SUMMARY

In June of 2001, 12 periphyton samples were collected from the Blackfoot River above Nevada Creek and from four tributaries of the upper Blackfoot River in western Montana for the purpose of assessing whether these streams are water-quality limited and in need of TMDLs. The samples were collected following DEQ standard operating procedures, processed and analyzed using standard methods for periphyton, and evaluated following modified USEPA rapid bioassessment protocols for wadeable streams.

Diatoms with deformities were found in periphyton samples collected from all 12 sites on the upper Blackfoot River and tributaries. In samples from two sites--BlckftR-01 and SbrC-02--teratological diatoms accounted for more than 10% of the cells that were counted, indicating **severe impairment and nonsupport of aquatic life uses**. At five sites--BlckftR-02, SbrC-01, AraC-01, PoorC-02, and PoorC-01--the percentage of teratological cells indicated **moderate impairment and partial support of uses**. The most likely cause of this impairment is elevated concentrations of heavy metals. The remaining 5 sites suffered only minor impairment and fully supported their aquatic life uses.

In addition to having large percentages of teratological cells, the two sites on Sandbar Creek also supported very large populations of individual diatom species. At SbrC-02, *Achnanthes minutissimum* accounted for 86% of the cells in the diatom association. Streams receiving mining wastes in western Montana often support very large numbers of *Achnanthes minutissimum*, an indicator of chemical disturbance and elevated concentrations of heavy metals. The upstream site on Sandbar Creek (SbrC-01) supported a large number of *Diatoma mesodon*, a cold-water stenotherm that is common in streams receiving mine adit discharge water and flows recharged by groundwater.

INTRODUCTION

This report evaluates the biological integrity, support of aquatic life uses, and probable causes of impairment to those uses, in the upper Blackfoot River and in four tributaries of the upper Blackfoot River in western Montana. The purpose of this report is to provide information that will help the State of Montana determine whether these streams are water-quality limited and in need of TMDLs.

The federal Clean Water Act directs states to develop water pollution control plans (Total Maximum Daily Loads or TMDLs) that set limits on pollution loading to water-quality limited waters. Water-quality limited waters are lakes and stream segments that do not meet water-quality standards, that is, that do not fully support their beneficial uses. The Clean Water Act and USEPA regulations require each state to (1) identify waters that are water-quality limited, (2) prioritize and target waters for TMDLs, and (3) develop TMDL plans to attain and maintain water-quality standards for all water-quality limited waters.

Evaluation of use support in this report is based on the species composition and structure of the periphyton (benthic algae, phytobenthos) community at 12 sites that were sampled from mid to late June in 2001. The periphyton community is a basic biological component of all aquatic ecosystems. Periphyton accounts for much of the primary production and biological diversity in Montana streams (Bahls et al. 1992).

Plafkin et al. (1989) and Stevenson and Bahls (1999) list several advantages of using periphyton in biological assessments:

- Algae are universally present in large numbers in all streams and unimpaired periphyton assemblages typically support a large number (>30) of species;

- Algae have rapid reproduction rates and short life cycles, making them useful indicators of short-term impacts;
- As primary producers, algae are most directly affected by physical and chemical factors, such as temperature, nutrients, dissolved salts, and toxins;
- Sampling is quick, easy and inexpensive, and causes minimal damage to resident biota and their habitat;
- Standard methods and criteria exist for evaluating the composition, structure, and biomass of algal associations;
- Identification to species is straightforward for the diatoms, for which there is a large body of taxonomic and ecological literature;
- Excessive algae growth in streams is often correctly perceived as a problem by the public.
- Periphyton and other biological communities reflect the *biological integrity*¹ of waterbodies; restoring and maintaining the biological integrity of waterbodies is a goal of the federal Clean Water Act;
- Periphyton and other biological communities integrate the effects of different stressors and provide a measure of their aggregate impact; and
- Periphyton and other biological communities may be the only practical means of evaluating impacts from non-point sources of pollution where specific ambient criteria do not exist (e.g., impacts that degrade habitat or increase nutrients).

Periphyton is a diverse assortment of simple photosynthetic organisms called algae, and other microorganisms that live attached to or in close proximity of the stream bottom. Most algae, such as the diatoms, are microscopic. Diatoms are distinguished by having a cell wall composed of opaline glass--hydrated amorphous silica. Diatoms often carpet a stream bottom with a slippery brown film.

¹ *Biological integrity* is defined as "the ability of an aquatic ecosystem to support and maintain a balanced, integrated, adaptive community of organisms having a species composition, diversity, and functional organization comparable to that of natural habitats within a region" (Karr and Dudley 1981).

Some algae, such as the filamentous greens, are conspicuous and their excessive growth may be aesthetically displeasing, deplete dissolved oxygen, interfere with fishing and fish spawning, clog water filters and irrigation intakes, create tastes and odors in drinking water, and cause other problems.

PROJECT AREA AND SAMPLING SITES

The project area is located in Lewis & Clark and Powell Counties in western Montana. The surface geology of the upper Blackfoot River watershed consists mostly of Precambrian Belt Series rocks in the uplands and Quaternary basin fill in the valleys (Renfro and Feray 1972).

The Blackfoot River heads near Rogers Pass (elevation 5,610 feet) north of Helena. Most tributaries arise at elevations ranging from 5,000 to 9,000 feet. At 4,300 feet, the Blackfoot River above Nevada Creek is the lowest site in the study area. Vegetation is mainly mixed conifer forest with alpine tundra on the highest peaks and open parks of fescue grassland near the mouth of Poorman Creek and near the mouth of Nevada Creek at the lower end of the study area (USDA 1976).

The upper Blackfoot River watershed is within the Northern Rockies Ecoregion of Montana (Woods et al. 1999). The main land uses are recreation, livestock grazing, logging, and mining. The Blackfoot River is popular for fishing and floating, mainly below the study area. The upper Blackfoot River drainage has many abandoned mine sites and a long history of hardrock mining.

Periphyton samples were collected at 12 sites on the Blackfoot River and four of its tributaries (Maps 1-7, Table 1). Most sampling sites are on public (USFS, BLM, or State) land. The Blackfoot River and its tributaries are classified B-1 in the Montana Surface Water Quality Standards.

METHODS

Periphyton samples were collected following standard operating procedures of the MDEQ Planning, Prevention, and Assistance Division. Using appropriate tools, microalgae were scraped, brushed, or sucked from natural substrates in proportion to the rank of those substrates at the study site. Macroalgae were picked by hand in proportion to their abundance at the site. All collections of microalgae and macroalgae were pooled into a common container and preserved with Lugol's solution.

The samples were examined to estimate the relative abundance and rank by biovolume of diatoms and genera of soft (non-diatom) algae according to the method described in Bahls (1993). Soft algae were identified using Dillard (1999), Prescott (1978), Smith (1950), and Whitford and Schumacher (1984). These books also served as references on the ecology of the soft algae, along with Palmer (1969, 1977).

After the identification of soft algae, the raw periphyton samples were cleaned of organic matter using sulfuric acid, and permanent diatom slides were prepared using Naphrax, a high refractive index mounting medium, following *Standard Methods for the Examination of Water and Wastewater* (APHA 1998). Between 400 and 494 diatom cells (800 to 988 valves) were counted at random and identified to species. The following were used as the main taxonomic and autecological references for the diatoms: Krammer and Lange-Bertalot 1986, 1988, 1991a, 1991b; Patrick and Reimer 1966, 1975. Lowe (1974) was also used as an ecological reference for the diatoms.

The diatom proportional counts were used to generate an array of diatom association metrics (Table 2). A metric is a characteristic of the biota that changes in some predictable way with increased human influence (Barbour et al. 1999).

Metric values from the Blackfoot River and tributaries were compared to numeric biocriteria or threshold values developed for streams in the Rocky Mountain Ecoregions of Montana (Table 3). These criteria are based on metric values measured in least-impaired reference streams (Bahls et al. 1992) and on metric values measured in streams that are known to be impaired by various sources and causes of pollution (Bahls 1993).

The criteria in Table 3 distinguish among four levels of impairment and three levels of aquatic life use support: no impairment or only minor impairment (full support); moderate impairment (partial support); and severe impairment (nonsupport). These impairment levels correspond to excellent, good, fair, and poor *biological integrity*, respectively.

Quality Assurance. Several steps were taken to assure that the study results are accurate and reproducible.

Upon receipt of the samples, station and sample information were recorded in a laboratory notebook and the samples were assigned a unique number compatible with the Montana Diatom Database, e.g., 2156-01. The first part of this number (2156) designates the sampling site (Blackfoot River at Flesher Pass Road); the second part of this number (01) designates the number of periphyton samples that have been collected at this site for which data have been entered into the Montana Diatom Database.

Sample observations and analyses of soft (non-diatom) algae were recorded in a lab notebook along with station and sample information provided by MDEQ. A portion of the raw sample was used to make duplicate diatom slides. After completing the diatom proportional count, the slide used for the count will be deposited in the Montana Diatom Collection at University of Montana Herbarium in Missoula. The other slide will be retained by *Hannaea* in Helena.

On completion of the project, station information, sample information, and diatom proportional count data will be entered into the Montana Diatom Database.

RESULTS AND DISCUSSION

Results are presented in Figure 1 and Tables 4 through 7, which are located near the end of this report following the Literature Cited section. Spreadsheets containing completed diatom proportional counts, with species' pollution tolerance classes (PTC) and percent abundances, are attached as Appendix A.

SAMPLE NOTES

Blackfoot River. Deformed diatom valves were noted in all three of the periphyton samples from the upper Blackfoot River.

Arrastra Creek. Algae were very sparse in the sample from AraC-01, and the usually colonial alga *Hydrurus* was present only as individual cells. This implies that algal colonization and succession at this site were at a very early stage.

Poorman Creek. All three of the samples from Poorman Creek were dominated by moss. *Spirogyra* in the sample from PoorC-03 was senescent.

Willow Creek. The sample collected at WilC-01 was dominated by moss. *Ulothrix zonata* was the species of *Ulothrix* present at WilC-02.

Sandbar Creek. The sample from SbrC-01 was dominated by moss. Algae were sparse and diatoms were very sparse in the sample from SbrC-02.

NON-DIATOM ALGAE

Blackfoot River. Filamentous green algae dominated the periphyton community at all three sites on the upper Blackfoot River, and a different genus dominated at each site (Table 4).

Zygogonium dominated at the upstream site (Flesher Pass Road). This unusual alga, which is rare in periphyton samples, is primarily aerial and grows on moist acid soils, rocks, and peat (Smith 1950). When growing on soil, it may develop in patches several yards in diameter. "The remarkable capacity of *Zygogonium* for taking up and returning large quantities of water plays no inconsiderable role in colonization of bare soil by the smaller phanerogams" (Smith 1950).

Diatoms ranked second in biovolume at BlckftR-01, followed by *Tolypothrix*, a cyanobacterium that requires cool water. In total, 12 genera of green, blue-green, and golden nondiatom algae were found in the sample from this site (Table 4). These algae indicate cool waters with relatively low levels of nutrients.

Stigeoclonium dominated the periphyton at BlckftR-02, above Landers Fork. This alga is often found in waters that are enriched with organic wastes (Palmer 1969). The source of this organic load may be swampy areas upstream or old pit toilets at the Forest Service campground (Aspen Grove) just above the sampling site (Michael Pipp, MDEQ, pers. comm.). Diatoms ranked 2nd in biovolume at this site, followed by the cyanobacterium *Nostoc*, which indicates cool waters where nitrogen is limiting. A total of 9 genera of non-diatom algae in three divisions were recorded at this site (Table 4).

Ulothrix dominated the periphyton community at BlckftR-03, above Nevada Creek, followed by the cyanobacterium *Oscillatoria*. These algae indicate increasing nitrogen enrichment. Diatoms

ranked 3rd at this site. Ten genera of non-diatom algae were recorded here, in four different divisions, including the red alga *Audouinella* (Table 4).

Poorman Creek. Diatoms dominated the periphyton community in all three samples from Poorman Creek (Table 4). Cyanobacteria ranked second at the upper two sites: *Nostoc* at PoorC-01 and *Phormidium* at PoorC-02. These genera indicate cool waters with relatively low levels of nutrients. The filamentous green alga *Spirogyra* ranked second at PoorC-03. This alga, also known as "pond scum", indicates warmer water temperatures, which may be due to a large beaver dam complex just upstream (Michael Pipp, MDEQ, pers. comm.).

The number of non-diatom genera was lower in Poorman Creek than in the upper Blackfoot River: only 2 to 6 genera of non-diatom algae were recorded at each site (Table 4). This may be due to the smaller size of Poorman Creek and natural stresses associated with shading and cool waters of low mineral content. Diatoms, green algae, and cyanobacteria were present at PoorC-01, whereas only diatoms and cyanobacteria were present at PoorC-02. Cyanobacteria were absent at the downstream site (PoorC-03), but green algae and red algae were present here (Table 4).

Arastra Creek. On average, Arrastra Creek supported even fewer non-diatom algae than did Poorman Creek (Table 5). Only diatoms and the cold-water chrysophyte *Hydrurus foetidus* were found with regularity in the sample from AraC-01. *Hydrurus* dominated the sample from AraC-02, followed by diatoms and the filamentous green alga *Ulothrix*. These algae indicate cold waters with relatively low levels of nutrients.

Sandbar Creek. Diatoms dominated the periphyton sample collected at SbrC-01 and the cyanobacterium *Phormidium* accounted for the most biovolume at SbrC-02 (Table 5). Among the non-

diatom algae, both sites supported a mix of green algae and cyanobacteria, and a single genus of chrysophyte (*Tribonema*). Ten genera of non-diatom algae were found at the upstream site and seven genera at the downstream site (Table 5). As with the other streams in this study, the algal flora of Sandbar Creek indicated cool waters of low mineral content.

Willow Creek. Diatoms accounted for most of the biovolume in the periphyton sample collected at WilC-01 and the chrysophyte *Tribonema* ranked second at this site (Table 5). Nine other genera of green algae and cyanobacteria, most of them indicating cool waters of low nutrient and low mineral content, made up the rest of the flora.

The filamentous green alga *Ulothrix* dominated the periphyton sample from WilC-02, followed by *Chaetophora* (filamentous green), *Audouinella* (filamentous red), and *Tolypothrix* (filamentous cyanobacterium) (Table 5). These algae also indicate cool waters with relatively low nutrient and mineral content.

DIATOMS

Blackfoot River. Most of the major diatom species in samples from the upper Blackfoot River are sensitive to organic enrichment (Table 6). However, *Synedra rumpens*, the dominant species at the Flesher Pass Road, is somewhat tolerant of organic loading (Lange-Bertalot 1979). Organic loading at this site, which is also reflected by the borderline pollution index (2.50), may be internal and due to the naturally swampy nature of the stream at and above this location.

Aside from minor organic loading and disturbance, and a slightly elevated percent dominant species value at the upstream site, the most serious problem in the upper Blackfoot River

appears to be chronic metals toxicity resulting in large percentages of abnormal diatom valves (Table 6). The largest of these percentages (11.40%) is comparable to that found in the Eagle River of Colorado, a federal superfund site (McFarland et al. 1997). Large percentages of teratological diatom valves have also been observed in Tenmile Creek near Helena (Bahls 1998) and in Elkhorn Creek near Wise River (Bahls 2001). Both sites have elevated heavy metals associated with historic mining activities.

The percentage of abnormal diatom valves in the upper Blackfoot River decreases in a downstream direction (Figure 1, Table 6). This likely indicates dilution of heavy metals by cleanwater tributaries and/or an increase in buffering capacity as the river becomes more alkaline. The percentage of abnormal valves at the Flesher Pass Road (BlckftR-01) indicates severe impairment and nonsupport of aquatic life uses. The percentage above the Landers Fork (BlckftR-02) indicates moderate impairment and partial support of aquatic life uses, and the percentage above Nevada Creek (BlckftR-03) indicates minor impairment but full support of aquatic life uses.

Other than unusually large percentages of teratological diatoms at the two upstream sites, diatom metrics indicate good to excellent biological integrity and full support of aquatic life uses in the upper Blackfoot River. Diatom diversity, species richness, and the pollution index all increased in a downstream direction, indicating a decrease in organic loading and heavy metals concentrations. Except for small increases in the siltation index, the diatoms indicate that biological integrity improved from upstream to downstream in the upper Blackfoot. Adjacent sites in the upper Blackfoot River had about 40% of their diatom floras in common (Table 6), indicating that moderate environmental change (recovery) occurred between them.

Poorman Creek. The upper two sites on Poorman Creek also

had an elevated number of teratological diatom valves, but the percentages here were much smaller than they were at the upper two sites on the Blackfoot River (Table 6). These resulted in ratings of moderate impairment and fair biological integrity at PoorC-01 and PoorC-02. This impairment is probably due to elevated concentrations of heavy metals. Otherwise, diatom metrics indicated only minor impairment and full support of aquatic life uses in Poorman Creek.

Diatom diversity and species richness in Poorman Creek increased in a downstream direction, perhaps in response to a decline in concentrations of heavy metals. Slowing current velocities and warmer water temperatures may also contribute to an increase in diatom diversity. A slightly elevated siltation index indicates minor impairment from sedimentation at PoorC-02 (Table 6).

Most of the major diatom species in Poorman Creek are sensitive to pollution (Table 6). Pollution index values for Poorman Creek were relatively low for a mountain stream and were about the same at all three sites. The one major species present that is somewhat tolerant of organic enrichment--*Synedra ulna*--was most abundant at the upstream site (PoorC-01). In Table 6, the similarity index indicates a much greater floristic change occurred between the upper and middle sites (26% similar floras) than between the middle and lower sites (52% similar floras).

Arastra Creek. The upper site on Arrastra Creek had a high percentage of abnormal diatom valves (3.67%) that indicates moderate impairment and partial support of aquatic life uses (Table 7). As with Poorman Creek and the upper Blackfoot River, this impairment was likely due to elevated concentrations of heavy metals. The percentage of teratological diatom valves dropped to an acceptable level at AraC-02.

Diatom species diversity and species richness also declined from AraC-01 to AraC-02 (Table 7). This decline in diversity was due mainly to an abundance of *Hannaea arcus* at AraC-02. This diatom and *Hydrurus foetidus*, which dominated the periphyton at this site, both indicate cold waters of high quality. Hence the low diatom diversity and species richness values at this site are likely due to natural stressors, such as cold water temperatures, low concentrations of dissolved solids, and moderate current velocities.

Sandbar Creek. Both sites on Sandbar Creek had elevated percentages of abnormal diatoms (Table 7). The percentage at SbrC-01 (3.71%) indicated moderate impairment and partial support of aquatic life uses; the percentage at SbrC-02 (10.26) indicated severe impairment and nonsupport of aquatic life uses.

In addition, both sites on Sandbar Creek had depressed diatom diversity and species richness values, indicating moderate to severe stress (Table 7). *Diatoma mesodon*, the dominant diatom species at the upstream site, is a cold water stenotherm (Lowe 1974). I have recorded large numbers of this species in mine adit discharges and in streams that receive mine adit discharges (unpublished data). It appears to be a good indicator of stream sites that are fed primarily by groundwater.

The dominant diatom species at the downstream site (SbrC-02) was *Achnantheidium minutissimum* (synonym: *Achnanthes minutissima*) (Table 7). This is a pioneer species which, when present in very large numbers, indicates some form of chemical, physical or biological disturbance (Barbour et al. 1999). Although diatom associations in unpolluted streams in Montana may be composed of up to 70% *Achnantheidium minutissimum*, much larger percentages of this diatom almost always occur in streams that receive mining wastes (unpublished data). The large percentage of this diatom

(86.5%) at SbrC-02 and the resulting low diversity index (0.96) both indicate severe impairment and nonsupport of uses.

The two sites on Sandbar Creek shared only about a quarter of their diatom floras (Table 7). This indicates that a moderate amount of environmental change (impairment) occurred between the two sites.

Willow Creek. Willow Creek was the only one of the study streams where diatoms indicated that both sites suffered only minor impairment and fully supported their aquatic life uses (Table 7). The upstream site (WilC-01) had a slightly elevated siltation index and a few abnormal diatom valves. The lower site (WilC-02) had somewhat depressed pollution index, indicating some organic loading. This organic loading may be natural and due to the swampy nature of this stream.

Both sites supported relatively large numbers of small, free-living Fragilariaceae (*Fragilaria vaucheriae*, *Staurosira construens*, *Synedra rumpens*) (Table 7). These diatoms indicate highly stable stream flows and reflect the low gradient and stable flows of Willow Creek. The two sites on Willow Creek had almost half of their diatom floras in common, indicating only minor environmental change occurred between them.

Both sites on Willow Creek supported a few abnormal diatom valves (Table 7) but these sites had two of the three lowest percentages of abnormal valves of all the sites in the study area (Figure 1). The upper Blackfoot River and the tributaries sampled for this study are unusual in that abnormal valves were recorded at all study sites (Figure 1). This probably indicates the influence of elevated heavy metals in these waters.

Table 2. Diatom association metrics used to evaluate biological integrity in Montana streams: reference, range of values in Montana streams, and expected direction of metric response to increasing anthropogenic perturbation or natural stress.

Metric	Reference	Range of Values	Expected Response
Shannon Species Diversity	Bahls 1979	0.00-5.00+	Decrease ¹
Pollution Index ²	Bahls 1993	1.00-3.00	Decrease
Siltation Index ³	Bahls 1993	0.00-90.0+	Increase
Disturbance Index ⁴	Barbour et al. 1999	0.00-100.0	Increase
No. Species Counted	Bahls 1979, 1993	0-100+	Decrease ¹
Percent Dominant Species	Barbour et al. 1999	5.0-100.0	Increase
Percent Abnormal Cells	McFarland et al. 1997	0.0-20.0+	Increase
Similarity Index	Whittaker 1952	0.0-80.0+	Decrease
Percent Epithemiaceae	Stevenson & Pan 1999	0.0-80.0+	Decrease
Percent Aerophiles	Johansen 1999	0.0-100	Increase

¹ Shannon diversity and species richness may increase somewhat in naturally nutrient-poor mountain streams in response to slight to moderate increases in nutrients or sediment.

² Composite numeric expression of the pollution tolerances assigned by Lange-Bertalot (1979) to the common diatom species.

³ Sum of the percent abundances of all species in the genera *Navicula*, *Nitzschia*, and *Surirella*.

⁴ Percent abundance of *Achnanthes minutissima*.

Table 3. Criteria for rating levels of biological integrity, environmental impairment or natural stress, and aquatic life use support in wadeable **mountain** streams of Montana using selected metrics for benthic diatom associations. The lowest rating for any one metric is the overall rating for the study site.

Biological Integrity/ Impairment or Natural Stress/Use Support	Diversity Index (Shannon)	Pollution Index	Siltation Index	Disturbance Index	Number of Species Counted	Percent Dominant Species	Percent Abnormal Cells	Percent Similarity Index ¹
Excellent None/Full Support	>2.99	>2.50	<20.0	<25.0	>29	<25.0	0.0	>59.9
Good/Minor Full Support	2.00- 2.99	2.01- 2.50	20.0- 39.9	25.0- 49.9	20- 29	25.0- 49.9	>0.0- <1.0	40.0- 59.9
Fair/Moderate Partial Support	1.00- 1.99	1.50- 2.00	40.0- 59.9	50.0- 74.9	10- 19	50.0- 74.9	1.0- 9.9	20.0- 39.9
Poor/Severe Nonsupport	<1.00	<1.50	>59.9	>74.9	<10	>74.9	>9.9	<20.0

¹ The Similarity Index or Percent Community Similarity (Whittaker 1952) may be used to compare a study site to an unimpaired upstream control site on the same stream. This metric measures the degree of floristic similarity between diatom associations at the two sites and is the sum of the smaller of the two percent abundance values for each species that is common to both sites. Adjacent riffles on the same stream, without intervening tributaries or environmental perturbations, will generally have at least 60% of their diatom floras in common (Bahls 1993). PCS may also be used to gauge the relative amount of impairment or recovery that occurs between adjacent study sites: >59.9% = very similar floras, no change; 40.0-59.9% = somewhat similar floras, minor change; 20.0-39.9% = somewhat dissimilar floras, moderate change; <20.0% = very dissimilar floras, major change.

Table 4. Relative abundance of cells and ordinal rank by biovolume of diatoms (Class Bacillariophyceae) and genera of non-diatom algae in periphyton samples collected from the upper Blackfoot River and Poorman Creek in 2001: d = dominant; a = abundant; f = frequent; c = common; o = occasional; r = rare.
