two ions in a certain total concentration appears to depend upon the relation of these ions to all the other ions in the nutrient solution; that is, upon the complex balance of ions in the nutrient solution. A certain optimum ratio may be found between two ions, as calcium and magnesium, for example, when a certain balance exists between all the other ions present. But if this balance is altered, the optimum ratio between calcium and magnesium, for example, would be altered.

Water absorption.—Cultures T3R1C5 and T3R3C3 absorbed the greatest quantities of water in this series; the latter culture also absorbed the most in series I. This series agrees with series I in the culture showing lowest water absorption (T1R1C1). In a general way, also, there is an agreement between the two series in the direct relationship shown between dry yields of tops and roots, on the one hand, and water absorption on the other.

Water requirement.—The results of this series disagreed with those of the preceding one in the exact proportions giving high-

⁵¹ Gile, P. L., Lime-magnesia ratio as influenced by concentration, Bull. Porto Rico Agric. Exp. Sta. 12 (1912).

est and lowest top and highest and lowest root water requirements, though there was general agreement between the high and low and medium areas for the two series. The general features are the same as those for the preceding series and will not be discussed in detail here.

SERIES III

METHODS OF SERIES III

Series III extended over thirty-two days, from December 4, 1916, to January 5, 1917. The maximum temperature for this period was 28° C. (December 8, 13, 14, 21), and the minimum was 12° C. (December 15, 17, 30). The average daily maximum for the period was 25° C., and the average daily minimum was 16° C. The mean daily water loss from the atometer was 15.7 cubic centimeters, and the total loss for the period was 501 cubic centimeters.

All of the culture solutions employed in this series had the same total concentration (1.60 atmospheres) as was used in series I and II. But much higher partial concentrations of potassium chloride were included in this series, since the results obtained from the preceding series showed no very pronounced effects that might be attributed to potassium chloride. Four sets of culture solutions were used, in which potassium chloride contributed 0.2, 0.7, 0.8, and 0.9, respectively, of the total osmotic concentration. In each of these sets ten combinations of the other three salts were tested. The method of varying the other three salts may be most easily understood by referring to the diagrams of fig. 7. Each of the four triangles (T2, T7, T8, T9) represents one of these four sets. The cultures of the first set (T2) have 0.2, those of the second (T7) have 0.7, those of the third (T8) have 0.8, and those of the fourth (T9) have 0.9 of their total osmotic concentration due to potassium chloride.

In each of the sets the residual osmotic concentration is distributed among the other three salts in the way shown by the distribution of the dots on the diagrams. Thus in triangle 2 the distribution was 0.8 of the total concentration; in triangle 7, 0.3; in triangle 8, 0.2; and in triangle 9, 0.1. Each of the cultures indicated on the triangular diagrams of fig. 7 represents various proportions of monopotassium phosphate, calcium nitrate, and magnesium sulphate, the amount of potassium chloride being indicated by the number of the triangle. Thus the cul-

tures in each set may be regarded as comprising a series of three-salt solutions similar to the series employed by Shive. The diagram (T0) of fig. 7 represents Shive's series, consisting of

FIG. 7. Diagram for series III, showing culture numbers and osmotic proportions of the four salts.

thirty-six solutions having various proportions of monopotassium phosphate, calcium nitrate, and magnesium sulphate, all of which have the same total concentration (1.75 atmospheres). None of these solutions contains any potassium chloride at all. The set of cultures represented by triangle 2 may be considered as derived from Shive's series by first decreasing the total concentration of the latter to 1.28 atmospheres and then adding to each solution enough potassium chloride to give a total concentration of 1.60 atmospheres. Similarly, the sets represented by triangles 7, 8, and 9 may be derived from the Shive set by decreasing the total concentration to 0.48 atmosphere, 0.32 atmosphere, and 0.16 atmosphere, respectively, and then adding potassium chloride equivalent to 1.12 atmospheres, 1.28 atmospheres, and 1.44 atmospheres, respectively. It is thus seen that series III was planned to study the various physiological values (as indicated by the plants) of the different salt proportions in the Shive series, in the presence of four different partial concentrations of potassium chloride, the total concentration of the four-salt mixture being always the same (1.60 atmospheres).

The actual salt proportions tested in this series were not exactly the same as those employed by Shive, but the total range of salt proportions was the same. Instead of the thirty-six solutions tested by Shive, ten selected solutions were here employed. Only three of these ten correspond to sets of proportions actually used by Shive (those represented by the three apices of the diagram). The others fall on the diagram at different points from those actually tested by Shive, but they may be designated in the same general manner as was followed by Shive, by employing fractional numerals somewhat as in the case of series II. Culture T2R4 $\frac{1}{2}$ C1, for example, considered as a three-salt solution having an osmotic value of 1.28 atmospheres has 0.4 $\frac{1}{2}$ due to monopotassium phosphate, 0.1 due to calcium nitrate, and 0.4 $\frac{1}{2}$ due to magnesium sulphate, and the amount of potassium chloride present is shown by the number of the triangle (0.2 of 1.60=0.32 atmosphere). Besides the forty solutions belonging to this series, solution T2R4C2 (giving the highest top yield in series I) was also employed, for the sake of comparison.

Table 11 gives the chemical composition of each of the forty solutions in series III, in terms of the partial volume-molecular concentrations of the four salts; the values of the three cation ratios are also included in this table. The method used in cal-

culating these partial concentrations was similar to that employed heretofore.

TABLE 11.—*Partial concentrations of each of the salts in the solutions employed in series III; also, the values of the three cation ratios; total osmotic value of each solution, 1.60 atmospheres.*

RESULTS OF SERIES III

Appearance of the plants.—The same kinds of top and root modifications described for series I and II were observed in the present series, with the exception of the longitudinal striping of the leaves and the phenomenon similar to "stooling," which did not appear. Retardation of lateral roots was most pronounced in culture T2R1C1, but it was also severe in cultures T7R1C1, T8R1C1, and T9R1C1. Here also the color of the tops was seen to decrease in intensity in passing from left to right in the triangles; and all of the plants in the cultures of triangle 2 were greener than the plants in the corresponding cultures of triangles 7, 8, and 9. The forms of leaf injury apparently related to high partial concentrations of magnesium sulphate were observed in this series, and their distribution is shown upon the diagrams of fig. 8. In these diagrams the total number of leaves of the twelve plants grown in the duplicate cultures are indicated by the numerals placed near the points showing the location of culture solutions. Cultures marked by triangles showed severe injury; those marked by squares showed slight injury.

Dry weights.—The actual dry weights, in grams, of tops and of roots, are given in Table 12. The dry weights of the plants of each of the two duplicate cultures and the average weights are shown. High yields are indicated in the table by the letter H; and low, by the letter L; the two highest yields in each triangle are considered high and the two lowest are considered low, for tops and for roots. The actual yields obtained at the same time with the T2R4C2 cultures are given at the bottom of the table. The data given in this table are shown diagrammatically in fig. 7 (tops) and fig. 9 (roots). The method of plotting is somewhat different from that previously employed; in this case high values are indicated by small triangles and low values by small squares, no attempt being made to indicate areas of high and low values.

Water absorption.—The data on water absorption for the cultures in this series are shown in Table 13, where the arrangement is similar to that in the preceding table.

Water requirement.—The average amounts of water absorbed per unit of dry weight of tops and of roots are presented in the last two columns in Table 13.

FIG. 8. Diagram for series III, showing leaf injury.

DISCUSSION OF SERIES III

Appearance of plants.—From the data shown in fig. 8, it appears that the area of magnesium injury on the triangular diagram employed for this series is very small when the amount of potassium chloride present is low and becomes larger as the

FIG. 9. Diagram for series III, showing dry yields of roots.

amount of this salt is increased. Thus in triangle 2, where only 0.2 of the total concentration is due to potassium chloride, this area of injury is confined to the left margin; it extends somewhat more to the right in triangle 7; and occupies the left half of the diagram in triangles 8 and 9. In the last two cases potassium

chloride was present in very large amounts (0.8 and 0.9 of the total osmotic value, respectively). It is remarkable that the set of cultures represented by triangle 2 is most nearly like the Shive set (which contained no potassium chloride), but that

triangles 8 and 9 are the ones that approach most nearly to Shive's diagram of magnesium injury. Whether the Shive series containing the three other salts without any potassium chloride might have shown the distribution of this injury recorded by Shive, if it had been carried out simultaneously with these four sets, is of course uncertain.

The more-intense green color that characterized the cultures with a large supply of magnesium sulphate in series I and II was also noted in this series; the region of deepest green occurred at the left margin in the triangle in all four cases. Furthermore, the color intensity of these greenest plants decreased from set to set as the potassium chloride content of the solution increased. As has been mentioned, the high potassium chloride content of these sets was accompanied by lower absolute amounts of the three other salts, so that the last observation may well be related to the small absolute amount of magnesium sulphate present in these solutions. Dwarfing of the root system also occurred in this series with high relative amounts of magnesium sulphate, as has been noted for series I and II, and this dwarfing was much more pronounced with high absolute values of this salt than with lower ones. As has been mentioned, striping of the leaves and "stooling" were not observed in series III.

Dry weights.—Reference to the diagrams of fig. 7 shows that as the partial concentration of potassium chloride is increased, the partial concentration of the other three salts together being correspondingly decreased, the area of high top values migrates downward and to the right; that is, toward lower relative proportions of monopotassium phosphate and higher ones of calcium nitrate. That this migration of the area of high tops is not due merely to decreased partial concentration of monopotassium phosphate, calcium nitrate, and magnesium sulphate is suggested by the fact that a similar decrease in the total concentration of Shive's solution (see Shive's paper, figs. 2 and 3) produced a markedly different change in the configuration of the triangle. The migration of the area in question was from the central to the right central portion; that is, toward higher proportions of calcium nitrate, but not toward lower proportions of monopotassium phosphate. But other evidence from the absolute values presented in Table 12 appears to indicate that the main effect here produced by increasing the partial concentration of potassium chloride is primarily related to the concomitant

decrease in the partial concentration of the three salts used by Shive.

A set of cultures, which may be designated as series III A, was conducted in order to determine whether the low top yields obtained with high proportions of potassium chloride were due to the reduction in concentration of the essential salts or to the high concentration of potassium chloride itself. This series was carried out from January 23 to February 24, 1917. The dry-weight data for this series are shown in Table 14. Four solutions were used in this set. The first of these was the T7R1C1 solution, which was used in series I and II, and which, it will be remembered, has 0.7 of its osmotic concentration due to potassium chloride and 0.1 due to each of the other salts, monopotassium phosphate, calcium nitrate, and magnesium sulphate. This solution contains a very high proportion of potassium chloride. In both series I and series II it produced very low top yields. In the case of the second solution designated [T0R3 $\frac{1}{2}$ C3 $\frac{1}{2}$ (0.48 atmosphere)], the composition was the same as that of the T7R1C1 solution, except that the potassium chloride was omitted. The dry yield of tops produced by this solution was 0.764 gram, while the yield from the T7R1C1 culture was 0.700 gram. It is thus clear that the omission of the potassium chloride did not markedly increase the yield of tops. The next solution [T0R3 $\frac{1}{2}$ C3 $\frac{1}{2}$ (1.60 atmospheres)] was derived from the T7R1C1 solution by the omission of potassium chloride and the addition of sufficient amounts of the other salts to give a total concentration of 1.60 atmospheres. It will be seen that this solution is similar to the second solution, but that the total concentration is here increased from 0.48 atmosphere to 1.60 atmospheres. The yield from this culture was 1.221 grams. Thus a very marked increase in yield is brought about by increasing the essential salts from the concentration in which they occur in the T7R1C1 solution (0.48 atmosphere) to a total of 1.60 atmospheres. The fourth solution of this set (T10R0C0) was a single-salt solution containing potassium chloride in sufficient amount to give an osmotic concentration of 1.60 atmospheres. The yield from this culture is very low, being only 0.265 gram. From this set of cultures it may be concluded that the very low yields obtained in series I, II, and III with very high proportions of potassium chloride were due principally to the reductions in the amounts of the essential salts and not to any specific effect of the potassium chloride.

TABLE 14.—*Dry weights of wheat tops and roots; for series III A, conducted from January 23 to February 24, 1917.*

Culture No.	Nature of solution.	Dry weights (6 plants).	
		Tops.	Roots.
T7R1C1 (1.60 atmospheres) -----	0.7 of osmotic concentration due to KCl, 0.1 to each of the other salts.	<i>g.</i>	<i>g.</i>
		0.712	0.269
		0.687	0.255
		0.700	0.262
T0R3½C3½ (0.48 atmosphere) -----	The T7R1C1 solution with KCl omitted. Equal osmotic concentration of the essential salts.	0.753	0.257

T0R3½C3½ (1.60 atmospheres) -----	The T7R1C1 solution with KCl omitted and with concentration of other salts to give a total of 1.60 atmospheres.	1.220	0.879
		1.222	0.410
		1.221	0.395
T10R0C0 (1.60 atmospheres) -----	Single-salt solution with 1.60 atmospheres osmotic concentration due to KCl.	0.258	0.100
		0.272	0.105
		0.265	0.108

Returning to series III, it will be seen that with all of the ten sets of proportions of the salts other than potassium chloride the greatest dry weight of tops was produced in the solution having the least amount of potassium chloride; that is, for each set of proportions the cultures of triangle 2 gave higher yields than did the corresponding cultures of triangles 7, 8, and 9. The weight of tops varied inversely with the proportion of chloride for the following combinations: R1C1, R2½C5½, R3½C3½, R4½C1, R5½C2½, R8C1. These data indicate that (with a given set of proportions of the essential salts) increased proportions of potassium chloride give decreased top production; though, as has been emphasized, this decrease is probably due merely to the accompanying decrease in the amounts of the essential elements.

The highest dry yield of roots was obtained with the greatest partial concentration (that is, in triangle 9) of potassium chloride with the following combinations of the essential salts: R1C1, R1C4½, R2½C2½, R3½C3½, R4½C1, R5½C2½, R8C1. Considering all four triangles, the weight of roots varied directly with the proportion of chloride for the following cultures: R1C1, R4½C1, and R8C1. The combinations which did not give greatest dry weight of roots with the greatest amount of chloride were R1C8, R2½C5½, R4½C4½. These solutions were characterized by the

largest amounts of calcium nitrate and the smallest amounts of magnesium sulphate; that is, by low Mg/Ca values. These results indicate, therefore, that an increased proportion of potassium chloride gives increased root production, except in solutions having very low Mg/Ca values.

SERIES IV

METHODS OF SERIES IV

Series IV lasted thirty-two days, from January 23 to February 24, 1917, the period being of the same length as for series III. The maximum temperature during this period was 29° C. (February 4, 17, 21) and the minimum was 7° C. (February 11). The average daily maximum for the period was 25° C. and the average daily minimum was 13° C. The mean daily evaporation rate from the atmometers was 15.3 cubic centimeters, and the total loss was 491 cubic centimeters.

In this series it was planned to study the effect upon the plants of different total concentrations for the same set of salt proportions. Only three of the eighty-four sets were tested in this way, and with them was tested a three-salt solution, without potassium chloride, having the salt proportions nearly the same as those in Shive's best solution for wheat. For each one of these four sets of salt proportions eight different total concentrations were employed. The three sets of four-salt proportions used were as follows: (1) T7R1C1, which contained the maximum amount of potassium chloride occurring in any of the eighty-four solutions; (2) T1R1C1, which contained the maximum amount of magnesium sulphate present in any of the eighty-four solutions and which also had the poorest physiological balance for dry top yield in these plants; (3) T2R4C2, which had the best physiological balance for dry top yield. The three-salt solution in this series was one that is to be designated as R5C2½ on the Shive diagram.

For each one of these four sets of salt proportions the eight total concentrations tested, expressed in terms of their osmotic values, were as follows: 0.50, 1.00, 1.60, 2.50, 3.50, 4.50, 5.50 and 7.00 atmospheres. It will be noticed that the third one of these concentrations (1.60 atmospheres) is the one employed in all of the preceding series.

The calculations were based upon the data given for series I, and the various concentrations were obtained by first preparing a solution having an assumed osmotic value of 7.00 atmos-

pheres and then diluting this to give the concentrations required. The assumption is here made that the ionization constants for the salts are the same for the lower and higher concentrations as they are for the solution having an osmotic value of 1.60 atmospheres. This method, therefore, is not strictly accurate. The error thus introduced is practically negligible for the solutions having values below 1.60 atmospheres. For the higher concentrations, freezing-point determinations indicated that this error gradually increased with the total concentration until it amounted to about 8 per cent. Thus solution T1R1C1, planned to have an osmotic value of 7.00 atmospheres at 25° C., proved by the freezing-point method to have an actual value corresponding to 6.50 atmospheres at 25° C. Since the purpose of this series was to study only the general relations between the growth of the plants and the total concentration, the error just alluded to may be disregarded.

RESULTS OF SERIES IV

Appearance of the plants.—Most of the morphological modifications of tops and roots noticed in the preceding series were also observed in series IV; but the longitudinal striping of leaves and branching from the base of the stem were not seen in this series. Root development was retarded in the higher concentrations, both primary and secondary roots being thick and short. In the lowest concentrations the roots were long, slender, and flexible in appearance. Roots in the corresponding concentrations of cultures T7R1C1, T2R4C2, and R5C2½ were about equal in development; but those in the T1R1C1 cultures were all greatly retarded. With all of the sets of salt proportions, the greenness of the plants decreased with decrease in concentration of the nutrient solution. The greenest plants were those having the T1R1C1 salt proportions; those in the R5C2½ and T2R4C2 proportions were somewhat lighter in shade, and those in the T7R1C1 proportions were much lighter. Magnesium injury was not observed in any of the T7R1C1 cultures. Only one plant in the R5C2½ cultures showed injury, this occurring in the 5.50-atmosphere concentration. Slight injury was observed in the T2R4C2 cultures in the 5.50-, 4.50-, and 2.50-atmosphere concentrations. Severe injury, with coiling of the leaves, was observed in all concentrations with the T1R1C1 salt proportions, the more severe injury appearing in the higher concentration.

Dry weights.—The actual dry weights of tops and of roots for this series are given in Table 15, the weights of the plants in each of the duplicate cultures and the average weights being shown. The data given in this table have been plotted as graphs in fig. 10. In these graphs abscissas represent concentration, in terms of osmotic pressure in atmospheres, and ordinates represent yields in grams. The heavy line is the graph for the T2R4C2 cultures, the light line for the T1R1C1 cultures, the dotted line for the T7R1C1 cultures, and the broken line for the R5C2½ cultures.

Fig. 10. Graphs of average actual yields (grams) of wheat tops and of roots for series IV.

Water-absorption.—The water-absorption data for this series are shown in Table 16, which corresponds in arrangement to the preceding table. These data have been plotted as graphs in fig. 11, where the method of plotting is similar to that employed in the preceding figure.

FIG. 11. Graphs of average total amounts of water absorption for series IV.

Water requirement.—The data of the amounts of water absorbed per unit of dry top and dry root yields are shown in Table 16. These data are plotted as graphs in fig. 12, where the method of plotting is similar to that heretofore employed for this series.

DISCUSSION OF SERIES IV

Appearance of plants.—In this incomplete series bearing on the relation of total concentration to the growth of the plants (it being remembered that only three of the many possible sets of salt proportions were tested) there was evidence again that the occurrence of magnesium injury is generally accompanied by a more-intense green color of the foliage. With the set of salt proportions producing greatest injury in a concentration corresponding to 1.60 atmospheres of osmotic pressure (T1R1C1), the severity of the injury as well as the number of leaves injured increased with higher total concentrations and decreased with lower. When salt proportions were employed that gave the highest dry weight with an osmotic value of 1.60 atmospheres (T2R4C2)—which did produce some magnesium injury in series I—no magnesium injury occurred with concentration values below 2.50 atmospheres, though such injury did occur with higher concentration values. The fact that aërial conditions were different from those present for series I may possibly explain why

this injury was not apparent with these proportions with a concentration value of 1.60 atmospheres, for which injury was observed in series I. At any rate, these results indicate that magnesium injury is not to be expected with the lower concentrations of this set of salt proportions, but that it is to be expected with higher concentrations. With the other four-salt mixture here tested (T7R1C1, having the highest content of potassium chloride of all the original eighty-four solutions) no magnesium

FIG. 12. Graphs of average water requirement of tops and of roots for series IV.

injury occurred, although it did occur in series I with this set of salt proportions for a total concentration corresponding to 1.60 atmospheres. It is clear that magnesium injury does not increase with total concentration with this set of salt proportions. The fourth set of salt proportions tested in this series ($R5C2\frac{1}{2}$ on the Shive diagram, which resembled very closely Shive's best solution) showed no magnesium injury in any of these concentrations, except a slight indication with a concentration value of 5.50 atmospheres, although Shive's best solution regularly produces this form of injury. It is to be noted that while this set of salt proportions differed from that of Shive's best solution to only a small degree, yet this difference was in such a direction as to justify an expectation of less magnesium injury than occurred in the Shive solution. It appears that solution $R5C2\frac{1}{2}$ lies on the border line where more or less marked magnesium injury may or may not occur, according to conditions so far uncontrolled, such as those of the climate or the susceptibility of the individual plants.

Dry weights.—The top yields of this series (fig. 10) bring out what appear to be some very important considerations. With the set of salt proportions ($T2R4C2$) giving highest yields in series I a concentration value of 1.60 atmospheres, or perhaps somewhat higher, appears to be optimal for dry yield of tops. Both lower and higher concentrations give lower yields. With concentrations below this optimum, the yield falls off much more rapidly than with those above. It is especially interesting to note that a total concentration value of 0.50 atmosphere nearly corresponds in top yield with a total concentration value of 4.50 atmospheres. Lower total concentrations than the lowest here employed (0.50 atmosphere) would doubtless have given still lower dry weight values, but it is not to be expected that the latter would have been reduced very much in this way. It is noticeable, on the other hand, that the low top yield occurring with the highest concentration here used (7.00 atmospheres) is much lower than that occurring with a concentration value of 0.50 atmosphere. The three-salt mixture of this series ($R5C2\frac{1}{2}$, on the Shive triangle) agreed very well in all particulars with solution $T2R4C2$. The graph of this set of three-salt proportions may be regarded as indicating what would have been obtained if Shive's set of salt proportions had actually been used. On the basis of this supposition, and on that of the data here given for solution $T2R4C2$, it is not to be expected that either this four-salt solution with chloride, or the Shive three-salt solution

without chloride, can be significantly improved for the production of top yield under these general conditions by altering the total concentration. As has been mentioned, it is possible that the yield might have been a little higher had the total concentration been slightly increased. But it is safe to regard a concentration value of 1.60 or 1.75 atmospheres as optimum for both sets of salt proportions, under the aerial conditions furnished by the greenhouse used in this study, and with the plants and frequency of solution renewal employed.

The two other four-salt proportions included in this series (T1R1C1 and T7R1C1), both of which gave very low top yields with a total concentration value of 1.60 atmospheres in series I and II, here show their highest top yields with a concentration value of 3.50 atmospheres and 4.50 atmospheres, respectively. As in the case just discussed, concentrations below and above the optimum show much lower yields. The two graphs are seen to be nearly parallel throughout. Their form differs from that of the other two graphs of this series, not only in position of the maximum but also in the fact that they are nearly symmetrical about the maximum. Both are rather flat-topped.

While root yields (fig. 10) agree in a general way with top yields as related to the total concentration of the nutrient solution, some rather marked differences occur in other respects. It will be noticed that both the heights of the graphs, indicating actual yields, and the forms of the graphs, showing the relation of changes in concentration to changes in yield, differ for the four sets of salt proportions tested. The graph for the T2R4C2 cultures shows that maximum root yields were obtained with a concentration of 1.60 atmospheres, from which it appears that this solution cannot be significantly improved for root production by changing its total concentration from 1.60 atmospheres. It will be observed, however, that solution R5C2 $\frac{1}{2}$, which had no chloride and resembled Shive's best solution for tops, gave a slightly higher root yield with a concentration of 2.50 atmospheres than with one of 1.60 atmospheres. The difference, however, is small. With the two concentrations higher than 4.50 atmospheres root yields were significantly higher with the solution containing the chloride (T2R4C2) than with the one that lacked it (R5C2 $\frac{1}{2}$). Apparently, high total concentrations are less injurious to roots in the presence of the chloride than in its absence. The graph for culture T7R1C1 (having 0.7 of its concentration due to potassium chloride) is

very different in form from those just considered. This graph exhibits a marked maximum at 4.50 atmospheres, instead of at 1.60 or 2.50 atmospheres. The fourth graph, that for the T1R1C1 cultures, having 0.7 of their total concentration due to magnesium sulphate and 0.1 due to each of the other three salts, resembles the first two graphs much more closely than it does the third. With these solutions having very high proportions of magnesium sulphate, the optimum concentration was 1.60 atmospheres, and the yields decreased rather slowly with increasing concentrations above that value. Very high total concentrations retarded root production much less when the solution had high proportions of potassium chloride than when it had high proportions of magnesium sulphate.

This series furnishes very conclusive proof of the point already brought out by Shive and Tottingham; namely, that the optimum total concentration may be expected to vary with the sets of salt proportions used, and that for any total concentration an optimal set of salt proportions may be found. There appears to be no such thing as an optimal total concentration without reference to the salts and salt proportions used, and there is no optimal set of salt proportions except for some specific range of total concentrations.

Water absorption.—The most striking feature of the graphs shown in fig. 11 is the nearly linear decrease in total water absorption with an increase in concentration between the limits 1.60 and 7.00 atmospheres. It will be observed that the graph for the T2R4C2 cultures tends to parallel and lie slightly above that for the R5C2 $\frac{1}{2}$ cultures. The graph for the T7R1C1 cultures (which have 0.7 of their concentration due to potassium chloride) lies considerably below these two and tends to parallel but remain above that for the T1R1C1 cultures (having 0.7 of their concentration due to magnesium sulphate).

The graphs for the T2R4C2 and the R5C2 $\frac{1}{2}$ cultures are irregular below 1.60 atmospheres. The R5C2 $\frac{1}{2}$ cultures, it will be remembered, have no potassium chloride but otherwise are approximately the same in composition as the T2R4C2 ones. It is impossible to determine from these graphs what concentration may be expected to give maximum water absorption, because the values for 0.50, 1.00, and 1.60 atmospheres are so nearly alike. But a markedly lower absorption is evident for concentrations higher than 1.60 atmospheres. Both graphs show an approximately linear decrease in water absorption with an increase in

concentration, between the limits 1.60 and 7.00 atmospheres. The omission of potassium chloride did not alter the relationship between concentration and absorption for concentrations lying between these limits.

The graphs for the T7R1C1 cultures and the T1R1C1 cultures both show perfectly definite maxima at 1.60 atmospheres. Above this concentration, water absorption bears an approximately linear relationship to concentration.

The most interesting portions of all of these graphs are those between the concentrations 1.60 and 7.00 atmospheres. It will be seen that the slopes of the T2R4C2 and R5C2½ graphs are about the same. But the slopes of the T7R1C1 and T1R1C1 graphs are much less steep. Thus changes in concentration in the T7R1C1 and T1R1C1 sets of proportions (both of which were unfavorable media at all concentrations) produced much less marked changes in water absorption than did similar changes in the very favorable T2R4C2 and R5C2½ solutions.

By comparing figs. 10 and 11 it will be seen that for cultures T2R4C2 and R5C2½, between 1.60 and 7.00 atmospheres at least, water absorption is a good measure of top yield, and appears to depend principally upon the size of the plants. But for the T7R1C1 and T1R1C1 cultures, water absorption does not vary in the same way as do top yields. In both of these sets of cultures absorption decreases with increasing concentration between 1.60 and 7.00 atmospheres, while dry weight of tops increases with concentrations of from 1.60 to 3.50 (for T7R1C1) and to 4.50 (for T1R1C1) atmospheres and then decreases. Thus, as the concentration changes from 1.60 to 3.50 or 4.50 atmospheres, top yields increase while water absorption decreases. The difference in amount of water absorbed in this case is not at all a measure of the change in dry weight.

Water requirement.—As shown in fig. 12, a decrease in water requirement of tops accompanies an increase in the concentration of the culture medium. This is true for the T2R4C2 and R5C2½ cultures throughout the whole range of concentrations studied; while for the T1R1C1 cultures it holds only between 1.00 and 7.00 atmospheres, and for the T7R1C1 cultures only between 1.60 and 7.00 atmospheres. This decrease approximates in most cases a straight line; though, for a given change in concentration, there is apparently a more rapid decrease in water requirement with the lower concentrations than with the higher. This is especially marked for the T2R4C2 and R5C2½ cultures, between the concentrations 0.50 and 1.60 atmospheres.

For concentrations above 1.60 atmospheres the T7R1C1 graph lies above the other three for all concentrations. The water requirement for these cultures, which are very high in chloride, is thus higher than for the other three sets for all concentrations between these limits. The graphs for the other three sets of salt proportions lie very close together, and cross one another frequently, so that there appear to be no significant differences between them.

If equal dry weights in different cultures corresponded to equal leaf areas, then the water requirement would of course give an approximate measure of the transpiring power per unit area of leaf surface; that is, of the ability of a unit area of leaf surface to give off water by transpiration.⁵² It is of course not to be expected that equal dry weights do correspond at all rigidly to equal leaf areas, and hence the use of water requirement as a measure of transpiring power would be only a rough approximation at best. But the relations that have been observed in these studies between concentration and water requirement are likely to be approximately the same as those between concentration and transpiring power of unit leaf area. Transpiring power might be expected to decrease, in the way represented by the graphs, with increasing osmotic concentration of the medium surrounding the roots. Transpiring power, for the whole plant, is taken to be practically identical with water-absorbing power, measured by total water absorption.

The graphs for the water requirement of roots (fig. 12) show the same general features as those already described for tops. There is a general decrease in the water requirement of roots with an increase in concentration of the culture medium. The graphs frequently cross, and all have about the same slope, though above 3.50 atmospheres the T1R1C1 graph falls less rapidly than do the others.

The water requirements of roots may be taken as an approximation of the water-absorbing power of the roots per unit root weight and also of their absorbing power per unit area of root surface. This is seen to decrease with an increase in the osmotic concentration of the medium surrounding the roots, as might be expected on physico-chemical grounds.

GENERAL CONCLUSIONS

A mass of experimental data such as is furnished by the present study suggests a very large number of questions and interpretations pertaining to the numerous details of the results. But it is desirable that the first analysis of these results should refer to none but the more broadly general problems. Only these general relations have been included in this study and, of these, those pertaining to the appearance of the plants and the dry yields have received principal attention in this discussion.

It appears that the growth of these wheat plants for twenty-four days was nearly the same, whether a nutrient solution containing (1) Tottigham's four salts, (2) Shive's three salts, or (3) the latter with potassium chloride was employed, provided the set of salt proportions giving the best growth was selected in each case. These three types of solutions appear to have been equally efficient for promoting the growth of the plants. The four-salt solution with potassium chloride apparently offers no advantages or disadvantages, as compared with either of the mixtures previously studied systematically. It was found that the presence of potassium chloride exerted no marked influence, at least for the total concentration principally studied (1.60 atmospheres), when the four salts were used in the proportions giving highest top yields; and the best four-salt solution with potassium chloride contains the other three salts in nearly the same relative proportions as those in which the same salts occur in Shive's best three-salt solution of the same total concentration.

No injurious or retarding effect was observed that could be definitely ascribed to high partial concentrations of potassium chloride, even when this salt made up 0.9 of the osmotic value of the solution; and no characteristic injury was seen that could with certainty be related to the chloride. Retardation of growth associated with high chloride content of the culture solution appeared to be due to the accompanying low concentrations of the other three salts rather than to high partial concentration of the chloride. It is possible that a rather pronounced chlorosis may have been related to a high chloride content of the solution, but the evidence is not definite upon this point.

While it seemed to be impossible to obtain better growth of these plants in the four-salt solution containing potassium chloride than in Shive's best three-salt solution, there is some evidence, nevertheless, that poorly balanced proportions of Shive's three salts may have been improved for the growth of the plants,

especially with reference to root yields, by the addition to the solution of a proper amount of potassium chloride.

Since the wheat plant is not very sensitive to changes in concentration of potassium chloride, the osmotic value of the solution must be changed when potassium chloride is added in large enough amounts to cause a physiological response. If the nutrient solution is to remain the same in total osmotic value, the concentrations of the other three salts must be decreased when potassium chloride is added to give high partial concentrations. It is impossible to decide whether such plant responses as are thus obtained are due to the high partial concentration of the chloride or to the low partial concentrations of the three other salts. This dilemma was always encountered in seeking to obtain evidence on the points just mentioned, and this whole general problem is too complicated to treat experimentally.

It is also difficult to interpret the results in such a way as to determine the action of the chlorine ion (Cl), as such. The problem is complicated by the fact that additions of the chlorine ion to the nutrient solution were always accompanied by equal additions of the potassium ion. It is possible that such additions of the potassium ion may have modified any effects of the chlorine ion that might have been observed under other conditions.

Data on root development are never so easily interpreted as are those on the development of tops in such plants as wheat, a difficulty experienced also in the present study. But effects upon the root system are of especial physiological importance, because this is the part of the plant that is in immediate contact with the culture solution, and it is through the roots that all the water and salts absorbed by the plant must enter. It appears to have been true, in a general way at least, that those salt proportions of the four-salt solution with chloride that gave high top yields also gave high root yields. Conversely, salt proportions giving low top yields generally gave low root yields also. This statement is the opposite of the one given by Shive, based upon his studies with the three-salt solutions. It is possible that the addition of the chlorine ion to the ones already present in the three-salt solution, or some special influence of potassium chloride, may account for this difference. The general indefiniteness, however, of the root data makes superfluous a further discussion of this point without further experimentation.

Certain of the sets of salt proportions with chloride produced a characteristic form of leaf injury, which was observed in

Tottingham's and in Shive's studies, and has been termed "magnesium injury" by Tottingham. The plants giving lowest yields in all three studies exhibited this form of injury, and all three studies support the conclusion that the occurrence and severity of this injury is related to the ionic ratio of magnesium to calcium in the culture solution. This is the only case brought out by any of these three studies (Tottingham's, Shive's, and the present one) in which a clear relation may be regarded as demonstrated between the value of an ionic ratio and the development of the plant. The occurrence of this injury was, in general, not altered by the presence in the solution of potassium chloride, except perhaps with very high proportions of that salt. In the present study the greenness of the foliage was roughly proportional to the severity of the injury, the color being darkest green in the most severely injured plants. Only two sets of salt proportions producing this injury were tested with total concentrations other than the one generally employed in this study; but these agreed in showing that both severity of injury and intensity of color increased with increase in the osmotic value of the solution. The plants in the most dilute solution (0.50 atmosphere) were markedly chlorotic.

The occurrence of magnesium injury is apparently limited, as has been stated, by the value of the Mg/Ca-ratio. With solutions having an osmotic value of 1.60 atmospheres this injury is to be looked for, under the conditions of the present study, when the value of the ratio Mg/Ca is greater than 1.70. Also, the plants may be expected to be without this injury when this ratio value is below 0.80. Since neither Shive nor Tottingham detected any injured plants in their series of lowest concentrations, and since in series IV of the present study injury was found to increase with increase in concentration, it may be expected that these approximate limits will differ with difference in the total concentration.

The solution giving highest top yields with a total osmotic value of 1.60 atmospheres (T2R4C2) contained the four salts in the following partial volume-molecular concentrations: 0.0047 M calcium nitrate, 0.0138 M monopotassium phosphate, 0.0081 M magnesium sulphate, and 0.0067 M potassium chloride. This solution is not very different from what would be obtained by diluting Shive's best solution for wheat to an osmotic value of 1.28 atmospheres, and then adding sufficient potassium chloride to give a partial volume-molecular concentration of this salt of 0.0067 M. Shive's best solution contains the other three

salts in the following partial volume-molecular concentrations: 0.0052 M calcium nitrate, 0.0180 M monopotassium phosphate, and 0.0150 M magnesium sulphate. The two solutions differ in the value of the Mg/Ca-ratio, which in Shive's solution has a value of 2.88, while in the four-salt solution with chlorine it has a value of only 1.72. As would be expected from this difference in the Mg/Ca-ratios, magnesium injury was less pronounced in the four-salt solution than in Shive's best solution. The best solution with chloride for tops has quite different salt proportions from Tottingham's best four-salt solution without chloride, which has potassium nitrate instead of potassium chloride and has a higher partial concentration of calcium nitrate.

The four salts used by Tottingham (potassium nitrate, magnesium sulphate, calcium nitrate, and monopotassium phosphate) are the same as are employed in the solution generally called Knop's solution, and the three salts used by Shive (magnesium sulphate, calcium nitrate, and monopotassium phosphate) are those used in the Birner and Lucanus solution. Likewise, the four salts used in the present study are the same as those of the solution that has come to be known as Detmer's, which contains the four salts in the following volume-molecular proportions: 0.0130 M calcium nitrate, 0.0039 M monopotassium phosphate, 0.0044 M magnesium sulphate, and 0.0072 M potassium chloride. In the case of each of the three solutions, it has been found that the well-known solution could be markedly improved for the growth of wheat by altering the salt proportions. As indicated in the present study, Detmer's solution may be expected to give only about 0.80 as high top yields as does solution T2R4C2. It is important to note that at least thirty out of the eighty-four different sets of salt proportions employed in the first series of this study gave higher yields than the one indicated for the Detmer proportions.

It is worthy of particular attention that, with an osmotic value of 1.60 atmospheres or higher, the Shive three-salt mixture produced magnesium injury when the salt proportions were such as to give the highest yield of tops. This was also true of the four-salt mixture of the present study in the first series; but the solution giving highest top yields did not exhibit this injury in the second series. It has been suggested that increased growth is the first response to agents or circumstances which would prove injuriously toxic in greater concentration or on longer exposure; in other words, that slight poisoning, such as is caused

by magnesium, is essential for the greatest dry weight of tops.⁵³ The problem thus suggested will not be discussed here, but it is important to consider what salt proportions may be expected to give the highest top yields without magnesium injury. The results of the first two series indicate that either solution T3R3C3 or T2R3½C3½ may fulfill these requirements. An examination of Shive's data makes it appear that his solution R7C2, having an osmotic value of 1.75 atmospheres, should produce highest top yield without magnesium injury. The various characteristics of the solutions just mentioned are brought together for comparison in Table 17.

From a study of the osmotic properties of the nutrient solution, as distinguished from its chemical properties, it was found that the optimum concentration for the yield of tops corresponded to an osmotic pressure of about 1.60 atmospheres, at 25° C., when the salt proportions were those of solution T2R4C2. The indications are that for these salt proportions the optimum concentration may be somewhat higher than 1.60 atmospheres, rather than lower. From the results of the present study this statement is true also for a three-salt mixture which would be designated on Shive's composition triangles as R5C2½ and which, therefore, very closely resembles his best three-salt solution for wheat tops.

The optimum concentration was found to be markedly higher for two other sets of salt proportions of the four-salt solution used in this study. The osmotic value was 3.50 atmospheres for solution T1R1C1 and 4.50 atmospheres for solution T7R1C1. These two solutions had salt proportions that gave relatively low top yields, and the yields from their optimal concentrations were very much lower than those obtained from the optimal concentration of solution T2R4C2, which had the best proportions for top yield. It may be tentatively concluded that solution T2R4C2 with an osmotic value of 1.60 atmospheres, or perhaps a little higher, is about the absolute optimum for these four salts, for the frequency of solution renewal and for the plants employed, and for the general greenhouse conditions and length of growing period of the present study.

It seems worth while to lay stress upon some of the prominent considerations that must be constantly borne in mind in trying

⁵³ Free, E. E., and Trelease, S. F., The effects of certain mineral poisons on young wheat plants in three-salt nutrient solutions, Johns Hopkins Circular N. S. No. 3 (March, 1917) 199-201.

to interpret the experimental results furnished by this study. The growth and development of a particular set of culture plants is, of course, controlled by the environment, which comprises a large number of different kinds of effective conditions. An attempt was made in these experiments to control only a small number of the conditions that may influence the plant. Of these effective conditions of the environment, only the initial concentration (osmotic value), the initial salt content of the solution, the frequency of renewal of the latter, and the duration of the experiment were controlled and taken into account. Other conditions that might act upon the plants and might alter the influence of the controlled conditions were allowed to vary as they did in the experiment greenhouse, without being taken into account at all. Among such uncontrolled conditions may be mentioned, for illustration, the temperature of the nutrient solution and of the air around the foliage, the composition of this air, the radiation, etc.

Since it is apparent that no solution remains unaltered after the introduction of the plants, the frequency of renewal of the nutrient solution must be considered a very important environmental condition. It is well known that the absolute plant values may be greatly changed by altering the frequency of renewal of the solution, and with any other frequency of renewal than the one employed in these experiments the comparative results might have been very different from those recorded in this paper. Other changes in the comparative plant values might have been induced by aërating the culture solutions. The temperature of the culture solution also must have an important effect upon the comparative plant values. With other solution temperatures than those employed, the comparative values obtained might have been very different from those that were obtained in these studies.

It appears probable that any given set of solution conditions may produce very different effects upon the plant according to the kinds and intensities of the conditions other than the solution that are effective. If two duplicate series of different sets of salt proportions or of different total concentrations of the nutrient solution were carried out, one with higher air temperature or with more sunshine than the other, it might well happen that the comparative plant values obtained from one series might be very different from those obtained from the other. It seems possible, for example, that lower optimal concentrations might have been obtained in series IV under aërial conditions that favored higher

rates of transpiration. It may be added that the length of the period during which the plants are exposed to the environmental conditions is unquestionably very important in determining the nature of such results as were obtained in the present study. In consequence of these considerations, it is evident that conclusions drawn from this study can be regarded as applicable only for nonsolution conditions that are not greatly different from those encountered in these experiments. As has been mentioned, these conditions were, in a general way, those of a greenhouse in the winter and spring in the temperate region.

Aside from the conditions of environment there is of course another set of conditions that is very influential in determining plant activities. This is the group of internal conditions, which are effective from within the plant body itself. All that can be done toward the control of these internal conditions must be accomplished either by employing for the experiments plants that are as nearly alike internally as possible, or by subjecting the available plants to thoroughly controlled environments for an adequate period to make them alike. In this work, as in most experimentation of this kind, considerable care was exercised to employ plants, for the different cultures of any series, that were very nearly alike in size and general appearance. This method is clearly not entirely satisfactory, but it is about as good as the present state of our knowledge permits. Of course it is evident, just as in the case of the environmental conditions, that the conclusions of this study can be interpreted only with reference to the particular, initial, internal conditions of the plants used. It is not to be expected that the results would have been quite the same if some other species or variety of plant had been used, or if the plants had been introduced into the experiments at a different stage of their development.

While the somewhat complicated considerations just expressed may make such problems as those dealt with in this study seem very difficult, or even practically impossible of solution, from our present point of view, yet, physiological progress seems to lie in the accumulation of such partial answers to these questions as may be obtained experimentally, and in the careful correlation of these partial answers as they become available. It was with this idea in mind that the study here reported was carried out.
