PREFACE TO THE FOURTH EDITION.

THE fourth edition of Cunningham's *Text-book of Anatomy* has lacked during its preparation the able guidance of its original editor, but the various contributors have attempted to maintain the standard of excellence which was Professor Cunningham's ideal.

The deaths of Professor Cunningham, Professor Birmingham, and Professor A. H. Young have necessitated changes in the authorship of several of the articles.

Every section has been fully revised; some have been partially and others have been completely rewritten.

In the majority of the sections numerous additional illustrations have been added, or the original illustrations have been replaced by new figures better adapted to their purpose, and colour has been largely used, particularly in diagrams.

The sections originally written by Professor Cunningham were the Central Nervous System, the Respiratory System, and the Ductless Glands. The account of the Central Nervous System has been revised and largely rewritten by Professor Elliot Smith of Manchester. The Respiratory System has been revised and partly rewritten by Professor Berry of Melbourne; and the section dealing with the Ductless Glands has been rewritten by Professor A. Campbell Geddes of Dublin.

The description of the Alimentary System, originally written by Professor Birmingham, has been revised and partially rewritten by Professor Waterston of King's College, London.

With regard to the sections dealing with General Embryology and the Vascular System, in the original preparation of which I was associated with my senior colleague and friend, Professor A. H. Young, I have completely rewritten the account of General Embryology, and have revised and partially rewritten the account of the Vascular System.

It may be found, where the sections written by various authors overlap one another, that there occur, in this as in previous editions, different accounts of certain phenomena concerning which our knowledge is still in an indefinite stage, and it must be understood that the authors of the various sections are solely responsible for the opinions expressed in their own sections.

The Basle anatomical terminology has been adopted throughout, except in those cases where the results of recent researches have shown that the terms of that nomenclature are incorrect, or where the terms themselves did not conform with the principles of the terminology.

It is scarcely necessary, to-day, to urge reasons for the use of the Basle nomenclature, for it is now generally recognised, not only that it is based on

sound general principles, but also that it is, at the same time, less cumbrous and more definitely instructive than the terminology previously in use in this country.

One of the recognised functions of a preface is to give the editor the opportunity of expressing his thanks to those who have assisted in the production of the work, and I gladly avail myself of this function.

My thanks are due to all the authors for their courtesy and consideration. To Mr. J. Keogh Murphy, F.R.C.S., for the preparation of an extremely useful glossary and index, and for ever-ready help and many valuable suggestions. To Dr. E. B. Jamieson for assistance in the revision of the text, and for the preparation of specimens from which some of the new illustrations were made.

I am also greatly indebted to Professor Keibel, and to Mr. Gustav Fischer of Jena for permission to copy eight figures from *Normentafeln zur Entwicklungsgeschichte des Menschen*; to Professor Gustav Retzius for permission to use figures from his monographs; and to Professors Mall, Felix, and Tandler for permission to utilise the results of their work in the preparation of diagrams.

Most of the new figures in this edition have been drawn by Mr. J. T. Murray with his usual skill and appreciation, and the remainder have been prepared by Mr. Frank Butterworth from designs made by the authors of the articles in which the figures appear.

ARTHUR ROBINSON.

EDINBURGH, *April* 1913.

Oliver Sheppard, R.H.A., fecit.

DANIEL JOHANNES CUNNINGHAM ADHUC LOQUITUR.

DEMONSTRATOR OF ANATOMY, UNIVERSITY OF EDINBURGH, 1874-1882.

PROFESSOR OF ANATOMY, ROYAL COLLEGE OF SURGEONS, DUBLIN, 1882-1883.

PROFESSOR OF ANATOMY, TRINITY COLLEGE, DUBLIN, 1883-1903.

PROFESSOR OF ANATOMY, UNIVERSITY OF EDINBURGH, 1903-1909.

LIST OF CONTRIBUTORS

- RICHARD J. A. BERRY, M.D., F.R.C.S. Ed.,
Professor of Anatomy, University of Melbourne.
(*The Respiratory System.*)
- A. FRANCIS DIXON, M.B., D.Sc. (Dubl.),
Professor of Anatomy, Trinity College, Dublin.
(*The Urino-genital System.*)
- A. CAMPBELL GEDDES, M.D.,
Professor of Anatomy, Royal College of Surgeons of Ireland.
(*The Ductless Glands.*)
- DAVID HEPBURN, M.D., F.R.S.E.,
Professor of Anatomy, University College, Cardiff.
(*Arthrology.*)
- ROBERT HOWDEN, M.A., M.B.,
Professor of Anatomy, University of Durham.
(*The Organs of Sense and the Integument.*)
- A. M. PATERSON, M.D., F.R.C.S.,
Professor of Anatomy, University of Liverpool.
(*Myology, The Spinal and Cerebral Nerves, The Sympathetic Nervous System.*)
- ARTHUR ROBINSON, M.D., F.R.C.S. Ed.,
Professor of Anatomy, University of Edinburgh.
(*General Embryology, The Vascular System.*)
- G. ELLIOT SMITH, M.D., F.R.S.,
Professor of Anatomy, University of Manchester.
(*The Central Nervous System.*)
- HAROLD J. STILES, M.B., F.R.C.S. Ed.,
Surgeon to the Royal Hospital for Sick Children, Edinburgh.
(*Surface and Surgical Anatomy.*)
- ARTHUR THOMSON, M.A., M.B., F.R.C.S.,
Professor of Human Anatomy, University of Oxford.
(*Osteology.*)
- DAVID WATERSTON, M.A., M.D., F.R.C.S. Ed.,
Professor of Anatomy, University of London.
(*The Digestive System.*)

A GLOSSARY

OF THE

INTERNATIONAL (B.N.A.)

ANATOMICAL TERMINOLOGY

GENERAL TERMS.

TERMS INDICATING SITUATION AND DIRECTION.

Longitudinalis	Longitudinal	Referring to the long axis of the body.
Verticalis	Vertical	{ Referring to the position of the long axis of the body in the erect posture.
Anterior	Anterior	{ Referring to the front and back of the body or the limbs.
Posterior	Posterior	
Ventral	Ventral	
Dorsal	Dorsal	{ Referring to the anterior and posterior aspects, respectively, of the body, and to the flexor and extensor aspects of the limbs, respectively.
Cranial	Cranial	
Caudal	Caudal	{ Referring to position nearer the head or the tail end of the long axis. Used only in reference to parts of the head, neck, or trunk. <i>Cephalic</i> is sometimes used instead of <i>cranial</i> .
Superior	Superior	
Inferior	Inferior	{ Used in reference to the head, neck, and trunk. Equivalent to cranial and caudal respectively.
Proximalis	Proximal	
Distalis	Distal	{ Used only in reference to the limbs. Proximal, nearer the attached end. Distal, nearer the free end.
Sagittalis	Sagittal	{ Used in reference to planes parallel with the sagittal suture of the skull, <i>i.e.</i> vertical antero-posterior planes.
Frontalis	Frontal	{ Used in reference to planes parallel with the coronal suture of the skull, <i>i.e.</i> vertical transverse planes.
Horizontalis	Horizontal	Used in reference to planes at right angles to vertical planes.
Medianus	Median	{ Referring to the median vertical antero-posterior plane of the body.
Medialis	Medial	{ Referring to structures relatively nearer to or further away from the median plane.
Lateralis	Lateral	
Intermedius	Intermediate	{ Referring to structures situated between more medial and more lateral structures.
Superficialis	Superficial	{ Referring to structures nearer to and further away from the surface.
Profundus	Deep	
Externus	External	{ Referring, with few exceptions, to the walls of cavities and hollow organs. Not to be used as synonymous with medial and lateral.
Internus	Internal	
Ulnaris	Ulnar	{ Used in reference to the medial and lateral borders, respectively, of the forearm and hand.
Radialis	Radial	
Tibial	Tibial	{ Used in reference to the medial and lateral borders, respectively, of the leg and foot.
Fibular	Fibular	

THE BONES.

B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.	B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.
Vertebræ Fovea costalis superior Fovea costalis inferior Fovea costalis transversalis Radix arcus vertebræ	Vertebræ Incomplete facet for head of rib, upper Incomplete facet for head of rib, lower Facet for tubercle of the rib Pedicle	Sulcus caroticus Conchæ sphenoidales Hamulus pterygoideus Canalis pharyngeus Tuberculum sellæ Fissura orbitalis superior	Cavernous groove Sphenoidal turbinal bones Hamular process Pterygo-palatine canal Olivary eminence Sphenoidal fissure
Atlas Fovea dentis	Atlas Facet for odontoid process	Os temporale Canalis facialis [Fallopii] Hiatus canalis facialis Vagina processus styloidei Incisura mastoidea Impressio trigemini Eminentia arcuata Sulcus sigmoideus Fissura petrotympanica Fossa mandibularis Semicanalis tubæ auditivæ	Temporal Bone Aqueduct of Fallopius Hiatus Fallopii Vaginal process of tympanic plate Digastric fossa Impression for Gasserian ganglion Eminence for sup. semicircular canal Sigmoid fossa Glaserian fissure Glenoid cavity Eustachian tube
Epistropheus Dens	Axis Odontoid process	Os ethmoidale Labyrinthus ethmoidalis Lamina papyracea Processus uncinatus	Ethmoid Lateral mass Os planum Unciform process
Sternum Corpus sterni Processus xiphoideus Incisura jugularis Planum sternale	Sternum Gladiolus Ensiform process Supra-sternal notch Anterior surface	Os lacrimale Hamulus lacrimalis Crista lacrimalis posterior	Lachrymal Bone Hamular process Lachrymal crest
Ossa Cranii. Os frontale Spina frontalis Processus zygomaticus Facies cerebrialis Facies frontalis Pars orbitalis	Bones of Skull. Frontal Nasal spine External angular process Internal surface Frontal surface Orbital plate	Os nasale Sulcus ethmoidalis	Nasal Bone Groove for nasal nerve
Os parietale Lineæ temporales Sulcus transversus Sulcus sagittalis	Parietal Temporal ridges Groove for lateral sinus Groove for sup. longitudinal sinus	Maxilla Facies anterior Facies infratemporalis Sinus maxillaris Processus frontalis Processus zygomaticus Canales alveolares Canalis naso-lacrimalis Os incisivum Foramen incisivum	Superior Maxillary Bone Facial or external surface Zygomatic surface Antrum of Highmore Nasal process Malar process Posterior dental canals Lachrymal groove Premaxilla Anterior palatine foramen
Os occipitale Canalis hypoglossi Foramen occipitale magnum Canalis condyloideus Sulcus transversus Sulcus sagittalis Clivus Linea nuchæ suprema Linea nuchæ superior Linea nuchæ inferior	Occipital Anterior condyloid foramen Foramen magnum Posterior condyloid foramen Groove for lateral sinus Groove for sup. long. sinus Median part of upper surface of basioccipital Highest curved line Superior curved line Inferior curved line	Os palatinum Pars perpendicularis Crista conchalis Crista ethmoidalis Pars horizontalis	Palate Bone Vertical plate Inferior turbinate crest Superior turbinate crest Horizontal plate
Os sphenoidale Crista infratemporalis Sulcus chiasmatis Crista sphenoidalis Spina angularis Lamina medialis processus pterygoidei Lamina lateralis processus pterygoidei Canalis pterygoideus [Vidii] Fossa hypophyseos	Sphenoid Pterygoid ridge Optic groove Ethmoidal crest Spinous process Internal pterygoid plate External pterygoid plate Vidian canal Pituitary fossa		

B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.	B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.
Condylus medialis	Inner condyle	Bones of the Foot.	
Condylus lateralis	Outer condyle		
Epicondylus medialis	Inner tuberosity		
Epicondylus lateralis	Outer tuberosity		
Tibia	Tibia	Talus	Astragalus
Condylus medialis	Internal tuberosity	Calcaneus	Os calcis
Condylus lateralis	External tuberosity	Tuber calcanei	Tuberosity of os calcis
Eminentia intercondyloidea	Spine	Processus medialis tuberis calcanei	Inner } tuberosities
Tuberositas tibiæ	Tubercle	Processus lateralis tuberis calcanei	Outer } of os calcis
Malleolus medialis	Internal malleolus	Os cuneiforme primum	Inner cuneiform
		Os cuneiforme secundum	Middle cuneiform
Fibula	Fibula	Os cuneiforme tertium	Outer cuneiform
Apex capituli fibulæ	Styloid process		
Malleolus lateralis	External malleolus		

THE LIGAMENTS.

Ligaments of the Spine.

Lig. longitudinale anterior	Anterior common liga- ment
Lig. longitudinale posterior	Posterior common liga- ment
Lig. flava	Ligamenta subflava
Membrana tectoria	Posterior occipito-axial ligament
Articulatio atlanto- epistrophica	Joint between the atlas and the axis
Lig. alaria	Odontoid or check liga- ments
Lig. apicis dentis	Suspensory ligament

The Ribs.

Lig. capituli costæ radiatum	Anterior costo - verte- bral or stellate liga- ment
Lig. sterno - costale interarticulare	Interarticular chon- dro - sternal liga- ment
Lig. sterno - costalia radiata	Anterior and posterior chondro-sternal liga- ment
Lig. costoxiphoidea	Chondro-xiphoid liga- ments

The Jaw.

Lig. temporo-mandi- bulare	External lateral liga- ment of the jaw
Lig. spheno-mandi- bulare	Internal lateral liga- ment of the jaw
Lig. stylo - mandi- bulare	Stylo - maxillary liga- ment

Upper Extremity.

Lig. costo-claviculare	Rhomboid ligament
Labrum glenoidale	Glenoid ligament
Articulatio radio - ulnaris proximalis	Superior radio - ulnar joint
Lig. collaterale ulnare	Internal lateral liga- ment of elbow-joint
Lig. collaterale radiale	External lateral liga- ment
Lig. annulare radii	Orbicular ligament
Chorda obliqua	Oblique ligament of ulna
Articulatio radio - ulnaris distalis	Inferior radio - ulnar joint

Discus articularis	Triangular fibro- cartilage
Recessus sacciformis	Membrana sacci- formis
Lig. radio - carpeum volare	Anterior ligament of theradio-carpal joint
Lig. radio - carpeum dorsale	Posterior ligament of the radio - carpal joint
Lig. collaterale carpi ulnare	Internal lateral liga- ment of the wrist- joint
Lig. collaterale carpi radiale	External lateral ligament of the wrist-joint
Articulationes inter- carpeæ	Carpal joints
Lig. accessoria volaria	Palmar ligaments of the metacarpo - phalangeal joints
Lig. capitulorum ossium metacarpalium transversa	Transverse metacar- pal ligament
Lig. collateralia	Lateral phalangeal ligaments

The Lower Extremity.

Lig. arcuatum	Subpubic ligament
Lig. sacro-tuberosum	Great sacro - sciatic ligament
Processus falci- formis	Falciform process
Lig. sacro-spinosum	Small sacro - sciatic ligament
Labrum glenoidale	Cotyloid ligament
Zona orbicularis	Zonular band
Ligamentum ilio - femorale	Y-shaped ligament
Lig. ischio-capsulare	Ischio-capsular band
Lig. pubo-capsulare	Pubo-femoral ligament
Lig. popliteum obli- quum	Ligament of Winslow
Lig. collaterale fibulare	Long external lateral ligament
Lig. collaterale tibiale	Internal lateral liga- ment
Lig. popliteum arcu- atum	Arcuate popliteal liga- ment
Meniscus lateralis	External semilunar cartilage

B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.	B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.
Meniscus medialis	Internal semilunar cartilage	Lig. calcaneo-fibulare	Middle fasciculus of external lateral ligament
Plica synovialis patellaris	Lig. mucosum	Lig. talo - calcaneum laterale	External calcaneo-astragaloid ligament
Plicæ alares	Ligamenta alaria	Lig. talo - calcaneum mediale	Internal calcaneo-astragaloid ligament
Articulatio tibio - fibularis	Superior tibio - fibular articulation	Lig. calcaneo - naviculare plantare	Inferior calcaneo - navicular ligament
Lig. capituli fibulæ	Anterior and posterior superior tibio-fibular ligaments	Lig. talo-naviculare	Astragalo - scaphoid ligament
Syndesmosis tibio-fibularis	Inferior tibio - fibular articulation	Pars calcaneo-navicularis	Superior calcaneo - scaphoid ligament
Lig. deltoideum	Internal lateral ligament of ankle	Pars calcaneo-cuboidea	Internal calcaneo-cuboid ligament
Lig. talo - fibulare anterius	Anterior fasciculus of external lateral ligament		
Lig. talo-fibulare posterius	Posterior fasciculus of external lateral ligament		

THE MUSCLES.

Muscles of the Back.**Superficial.**

Levator scapulæ Levator anguli scapulæ

Muscles of the Chest.

Serratus anterior Serratus magnus

Muscles of Upper Extremity.

Biceps brachii	Biceps
Lacertus fibrosus	Bicipital fascia
Brachialis	Brachialis anticus
Triceps brachii	Triceps
Caput mediale	Inner head
Caput laterale	Outer head
Pronator teres	Pronator radii teres
Caput ulnare	Coronoid head
Brachio-radialis	Supinator longus
Supinator	Supinator brevis
Extensor carpi radialis longus	Extensor carpi radialis longior
Extensor carpi radialis brevis	Extensor carpi radialis brevior
Extensor indicis proprius	Extensor indicis
Extensor digiti quinti proprius	Extensor minimi digiti
Abductor pollicis longus	Extensor ossis metacarpi pollicis
Abductor pollicis brevis	Abductor pollicis
Extensor pollicis brevis	Extensor primi interodii pollicis
Extensor pollicis longus	Extensor secundi interodii pollicis
Lig. carpi transversum	Anterior annular ligament
Lig. carpi dorsale	Posterior annular ligament

Muscles of Lower Extremity.

Tensor fasciæ latæ	Tensor fasciæ femoris
Canalis adductorius (Hunteri)	Hunter's canal

Trigonum femorale (fossa Scarpæ major)	Scarpa's triangle
Canalis femoralis	Crural canal
Annulus femoralis	Crural ring
M. quadriceps femoris—	Quadriceps—
Rectus femoris	Rectus femoris
Vastus lateralis	Vastus externus
Vastus intermedius	Crureus
Vastus medialis	Vastus internus
M. articularis genu	Subcrureus
Tibialis anterior	Tibialis anticus
Tendo calcaneus	Tendo Achillis
Tibialis posterior	Tibialis posticus
Quadratus plantæ	Accessorius
Lig. transversum cruris	Upper anterior annular ligament
Lig. cruciatum cruris	Lower anterior annular ligament
Lig. laciniatum	Internal annular ligament
Retinaculum musculorum peronæorum superius	External annular ligament
Retinaculum musculorum peronæorum inferius	

Axial Muscles.**Muscles of the Back.**

Serratus posterior superior	Serratus posticus superior
Serratus posterior inferior	Serratus posticus inferior
Splenius cervicis	Splenius colli
Sacro-spinalis	Erector spinæ
Ilio-costalis—	Ilio-costalis—
Lumborum	Sacro-lumbalis
Dorsi	Accessorius
Cervicis	Cervicalis ascendens
Longissimus—	Longissimus—
Dorsi	Dorsi
Cervicis	Transversalis cervicis
Capitis	Trachelo-mastoid

B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.
Spinalis—	Spinalis—
Dorsi	Dorsi
Cervicis	Colli
Capitis	Capitis
Semispinalis—	Semispinalis—
Dorsi	Dorsi
Cervicis	Colli
Capitis	Complexus
Multifidus	Multifidus spinæ

Muscles of Head and Neck.

Epicranius	Occipito-frontalis
Galea aponeurotica	Epicranial aponeurosis
Procerus	Pyramidalis nasi
Pars transversa (nasalis)	Compressor naris
Pars alaris (nasalis)	Dilatores naris
Auricularis anterior	Attrahens aurem
Auricularis posterior	Retrahens aurem
Auricularis superior	Attollens aurem
Orbicularis oculi	Orbicularis palpebrarum
Pars lacrimalis	Tensor tarsi
Triangularis	Depressor anguli oris
Quadratus labii superioris—	
Caput zygomaticum	Zygomaticus minor
Caput infraorbitale	Levator labii superioris
Caput angulare	Levator labii superioris alæque nasi
Zygomaticus	Zygomaticus major
Caninus	Levator anguli oris
Quadratus labii inferioris	Depressor labii inferioris
Mentalis	Levator menti
Platysma	Platysma myoides
Sterno-thyroid	Sterno-thyroid
Thyreo-hyoid	Thyreo-hyoid

Muscles and Fascia of the Orbit.

Fascia bulbi	Capsule of Tenon
Septum orbitale	Palpebral ligaments
Rectus lateralis	Rectus externus
Rectus medialis	Rectus internus

Muscles of the Tongue.

Genio-glossus	Genio-hyo-glossus
Longitudinalis superior	Superior lingualis
Longitudinalis inferior	Inferior lingualis
Transversus linguae	Transverse fibres
Verticalis linguae	Vertical fibres

Muscles of the Pharynx.

Pharyngo-palatinus	Palato-pharyngeus
M. uvulae	Azygos uvulae
Levator veli palatini	Levator palati
Tensor veli palatini	Tensor palati
Glosso-palatinus	Palato-glossus

Deep Lateral Muscles of Neck.

B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.
Scalenus anterior	Scalenus anticus
Scalenus posterior	Scalenus posticus
Longus capitis	Rectus capitis anticus major
Rectus capitis anterior	Rectus capitis anticus minor

Muscles of Thorax.

Transversus thoracis	Triangularis sterni
Diaphragma, pars lumbalis	Diaphragm, lumbar part—
Crus mediale	Crus and origin from internal arcuate ligaments
Crus intermedium	
Crus laterale	
Arcus lumbocostalis medialis (Halleri)	Ligamentum arcuatum internum
Arcus lumbocostalis lateralis (Halleri)	Ligamentum arcuatum externum

Muscles of the Abdomen.

Ligamentum inguinale (Pouparti)	Poupart's ligament
Ligamentum lacunare (Gimbernati)	Gimbernati's ligament
Fibræ intercrurales	Intercolumnar fibres
Ligamentum inguinale reflexum (Collesi)	Triangular fascia
Annulus inguinalis subcutaneus	External abdominal ring
Crus superius	Internal pillar
Crus inferius	External pillar
Falx (aponeurotica) inguinalis	Conjoined tendon
M. transversus abdominis	Transversalis muscle
Linea semicircularis (Douglassi)	Fold of Douglas
Annulus inguinalis abdominalis	Internal abdominal ring

Perineum and Pelvis.

Transversus perinei superficialis	Transversus perinei
M. sphincter urethræ membranaceæ	Compressor urethræ
Diaphragma urogenitale	Deep transverse muscle and compressor urethræ
Fascia diaphragmatis urogenitalis superior	Deep layer of triangular ligament
Fascia diaphragmatis urogenitalis inferior	Superficial layer of the triangular ligament
Arcus tendineus fasciæ pelvis	White line of pelvis
Ligamenta pubo-prostatica	Anterior and lateral true ligaments of bladder
Fascia diaphragmatis pelvis superior	Visceral layer of pelvic fascia
Fascia diaphragmatis pelvis inferior	Anal fascia

THE NERVOUS SYSTEM.

Spinal Medulla.

B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.	B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.
Fasciculus anterior proprius (Flechsig)	Anterior ground or basis bundle	Columnæ anteriores, etc.	Anterior grey horns, etc.
Fasciculus lateralis proprius	Lateral ground bundle	Fasciculus cerebro-spinalis anterior	Direct pyramidal tract
Nucleus dorsalis	Clarke's column	Fasciculus cerebro-spinalis lateralis (pyramidalis)	Crossed pyramidal tract
Pars thoracalis	Dorsal part of spinal medulla	Fasciculus cerebello-spinalis	Direct cerebellar tract
Sulcus intermedius posterior	Paramedian furrow	Fasciculus antero-lateralis superficialis	Gowers' tract

The **Brain** or **Encephalon** is divided into parts as follows:—

RHOMBENCEPHALON = Myelencephalon (medulla oblongata) (after-brain)
Metencephalon (pons and cerebellum) (hind-brain) } Posterior primary vesicle.

Brain.

Rhombencephalon

Eminentia medialis	Eminentia teres
Ala cinerea	Trigonum vagi
Area acustica	Trigonum acusticum
Nucleus nervi abducentis	Nucleus of 6th nerve
Nuclei n. acustici	Auditory nucleus
Fasciculus longitudinalis medialis	Posterior longitudinal bundle
Corpus trapezoideum	Corpus trapezoides
Incisura cerebelli anterior	Semilunar notch (of cerebellum)
Incisura cerebelli posterior	Marsupial notch
Sulcus horizontalis cerebelli	Great horizontal fissure
Lobulus centralis	Lobus centralis
Folium vermis	Folium cacuminis
Tuber vermis	Tuber valvulae
Lobulus quadrangularis	Quadrate lobule
Brachium conjunctivum cerebelli	Superior cerebellar peduncle
Brachium pontis	Middle cerebellar peduncle
Restiform body	Inferior cerebellar peduncle
Lobulus semilunaris superior	Postero-superior lobule
Lobulus semilunaris inferior	Postero-inferior lobule

Cerebrum

Pedunculus cerebri	Crus cerebri
Colliculus superior	Anterior corpus quadrigeminum
Colliculus inferior	Posterior corpus quadrigeminum
Aquæductus cerebri	Iter e tertio ad quartum ventriculum, oraqued. of Sylvius
Foramen interventriculare	Foramen of Monro
Hypothalamus	Subthalamic region
Sulcus hypothalamicus	Sulcus of Monro
Massa intermedia	Middle commissure
Fasciculus thalamo-mamillaris	Bundle of Vicq d'Azyr
Pars opercularis	Pars basilaris
Thalamus	Optic thalamus
Pallium	Cortex cerebri
Gyri transitivi	Annectant gyri
Fissura cerebri lateralis	Fissure of Sylvius
Gyrus temporalis superior	First temporal gyrus
Gyrus temporalis medius	Second temporal gyrus
Gyrus temporalis inferior	Third temporal gyrus
Sulcus centralis (Rolandi)	Fissure of Rolando
Sulcus temporalis superior	Parallel sulcus

B.N.A. TERMINOLOGY.

Sulcus temporalis medius
Sulcus circularis

Sulcus temporalis inferior
Gyrus fusiformis

Sulcus interparietalis
Sulcus corporis callosi
Sulcus cinguli

Fissura hippocampi
Gyrus cinguli
Stria terminalis
Trigonum collaterale
Hippocampus
Digitationes hippocampi
Fascia dentata hippocampi
Columna fornicis

Septum pellucidum
Cornu inferius

Commissura hippocampi
Nucleus lentiformis
Pars frontalis capsulæ internæ
Pars occipitalis capsulæ internæ
Radiatio occipito-thalamica
Radiatio corporis callosi
Pars frontalis
Pars occipitalis

Membranes of Brain.

Cisterna cerebello-medullaris
Cisterna interpeduncularis
Granulationes arachnoideales
Tela chorioidea ventriculi tertii
Tela chorioidea ventriculi quarti

Cerebral Nerves.

N. oculomotorius
N. trochlearis
N. trigeminus
Ganglion semilunare (Gasseri)
N. naso-ciliaris
N. maxillaris
N. meningeus (medius)
N. zygomaticus
Rami alveolares superiores posteriores
Rami alveolares superiores medii

OLD TERMINOLOGY.

Second temporal sulcus
Limiting sulcus of Reil
Occipito-temporal sulcus
Occipito-temporal convolution
Intraparietal sulcus
Callosal sulcus
Calloso-marginal fissure
Dentate fissure
Callosal convolution
Tænia semicircularis
Trigonum ventriculi
Hippocampus major
Pes hippocampi

Gyrus dentatus
Anterior pillar of fornix
Septum lucidum
Descending horn of lateral ventricle
Lyra

Lenticular nucleus
Anterior limb (of internal capsule)
Posterior limb (of internal capsule)
Optic radiation

Radiation of corpus callosum
Forceps minor
Forceps major

B.N.A. TERMINOLOGY.

Rami alveolares superiores anteriores
Ganglion sphenopalatinum
N. palatinus medius
N. mandibularis

Nervus spinosus
N. alveolaris inferior

N. abducens
N. facialis
N. intermedius

N. acusticus

Ganglion superius

N. recurrens

Ganglion jugulare

Ganglion nodosum

Plexus œsophageus anterior
Plexus œsophageus posterior

Nervus accessorius
Ramus internus

Ramus externus

Spinal Nerves.

Rami posteriores
Rami anteriores
N. cutaneus colli
Nn. supraclaviculares anteriores
Nn. supraclaviculares medii
Nn. supraclaviculares posteriores
N. dorsalis scapulæ
Nn. intercosto-brachiales
N. thoracalis longus
N. thoraco-dorsalis
N. cutaneus brachii medialis
N. cutaneus brachii lateralis
Fasciculus lateralis
Fasciculus medialis
N. cutaneus anti-brachii lateralis
N. cutaneus anti-brachii medialis
Ramus volaris
Ramus ulnaris
N. axillaris

OLD TERMINOLOGY.

Anterior superior dental
Meckel's ganglion
External palatine nerve
Inferior maxillary nerve
Recurrent nerve
Inferior dental

Sixth nerve
Seventh nerve
Pars intermedia of Wrisberg
Eighth or auditory nerve
Jugular ganglion of 9th nerve
Recurrent laryngeal nerve
Ganglion of root of
Ganglion of trunk of

Plexus gulæ

Spinal accessory
Accessory portion of spinal accessory nerve
Spinal portion

B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.	B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.
N. interosseus volaris	Anterior interosseous	N. genito-femoralis	Genito-crural nerve
Ramus palmaris N. mediani	Palmar cutaneous branch of the median nerve	N. lumbi-in-guinalis	Crural branch of genito-crural nerve
Nn. digitales volares proprii	Collateral palmar digital branches of median nerve	N. spermaticus externus	Genital branch of genito-crural nerve
Ramus dorsalis manus	Dorsal cutaneous branch of ulnar nerve	N. cutaneus femoris lateralis	External cutaneous nerve
Ramus cutaneus palmaris	Palmar cutaneous branch of ulnar nerve	N. femoralis	Anterior crural nerve
N. radialis	Musculo-spiral nerve	N. saphenus	Long saphenous nerve
N. cutaneus brachii posterior	Internal cutaneous branch of musculo-spiral nerve	Ramus infrapatellaris	Patellar branch of long saphenous nerve
N. cutaneus anti-brachii dorsalis	External cutaneous branches of musculo-spiral nerve	N. ischiadicus	Great sciatic nerve
Ramus superficialis	Radial nerve	N. peronæus communis	External popliteal nerve
N. interosseus dorsalis	Posterior interosseous nerve	Ramus anastomoticus peronæus	Nervus communis fibularis
Nn. digitales dorsales	Dorsal digital nerves	N. peronæus superficialis	Musculo-cutaneous nerve
N. ilio-hypogastricus	Ilio-hypogastric nerve	N. peronæus profundus	Anterior tibial nerve
Ramus cutaneus lateralis	Iliac branch of ilio-hypogastric nerve	N. tibialis	Internal popliteal and posterior tibial nerves
Ramus cutaneus anterior	Hypogastric branch of ilio-hypogastric nerve	N. cutaneus suræ medialis	Nervus communis tibialis
		N. suralis	Short saphenous nerve
		N. plantaris medialis	Internal plantar
		N. plantaris lateralis	External plantar
		N. pudendus	Pudic nerve

THE HEART AND BLOOD-VESSELS.

Heart.

Atrium	Auricle
Auricula cordis	Auricular appendix
Incisura cordis	Notch at apex of heart
Trabecula carneæ	Columnæ carneæ
Tuberculum inter-venosum	Interveinous tubercle of Lower
Sulcus longitudinalis anterior	Anterior interven-tricular groove
Sulcus coronarius	Auriculo-ventricular groove
Limbus fossæ ovalis	Annulus ovalis
Valvula venæ cavæ	Eustachian valve
Valvula sinus coronarii	Valve of Thebesius

Arteries.

Sinus aortæ	Sinuses of Valsalva
A. profunda linguæ	Ramæ artery
A. maxillaris externa	Facial artery
A. alveolaris inferior	Inferior dental artery
Ramus meningæus accessorius	Small meningeal artery
A. buccinatoria	Buccal artery
A. alveolaris superior posterior	Posterior superior dental artery
Aa. alveolares superiores anteriores	Anterior superior dental arteries
Ramus carotico-tympanicus	Tympanic branch of int. carotid

A. chorioidea	Anterior choroidal artery
A. auditiva interna	Auditory artery
Rami ad pontem	Transverse arteries (branches of basilar artery)
A. pericardiaco-phrenica	Arteria comes nervi phrenici
Rami intercostales	Anterior intercostal arteries
Truncus thyreo-cervicalis	Thyroid axis
A. transversa scapulæ	Suprascapular artery
A. intercostalis suprema	Superior intercostal
A. transversa colli	Transversalis colli
A. thoracalis suprema	Superior thoracic artery
A. thoraco-acromialis	Acromio-thoracic artery
A. thoracalis lateralis	Long thoracic artery
A. circumflexa scapulæ	Dorsalis scapulæ
A. profunda brachii	Superior profunda
A. collateralis radialis	Anterior branch of superior profunda
A. collateralis ulnaris superior	Inferior profunda
A. collateralis ulnaris inferior	Anastomotica magna
Ramus carpeus volaris	Anterior radial carpal

B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.
Ramus carpeus dorsalis	Posterior radial carpal
Aa. metacarpeæ dorsales	Dorsal interosseous arteries
A. volaris indicis radialis	Radialis indicis
Arcus volaris superficialis	Superficial palmar arch
Arcus volaris profundus	Deep palmar arch
A. interossea dorsalis	Posterior interosseous artery
A. interossea recurrens	Posterior interosseous recurrent artery
A. interossea volaris	Anterior interosseous artery
Ramus carpeus dorsalis	Posterior ulnar carpal
Ramus carpeus volaris	Anterior ulnar carpal
Aa. digitales volares communes	Palmar digital arteries
Aa. digitales volares propriæ	Collateral digital arteries
Arteriæ intestinales	Intestinal branches of sup. mesenteric
A. suprarenalis media	Middle capsular artery
A. hypogastrica	Internal iliac artery
A. umbilicalis	Obliterated hypogastric
A. pudenda interna	Internal pudic artery
A. epigastrica inferior	Deep epigastric artery
A. spermatica externa	Cremasteric artery
Aa. pudendæ externæ	Superficial and deep external pudic arteries
A. circumflexa femoris medialis	Internal circumflex artery
A. circumflexa femoris lateralis	External circumflex artery
A. genu suprema	Anastomotica magna
A. genu superior lateralis	Superior external articular artery
A. genu superior medialis	Superior internal articular artery
A. genu media	Azygos articular artery
A. genu inferior lateralis	Inferior external articular artery
A. genu inferior medialis	Inferior internal articular artery
A. malleolaris anterior lateralis	External malleolar artery
A. malleolaris anterior medialis	Internal malleolar artery
A. peronæa	Peroneal artery
Ramus perforans	Anterior peroneal artery
A. malleolaris posterior lateralis	Posterior peroneal artery

B.N.A. TERMINOLOGY.	OLD TERMINOLOGY.
A. malleolaris posterior medialis	Internal malleolar artery
Rami calcanei laterales	External calcanean artery
Rami calcanei mediales	Internal calcanean artery
A. plantaris medialis	Internal plantar artery
A. plantaris lateralis	External plantar artery
Aa. metatarsæ plantares	Digital branches
Aa. digitales plantares	Collateral digital branches

Veins.

V. cordis magna	Great cardiac vein
V. obliqua atrii sinistri	Oblique vein of Marshall
Lig. venæ cavæ sinistræ	Vestigial fold of Marshall
Vv. cordis minimæ	Veins of Thebesius
Sinus transversus	Lateral sinus
Confluens sinuum	Torcular Herophili
Plexus basilaris	Basilar sinus
Sinus sagittalis superior	Superior longitudinal sinus
Sinus sagittalis inferior	Inferior longitudinal sinus
Sinus spheno-parietalis	Sinus alæ parvæ
V. cerebri internæ	Veins of Galen
V. cerebri magna	Vena magna Galeni
V. terminalis	Vein of the corpus striatum
V. basalis	Basilar vein
V. transversa scapulæ	Suprascapular vein
V. thoraco-acromialis	Acromio - thoracic vein
Vv. transversæ colli	Transversalis colli veins
V. thoracalis lateralis	Long thoracic vein
V. azygos	Vena azygos major
V. hemiazygos	Vena azygos minor inferior
V. hemiazygos accessoria	Vena azygos minor superior
V. hypogastrica	Internal iliac vein
V. epigastrica inferior	Deep epigastric vein
V. saphena magna	Internal saphenous vein
V. saphena parva	External saphenous vein

Lymphatics.

Cisterna chyli	Receptaculum chyli
----------------	--------------------

THE VISCERA.

Digestive Apparatus.

Arcus glosso-palatinus	Anterior pillar of fauces	Dentes præmolares	Bicuspids teeth
Arcus pharyngo-palatinus	Posterior pillar of fauces	Dens serotinus	Wisdom tooth
Gl. lingualis anterior	Gland of Nuhn	Papillæ vallatæ	Circumvallate papillæ
Ductus submaxillaris	Wharton's duct	Recessus pharyngens	Lateral recess of pharynx
Gl. parotis accessoria	Socia parotidis	Tela submucosa	Pharyngeal aponeurosis
Ductus parotideus (Stenonis)	Stenson's duct	Plicæ circulares	Valvula conniventes
		Gl. intestinales	Crypts of Lieberkuhn
		Valvula coli	Ileo-cæcal valve
		Columnæ rectales	Columns of Morgagni

B.N.A. TERMINOLOGY.
 Plica transversales recti
 Valvula spiralis
 Noduli lymphatici
 aggregati (Peyeri)
 Intestinum jejunum
 Intestinum ileum
 Noduli lymphatici
 lienales (Malpighii)

OLD TERMINOLOGY.

Valves of Houston
 Valve of Heister
 Peyer's patches
 Jejunum
 Ileum
 Malpighian corpuscles

Respiratory Apparatus.**Larynx**

Prominentia laryngea
 Incisura thyreoidea
 superior
 M. ary-epiglotticus
 M. vocalis
 M. thyreo - epiglotticus
 Appendix ventriculi
 laryngis
 Plica vocalis
 Plica ventricularis
 Ligamentum ventriculare
 Ligamentum vocale
 Glottis
 Rima vestibuli
 Cartilago thyreoidea
 Membrana hyothyreoidea
 Cartilago corniculata
 (Santorini)
 Tuberculum epiglotticum
 Pars intermembranacea (rimæ glottidis)
 Pars intercartilaginea
 (rimæ glottidis)
 Conus elasticus (membranae elasticæ laryngis)
 Glandula thyreoidea

Adam's apple
 Superior thyroid notch
 Aryteno - epiglottidean muscle
 Internal thyro-arytenoid muscle
 Thyro - epiglottidean muscle
 Laryngeal sac
 True vocal cord
 False vocal cord
 Superior thyro - arytenoid ligament
 Inferior thyro - arytenoid ligament
 Glottis vera
 Glottis spuria
 Thyroid cartilage
 Thyro - hyoid membrane
 Cartilage of Santorini
 Cushion of epiglottis
 Glottis vocalis
 Glottis respiratoria
 Crico - thyroid membrane
 Thyroid gland

B.N.A. TERMINOLOGY.

Glomerus caroticum
 Nose
 Concha nasalis superior (Santorini)
 Concha nasalis superior
 Concha nasalis media
 Concha nasalis inferior

OLD TERMINOLOGY.

Intercarotid gland or body
 Highest turbinate bone
 Superior turbinate bone
 Middle turbinate bone
 Inferior turbinate bone

Urogenital Apparatus.

Corpuscula renis
 Paradidymis
 Appendix testis

Ductus deferens
 Gl. urethrales
 Glandula bulbo-urethralis (Cowperi)
 Folliculi oophori vesiculosi
 Cumulus oophorus
 Tuba uterina
 Epooophoron
 Appendices vesiculosi
 Ductus epooophori longitudinalis
 Orificium internum uteri
 Orificium externum
 Processus vaginalis
 Glandula vestibularis major

Malpighian corpuscles
 Organ of Giralde's
 Hydatid of Morgagni (male)
 Vas deferens
 Glands of Littre
 Cowper's gland
 Graafian follicles
 Discus proligerus
 Fallopian tube
 Parovarium
 Hydatids of Morgagni (female)
 Gärtner's duct
 Internal os (of uterus)
 External os
 Canal of Nuck
 Bartholin's gland

Peritoneum.

Bursa omentalis
 Foramen epiploicum
 Lig. phrenico - colicum
 Excavatio recto-uterina (cavum Douglasi)
 Lig. gastro-lienale

Lesser peritoneal sac
 Foramen of Winslow
 Costo-colic ligament
 Pouch of Douglas
 Gastro-splenic omentum

THE SENSE ORGANS.**The Eye.**

Sclera
 Lamina elastica anterior (Bowman)
 Lamina elastica posterior (Descemeti)
 Spatia anguli iridis
 Angulus iridis
 Zonula ciliaris
 Septum orbitale
 Fascia bulbi
 Commissura palpebrarum lateralis
 Commissura palpebrarum medialis
 Tarsus superior
 Tarsus inferior
 Lig. palpebrale mediale
 Raphe palpebralis lateralis

Sclerotic coat
 Bowman's membrane
 Descemet's membrane
 Spaces of Fontana
 Irido-corneal junction
 Zonule of Zinn
 Palpebral ligament
 Capsule of Tenon
 External canthus
 Internal canthus
 Superior tarsal plate
 Inferior tarsal plate
 Internal tarsal ligament
 External tarsal ligament

Tarsal glands**Meibomian glands****The Ear.**

Canalis semicircularis lateralis
 Ductus reuniens
 Ductus cochlearis
 Recessus sphaericus
 Recessus ellipticus
 Paries jugularis
 Paries labyrinthica
 Fenestra vestibuli
 Fenestra cochleæ
 Paries mastoidea
 Antrum tympanicum
 Paries carotica
 Processus lateralis
 Processus anterior

External semicircular canal
 Canalis reuniens
 Membranous cochlea
 Fovea hemispherica
 Fovea hemi-elliptica
 Floor of tympanum
 Inner wall
 Fenestra ovalis
 Fenestra rotunda
 Posterior wall
 Mastoid antrum
 Anterior wall
 Processus brevis (of malleus)
 Processus gracilis

TEXT-BOOK OF ANATOMY.

INTRODUCTION.

ANATOMY is a comprehensive term, which includes several closely related branches of study. Primarily it is employed to indicate the study of the several parts which build up the body, and the relationship which these present to each other. But the structure of an individual is not the same at all stages of its life, for many changes occur during the period of its existence. The ovum and the spermatozoon, which are the starting-points of every individual, are very different from the finished organism as represented by the adult, and the series of changes through which the organism passes until its structure is perfected and full growth is attained constitute the phenomena of **development**. The general term "development" includes not only the various and striking structural changes which occur during the intra-uterine life of the individual, to the study of which the term **embryology** is more specially applied, but also many growth processes which occur after birth, such as the later stages in the ossification and growth of the bones, the eruption of the two series of teeth, the adjustment of the vascular system to its new requirements, etc. The actual observation of the processes by which the parts of the body are gradually formed, and of the structural arrangements by means of which a temporary connexion is established between the ovum and the mother, through which an interchange of nutritive and other matters between the two takes place, renders embryology one of the most interesting of all the departments of anatomy. The term **ontogeny** also is used to denote the development of the individual. There is, however, another form of development, slower, but just as certain in its processes, which affects not only the individual, but all the members of the animal group to which it belongs. The theory of descent or evolution leads us to believe that between man of the present day and his remote ancestors there is a wide structural gap, which, if the geological record were perfect, would be seen to be completely occupied by long-lost intermediate forms. In the process of evolution, therefore, structural changes have gradually taken place which have modified the entire race. These evolutionary phases constitute the ancestral history or **phylogeny** of the individual. Ontogeny and phylogeny are intertwined in a remarkable manner, and present certain extraordinary relationships. In other words, the ancestral evolutionary development appears to be so stamped upon an individual that it repeats certain of the phylogenetic stages with more or less clearness during the process of its own individual development. Thus, at an early period in the embryology of man we recognise evanescent gill-pouches comparable with those of a fish, whilst a study of the development of his heart shows that it passes through transitory structural conditions similar, in many respects, to the permanent

condition of the heart in certain of the lower animals. It is in connexion with this that the phrase has arisen that every animal in its individual development or ontogeny climbs up its own genealogical tree—a saying which, taking it even in the broadest sense, is only partially true.

The broader conceptions of anatomy, which are obtained by taking a general survey of the structural aspects of the entire animal kingdom, constitute **morphology**. The morphologist investigates the laws of form and structure, and in his generalisations he gives attention to detail only in so far as this is necessary for the proper establishment of his views. The knowledge of anatomy which is required by the student of medicine is different. It is essentially one of detail, and often details important from the practical and utilitarian points of view have little or no morphological value. This want of balance in the interest attached to anatomical facts, according to the aspect from which they are examined, so far from being unfortunate, affords the teacher the means of making the study of anatomy at once fascinating and instructive. Almost every fact which is brought under the notice of the student can be accompanied by a morphological or a practical application. It is this that lightens a study which, presented to the student of medicine in any other way, would be at once dry and tedious.

Certain terms employed in morphology require early and definite explanation. These are homology, serial homology, and homoplasy. The same organ repeated in two different animals is said to present a case of **homology**. But this morphological identity between these two organs must be proved beyond dispute before the homology between them can be allowed. In deciding this identity the great and essential test is that the two organs in question should have a similar developmental origin. Thus, the fore-limb of a quadruped is homologous with the upper limb of man; the puny collar-bone of a tiger, the fibrous thread which is the only representative of this bone in the horse, and the strongly marked clavicle of the ape or man, are all, strictly speaking, homologous with one another. Homologous organs in different animals usually present a similar position and a similar structure, but not invariably so. It is not uncommon for a muscle to wander somewhat from its original position, and many cases could be quoted in which parts have become completely transformed in structure, either from disuse or for the purpose of meeting some special demand in the animal economy. In the study of the muscles and ligaments instances of this will be brought under the notice of the reader.

Often organs which perform totally different functions are yet perfectly homologous. Thus the wing of a bat or the wing of a bird, both of which are subservient to flight, are homologous with the upper limb of man, the office of which is the different one of prehension. Identity or correspondence in the function performed by two organs in two different animals is not taken into consideration in deciding questions of homology. The gills of a fish and the lungs of a higher vertebrate perform very much the same physiological office, and yet they are not homologous. The term **analogy** is often used to express functional correspondence of this kind.

In the construction of vertebrates and certain other animal groups a series of similar parts are repeated along a longitudinal axis, one after the other. Thus the series of vertebræ which build up the backbone, the series of ribs which gird round each side of the chest, the series of intercostal muscles which fill up the intervals between the ribs, the series of nerves which arise from the brain and spinal medulla, are all examples of this. An animal exhibiting such a condition of parts is said to present the **segmental type** of organisation, and in the early stages of development this segmentation is much more strongly marked, and is to be seen in parts which

subsequently lose all trace of such a subdivision. The parts thus repeated are said to be **serially homologous**. But there are other instances of serial homology besides those which are manifestly produced by segmentation. The upper limb is serially homologous with the lower limb: each is composed of parts which, to a large extent, are repeated in the other, and the correct adjustment of this comparison between the several parts of the upper and lower limbs constitutes one of the most difficult and yet interesting problems of morphology.

Homoplasia is a term which has been introduced to express a form of correspondence between organs in different animals which cannot be included under the term homology. Two animal groups, which originally have sprung from the same stem-form, may independently develop a similar structural character which is altogether absent in the ancestor common to both. Thus the common ancestor of man and the carnivora in all probability possessed a smooth brain, and yet the human brain and the carnivore brain are both richly convoluted. Not only this, but certain anatomists seek to reconcile the convolutionary pattern of the one with the convolutionary pattern of the other. What correspondence there is does not, in every instance, constitute a case of homology, because there is not in every case a community of origin. Correspondence of this kind is included under the term "homoplasia." Another example is afforded by the heart of the mammal and that of the bird. In both of these groups the ventricular portion of the heart consists of a right and a left chamber, and yet the ventricular septum in the one is not homologous with the corresponding septum in the other, because the common ancestor from which both have sprung possessed a heart with a single ventricular cavity, and the double-chambered condition has been a subsequent and independent development in the two groups.

Systematic Anatomy.—The human body is composed of a combination of several systems of organs, and the several parts of each system not only present a certain similarity in structure, but also fulfil special functions. Thus we have—

1. The *skeletal system*, composed of the bones and certain cartilaginous and membranous parts associated with them, the knowledge of which is known as **osteology**.

2. The *articulatory system*, which includes the joints or articulations, the knowledge of which is termed **arthrology**.

3. The *muscular system*, comprising the muscles, the knowledge of which constitutes **myology**.

4. The *nervous system*, in which are included the brain, the spinal medulla, the ganglia of the spinal and cerebral nerves, the sympathetic ganglia, and the various nerves proceeding from and entering these. The knowledge of these parts is expressed by the term **neurology**. In this system the organs of sense may also be included.

5. The *blood vascular and lymphatic system*, including the heart, blood-vessels, the lymph vessels, and the lymph glands. **Angiology** is the term applied to the knowledge of this system.

6. The *respiratory system*, in which we place the lungs, windpipe, and larynx.

7. The *digestive system*, which consists of the alimentary canal and its associated glands, and parts such as the tongue, teeth, liver, pancreas, etc.

8. The *urogenital system*, composed of the urinary organs and the reproductive organs—the latter differing in the two sexes.

The term **splanchnology** denotes the knowledge of the organs included in the respiratory, digestive, and urogenital systems.

9. The *integumentary system* consists of the skin, nails, hair, etc. The knowledge of this system is termed **dermatology**.

These numerous organs which form the various systems are themselves built up of tissues, the ultimate elements of which can be studied only by the aid of the microscope. The knowledge of these elements and of the manner in which they are grouped together to form the various tissues of the body forms an important branch of anatomy, which is termed **histology**.

The structure of the human body may be studied in two different ways. The several parts may be considered with reference to their relative positions, either as they are met with in the course of an ordinary dissection, or as they are seen on the surface of a section through the body. This is the *topographical method*. On the other hand, the several systems of organs may be treated separately and in sequence. This constitutes the *systematic method*, and it is the plan which is adhered to in this treatise.

Descriptive Terms.—Anatomy is a descriptive science founded on observation, and in order that precision and accuracy may be attained it is necessary that we should be provided with a series of well-defined descriptive terms. It must

FIG. 1.—HORIZONTAL SECTION THROUGH THE TRUNK AT THE LEVEL OF THE FIRST LUMBAR VERTEBRA.

be clearly understood that all descriptions are framed on the supposition that the body is in the erect position, with the arms by the side, and the hands held so that the palms look forwards and the thumbs laterally. An imaginary plane of section, passing longitudinally through the body so as to divide it accurately into a right and a left half, is called the **median plane**, Fig. 1 (M.P.). When the right and left halves of the body are studied it will be found that both are to a large extent formed of similar parts. The right and left limbs are alike; the right and left halves of the brain are the same; there are a right and a left kidney and a right and a left lung, and so on. So far the organs are said to be **symmetrically** arranged. But still a large amount of **asymmetry** may be observed. Thus, the chief bulk of the liver lies to the right side of the median plane, and the spleen is an organ which belongs wholly to the left half of the body. Indeed, it is well to state that perfect symmetry never does exist. There always will be, and always must be, a certain want of balance between symmetrically placed parts of the body. Thus the right upper limb is, as a rule, constructed upon a heavier and more massive plan than the left, and even in those organs where the symmetry appears most

perfect, as for instance the brain and spinal medulla, it requires only a closer study to reveal many points of difference between the right and left halves.

The line on the front of the body along which the median plane reaches the surface is termed the **anterior median line**; whilst the corresponding line behind is called the **posterior median line**.

It is convenient to employ other terms to indicate other imaginary planes of section through the body. The term **sagittal**, therefore, is used to denote any plane which cuts through the body along a path which is parallel to the median plane (S S'); and the term **coronal** or **frontal** is given to any vertical plane which passes through the body in a path which cuts the median plane at right angles (C C'). The term **horizontal**, as applied to a plane of section, requires no explanation.

Any structure which lies nearer to the median plane than another is said to be **medial** to it; and any structure placed further from the median plane than another is said to lie **lateral** to it. Thus in Fig. 1, A is lateral to B; whilst B is medial to A.

The terms **internal** and **external** are applied to the walls of hollow cavities or organs; thus, the ribs possess external surfaces, that is, surfaces away from the cavity of the thorax, and internal surfaces adjacent to the cavity.

The terms **anterior** and **ventral** are synonymous, and are used to indicate a structure (D) which lies nearer to the front or ventral surface of the body than another structure (E) which is placed nearer to the back or dorsal surface of the body, and which is thus said to be **posterior** or **dorsal**. In some respects it would be well to discard the terms "anterior" and "posterior" in favour of "ventral" and "dorsal," seeing that the former are only applicable to man in the erect attitude, and cannot be applied to an animal in the prone or quadrupedal position. They are, however, so deeply ingrained into the descriptive language of the human anatomist that they cannot be entirely discarded. A similar objection may be raised to the terms **superior** and **inferior**, which are employed to indicate the relative levels at which two structures lie with reference to the upper and lower ends of the body. The equivalent terms of **cephalic** or **cranial** and **preaxial** are, therefore, sometimes used in place of "superior," and **caudal** and **postaxial** in place of "inferior."

The terms **proximal** and **distal** should be applied only in the description of the limbs. They denote relative nearness to or distance from the root of the limb. Thus, the hand is distal to the forearm, whilst the arm or brachium is proximal to the forearm.

HUMAN EMBRYOLOGY.

By A. H. YOUNG and ARTHUR ROBINSON.

Rewritten by ARTHUR ROBINSON.

THE ontogenetic or developmental history of every human individual is separable into two main periods, **pre-natal** and **post-natal**.

It is to the knowledge of the phenomena of the earlier or pre-natal period that the term **human embryology** is applied, and as pre-natal development takes place in an organ called the uterus, it is frequently spoken of as *intra-uterine development*.

The period of pre-natal development extends through nine lunar months, and may be divided into three sub-periods: (1) the **pre-embryonic period**, during which the zygote, from which the embryo is formed, shows no definite separation into embryonic and non-embryonic portions. This period lasts about fourteen days; (2) the **period of the embryo**, in which the zygote is definitely separated into embryonic and non-embryonic portions, but the embryonic part has not yet assumed a clearly human form. This period terminates at the end of the second month; (3) the **fœtal period**, which commences at the end of the second month, when the embryo assumes a definitely human form and is called, thenceforth, a **fœtus**. The fœtal period ends at birth, when the fœtus becomes a child and *post-natal development* commences.

Only the general phenomena of the pre-natal period of development are considered in this section; the details of the pre- and post-natal development of the various organs and systems will be dealt with in the sections devoted to the descriptions of their adult conditions.

THE STRUCTURE OF ANIMAL CELLS.

The human body is formed by the multiplication and differentiation of animal cells, therefore it is essential that the student should possess a knowledge of the main features and capabilities of such cells before he commences the study of the details of human embryology.

Animal cells differ from each other in minor points of structure, in association with the positions they occupy and the functions they perform; nevertheless, they all possess some common and essential structural features, and, in the younger stages of their history, some common capabilities.

The following are the constituent parts of a typical animal cell:—

The **cell body**:—containing

(a) The nucleus ;	(d) The centrioles ;
(b) The nucleolus ;	(e) The mitochondria .
(c) The centrosome ;	

All the essential parts of the cell consist of a substance called **protoplasm**.

In its simplest form protoplasm is the semifluid, viscous, irritable, and con-

FIG. 2.—DIAGRAM OF AN ANIMAL CELL.

tractile substance which forms the "physical basis of life." It consists of C, H, N, O, and S, combined together in different ways and in differing proportions to form various modifications of protoplasm which possess definite physical and chemical characteristics, and receive, therefore, different names.

The **cell body** consists of a kind of protoplasm called cytoplasm, separable into two parts; the **spongioplasm** or **cyto-reticulum**, which forms a network or sponge-work; and a more fluid part, the **hyaloplasm** or **cytolymph**, which occupies the interstices of the reticulum.

The **nucleus** lies in the cytoplasm. It consists of a form of protoplasm, called **karyoplasm**, which is separable into a more fibrillar part, the **karyo-reticulum**, and a more fluid part, the **karyo-lymph** or **nuclear juice**. The reticulum also consists of two parts, the **achromatic** or non-stainable part formed of a substance called **linin**, and a part called **chromatin**, which is readily stainable.

Chromatin varies in appearance at various stages of the cell life. During the resting periods, which intervene between the periods of cell division, it is broken up into small particles which either are embedded in or are in close association with the linin network.

When cell division commences the chromatin particles are aggregated to form a thread-like strand, which ultimately breaks up into a number of segments called **chromosomes**. The chromosomes are always of definite number in the body cells of any given species of animal. In the human subject the typical number is probably 24.

According to Winiwarter's recent observations the number of chromosomes in each oocyte I (see p. 12) is 48, and in each spermatocyte I (see p. 12) it is 47. Each mature ovum (see p. 13), therefore, has 24 chromosomes, but some spermatids (see p. 17) have 24 and others 23. If a spermatozoon (see p. 17) with 24 chromosomes unites with a mature ovum a female results, but if a spermatozoon with 23 chromosomes unites with a mature ovum a male results.

During the resting period the nucleus is bounded by a distinct **nuclear membrane**, which is continuous on the one hand with the karyo-reticulum, and on the other with the cyto-reticulum.

The **nucleolus** is a spherical vesicle which lies in the karyo-lymph during the resting periods of the cell. It disappears entirely during the periods of division. The protoplasm of which it is formed is called pyrenin. In some cases several nucleoli are present.

The nodes of the karyo-reticulum are sometimes called false nucleoli.

The **centrosome** is a clear spherical area of the cytoplasm which lies usually in the neighbourhood of the nucleus. Around it the granules of the cytoplasm are arranged in radial lines, and in its interior lie one or two minute, deeply staining bodies, the **centrioles**. The centrosome appears to play a very important part in cell multiplication; and, in the more ordinary form of cell division, it divides before the division of the cell takes place, but in certain cases it disappears before the cell divides.

The **mitochondria** are minute particles. They are demonstrable in the majority of cells by means of certain stains, after special methods of fixation and preservation have been used. They are believed to play an important part in the economy and life-history of the cells, and they form a very definite part of the structure of the spermatozoon or male gamete.

THE LIFE-HISTORY AND CAPABILITIES OF ANIMAL CELLS.

Every animal cell is formed by the division of a pre-existing cell called the *mother cell*. The mother cell divides into two equal parts—the *daughter cells*, each of which, under ordinary conditions, possesses all the capabilities of its mother.

Reproduction of Cells.—Ordinary tissue cells increase in number by the division of the pre-existing cells into equal parts, each of which possesses similar capabilities. Every new cell has a definite life-history; it grows, performs its proper function, and ceases to exist, either by dividing into two daughter cells, or by dying and breaking up into fragments which disappear.

Whilst the multiplication rate exceeds the death-rate in any given tissue or organ, that tissue or organ grows. When the multiplication rate and the death-

rate are equal, the tissue or organ is in a state of equilibrium. As soon as the death-rate exceeds the multiplication rate, decay and atrophy set in; and when the decay and atrophy have proceeded to such an extent that an important tissue or organ can no longer perform its proper functions, general death ensues.

General decay and death are, therefore, the natural results of the loss of multiplication power of the cells of the body, but life may persist after multiplication power is lost, so long as the cells last produced retain their capabilities, and death may result whilst multiplication power of the cells is retained, if the newly produced cells are incapable of performing their proper functions. Nevertheless, speaking generally, it may be said that cell multiplication is a vital necessity, and it takes place in two ways—(1) by **amitotic** and (2) by **mitotic division** of pre-existing cells.

Amitotic Division.—The phenomena of amitotic division, so far as they are known, are much simpler than those of mitotic division. First the nucleus is constricted and divided; then the cell body is constricted and divided, and two similar daughter cells, each half the size of the mother cell, are produced. The part played by the centrosome during the process is not definitely known, but each daughter cell eventually possesses a centrosome. The apparently simple process of amitotic division occurs at some periods of growth, and the more complicated process of mitotic division at other periods, but the laws which govern the alternations are unknown.

Mitotic Division; Mitosis, or Karyokinesis.—Mitotic or karyokinetic division is not only the more complicated, but it appears also to be the more important form of cell division. It takes place in all rapidly growing tissues, especially in the embryonic and foetal stages of life, and it is the main form of cell division which occurs in the earliest embryonic periods. There are, however, two forms of mitosis, the homotype and the heterotype. Of the two, homotype is so much the more common that it may be looked upon as the ordinary form, for heterotype mitosis appears to be limited to one of the two cell divisions which occur during the maturation of the germ cells, and to some of the cell divisions which are associated with the production of malignant tumours.

Homotype Mitosis.—The phenomena of homotype mitosis occur in four phases, (1) the *prophase*, (2) the *metaphase*, (3) the *anaphase*, and (4) the *telophase*.

The Prophase.—During the prophase both the centrosome and the nucleus undergo very obvious transformations.

The centrosome and its contained centriole divide into two parts, of which one passes to one pole and the other to the opposite pole of the nucleus.

The nuclear transformations concern the nucleolus, the chromatic substance, and the nucleolar membrane.

The nucleolus disappears. In some cases it passes from the nucleus into the cytoplasm, where it breaks up; in other cases the details of its disappearance are entirely unknown.

FIG. 3.—SCHEMA OF ANIMAL CELL IN RESTING STAGE.

FIG. 4.—SCHEMA OF ANIMAL CELL IN EARLY PART OF PROPHASE OF HOMOTYPE MITOSIS.

FIG. 5.—SCHEMA OF ANIMAL CELL AT COMPLETION OF PROPHASE OF HOMOTYPE MITOSIS.

The chromatic substance is aggregated to form first a fine and afterwards a thicker thread or spirem. At the same time, a spindle of achromatic fibrils appears between the two daughter centrosomes, and the nuclear membrane disappears.

As soon as the **achromatic spindle** is definitely established the chromatic thread breaks up into a number of segments, the chromosomes, which arrange themselves around the equator of the achromatic spindle.

The **chromosomes** may be V-shaped, rod-like, cuboidal or spheroidal, and each may be a single structure, or it may consist of two or four parts which are closely bound together. There is evidence which tends to support the belief that, whether the chromosome appears to consist of one, two, or more segments, its constituent particles are derived partly from the maternal and partly from the paternal ancestor of the cell; and it is believed that the maternal and paternal portions undergo similar division during the last three phases of mitosis. In any case, whether the chromosomes are single or compound structures, each becomes associated with, or very closely associated with, one of the fibrils of the achromatic spindle.

FIG. 6.—SCHEMA OF ANIMAL CELL IN METAPHASE OF HOMOTYPE MITOSIS.

FIG. 7.—SCHEMA OF ANIMAL CELL AT END OF ANAPHASE OF HOMOTYPE MITOSIS.

FIG. 8.—SCHEMA OF ANIMAL CELL AT END OF TELOPHASE OF HOMOTYPE MITOSIS. The cell has divided into two daughter cells. Red and blue indicate the original paternal and maternal derivatives.

typical number of chromosomes, and a portion of the achromatic spindle.

The Resting Stage.—During the resting stage, which lasts for a variable period, a nucleus is formed in each daughter cell by the appearance of a nuclear membrane around the chromosomes, as they repass first to the thread-like and then to the granular form of chromatic substance, and by the reappearance of a nucleolus. The cell increases in size also.

The Period of Cell Life.—The period of cell life varies, but in all cases it ultimately ends in death; for a time comes when cells no longer transmit to their

At the end of the prophase the nucleus as such, and the nucleolus, have entirely disappeared, and the cell body contains in their place two centrosomes, an achromatic spindle, and the chromosomes. The centrosomes lie at the opposite poles of the achromatic spindle with the granules of the protoplasm grouped radially around them, and the chromosomes are grouped round the equator of the achromatic spindle.

The Metaphase.—During the metaphase each chromosome divides into two equal parts, the rods or loops dividing longitudinally; and the division, in all cases, commences at the point where the chromosome is in relation with the fibrils of the achromatic spindle.

The Anaphase.—In the anaphase the halves of the chromosomes, *i.e.* daughter chromosomes, move towards the opposite poles of the achromatic spindle, and when they reach the vicinity of the daughter centrosomes the anaphase ends and the telophase begins.

The Telophase.—At the end of the anaphase, or the commencement of the telophase, a constriction appears around the periphery of the cell, at the level of the equator of the achromatic spindle. After its appearance the constriction gradually deepens until the cell is completely divided into two halves, the daughter cells, each of which contains the

descendants the power of division, or the capability of growth and function. If it were not so, growth and function, or at least maintenance and function, would continue uninterruptedly, and in the absence of accident or disease individual life would continue for ever, and "old age" would be unknown.

It appears, therefore, that the ancestors of certain tissue cells are capable of producing only a certain number of descendants, which grow to the normal size and perform their proper functions for a more or less fixed period, whilst in other cases the power of division appears to be transmitted continuously, but the more remote descendants become less and less capable of performing their proper functions. The result in both cases is the same; gradual decay, terminating in death.

Heterotype Mitosis.—In ordinary or homotype mitosis the chromosomes are divided into equal parts, and, when the process of cell division is completed, each daughter cell possesses the same number and same kind of chromosomes as the mother cell from which it was derived (Figs. 3-8). In heterotype mitosis, the number of chromosomes is reduced during the cell division, and each daughter cell possesses only half the number of chromosomes that was present in the mother cell.

The details of the division of the chromosomes during heterotype mitosis differ in different groups of animals, but the end is the same in all cells in which the process occurs, and is the reduction of the number of the chromosomes in the daughter cells to half the number typical for the ordinary cells of the animal.

The most typical form of heterotype mitosis is seen during the first maturation division of many germ cells, in which, during the spirem or thread-like stage of the chromatic substance, careful examination of the thread shows that it consists of a number of alternate segments attached end to end, the number of segments corresponding with the number of the chromosomes typical for the ordinary cells of the animal. Towards the end of the prophase, the segments of the thread become attached together in pairs which form a number of twin chromosomes. These arrange themselves around the equator of the achromatic spindle, and it is obvious that the number of twin chromosomes is only half the number of the chromosomes originally present in the cell (Figs. 12 and 13).

The total number of chromatic segments is still the same, for each twin chromosome consists of two ordinary chromosomes attached side to side.

The process of reduction takes place during the metaphase, when the two segments of each twin chromosome become separated from each other. During the anaphase the separated segments pass to the opposite poles of the achromatic spindle, and when the telophase is completed the number of chromosomes in each daughter cell is half that which was present in the mother cell (Figs. 12-19).

In some cases, at the commencement of heterotype mitosis, the chromosomes are not arranged in pairs as twins, but in groups of four, called **tetrads**, each tetrad consisting of a pair of **dyads**. In these cases the two dyads of each tetrad are separated from each other during the metaphase, and when the telophase is completed each daughter cell possesses only half the number of chromatic particles which were present in the mother cell.

It is known that a cell which contains only half the typical number of chromosomes can divide once, therefore from each original cell which underwent heterotype mitosis four granddaughter cells may be produced. It is still uncertain, however, whether or not cells which contain only half the typical number of chromosomes can further subdivide, or whether they can continue to live and function. So far as the observations made can be relied upon, it appears that such cells either die or they unite with another cell containing half the typical number of chromosomes to produce a new cell which contains the typical number of chromosomes and which possesses also the capability of reproducing itself by division.

The Gametes.—The gametes are the germ elements by whose union, in pairs, new individuals are produced.

They are of two kinds, female gametes or **ova** and male gametes or **spermatozoa**. Both female and male gametes are modified cells, by means of which hereditary characteristics are transmitted from generation to generation, and they are derived from cells called **primitive germ cells**, whose origin will be considered in association with the development of the germinal layers.

The germ cells reach their full development in special sex glands, the ova in the **ovaries** of the female and the spermatozoa in the **testes** of the male.
 After the descendants of the primitive germ cells have increased, by ordinary

FIG. 9.—SCHEMA OF THE DEVELOPMENTAL HISTORY OF THE MATURE OVUM.

FIG. 10.—SCHEMA OF THE DEVELOPMENTAL HISTORY OF SPERMATOZOA.

cell division, to a number which is probably fixed and unchangeable, but which is not definitely known, they begin to increase in size, that is, they enter upon a period of growth, and at this time the female germ cells are called **oocytes of the first order**, oocytes I, and the male germ cells are called **spermatocytes of the first order**, spermatocytes I. Both the oocytes I and the spermatocytes I possess all the essential

parts of a typical animal cell, and, in addition, each has special peculiarities which differentiate it both from the germ-cells of the opposite sex and also from ordinary animal cells. Therefore the oocyte and the spermatocyte must be considered separately; but before this is done it must be noted that each oocyte I and each spermatocyte I is capable of producing only four descendants. The mitotic cell divisions by which the descendants are produced are called the **maturation divisions**, and they result, in the case of the oocyte, in the formation of one large functional cell—the **mature ovum**, and three small impotent cells—the **polar bodies**; whilst in the case of the spermatocyte the four descendants are of equal size and each becomes transformed into a potent **spermatozoon**.

THE OVUM.

An ovum presents all the characteristic structural features of an animal cell, but it is peculiar on account of its relatively large size, the large size of its nucleus, and the possession of an investing membrane, the **oolemma**. As the young ova or oocytes of the first order enter upon their period of growth, each is enclosed by a single layer of special cells, the **stratum granulosum**, which constitute, together with the oocyte, a **primary ovarian follicle** (O.T. **Graafian follicle**). The cells of the **stratum granulosum** multiply rapidly until they form a layer, several cells thick. At the same time, the oocyte increases in size and becomes surrounded by the membrane, called the **oolemma**, which intervenes between it and the innermost cells of the **stratum granulosum**.

Whilst the growth of the oocyte and the thickening of the oolemma are still proceeding, a fluid-filled cavity appears in the **stratum granulosum**. Whether the cavity is due to the imbibition of fluid or to the dehiscence of the cells of the **stratum granulosum** is still uncertain, but, after its appearance, the cavity with its surrounding walls and the enclosed oocyte is spoken of as a **vesicular ovarian follicle**. The cavity of the vesicular follicle gradually increases, and, as it grows, it separates the oocyte and the cells of the **stratum granulosum** immediately around the oocyte from the remainder of the cells of the **stratum**, except in a small area where the two parts of the **stratum granulosum** still remain in direct continuity. When this condition is attained the cells of the **stratum granulosum** which immediately surround the oolemma are spoken of as the **ovular cumulus**; they enclose the oocyte, and, together with it, they form a bold promontory which projects into the cavity of the follicle.

When its full growth is attained each oocyte I is a comparatively large cell, which measures 200μ in diameter. It consists of a cell body which is surrounded by a definite enclosing membrane, the oolemma, and it contains (1) a nucleus, (2) a centrosome, (3) numerous granules called deutoplasmic or yolk granules, and (4) mitochondria.

The Oolemma.—The limiting membrane or oolemma is also called the *zona pellucida*, on account of its appearance under low magnifying powers, and the *zona striata*, because it is pierced by numerous radial canals which are visible when highly magnified. It is a strong, elastic membrane, which not only protects the oocyte from pressure, but probably also prevents the **impregnated oocyte** or **zygote**

FIG. 11.—THE OVUM AND ITS COVERINGS (Diagrammatic).

from coming into close contact with the maternal tissues until it has attained the proper stage of development.

The exact origin of the oolemma is unknown. It must be formed either by the action of the cells of the stratum granulosum, or by the action of the oocyte, or by interaction between the two; but, up to the present, opinions regarding the origin are divided.

FIG. 12.—SCHEMA OF MATURATION OF OVUM, EARLY PART OF PROPHASE OF FIRST DIVISION.

FIG. 13.—SCHEMA OF MATURATION OF OVUM IN PROPHASE OF FIRST DIVISION. The chromatic thread has divided into twin chromosomes. Each twin may be assumed to consist of a maternal and a paternal part.

FIG. 14.—SCHEMA OF MATURATION OF OVUM AT END OF PROPHASE OF FIRST DIVISION. The twin chromosomes lie at the equator of the achromatic spindle.

(1) an achromatic reticulum, the *linin*; (2) *chromatic substance*, which is embedded in or closely connected with the strands of the *linin*; and (3) the *nuclear juice*, which fills the meshes of the reticulum; and it contains usually one, but sometimes several nucleoli.

The Centrosome.—The centrosome is not always very evident. It is usually present during the growth stage of the oocyte, and it disappears when the first maturation division commences. It may contain one or two centrioles, and it

It is stated that processes of the cells of the ovular cumulus pass through the radial canals of the oolemma and become continuous with or lie in close association with the protoplasm of the oocyte; and it is probable either that the processes are used as pabulum by the growing oocyte, or that they transmit nutritive material to the oocyte.

The Body of the Ovum.—The cell body, originally called the *yolk*, consists of spongio-plasm and hyaloplasm.

The Deutoplasm.—The deutoplasm consists of a number of more or less highly refractile granules, of varying size, which are embedded in the cytoplasm. They are largest in size and are most closely aggregated together in the region around the nucleus, where they form a definite deutoplasmic zone. But in the human ovum and in the ova of the majority of mammals, as contrasted with the ova of birds, reptiles, and amphibia, the amount of deutoplasm is relatively small; and for this reason the human ovum is classified as *oligolecithal*, the term *telolecithal* being applied to ova in which the deutoplasm is present in considerable amount, as in the ova of the frog; whilst the ova of birds, many reptiles, and the monotremes amongst mammals, in which the deutoplasm greatly preponderates over the cell protoplasm, are termed *eutelolecithal*.

The deutoplasmic granules are believed to serve as a store of nutritive material which is utilised during the early stage of the growth of the zygote, during which they disappear.

The Nucleus.—The nucleus, formerly called the *germinal vesicle*, is a spherical vesicle of comparatively large size; its diameter, which measures 50μ , being one-fourth of the diameter of the oocyte. It usually lies excentrically in the cytoplasm.

Its constituent parts are a *nuclear membrane*, surrounding the *karyoplasm*, which is separable, as in ordinary animal cells, into

lies in the region of the larger deutoplasmic granules by which its presence is frequently obscured.

The Mitochondria.—These minute particles can be demonstrated by suitable methods of fixation and staining.

The Maturation of the Ovum.—The process of maturation consists of two mitotic divisions, of which the first is heterotypical, and results in the reduction of the number of chromosomes, and the second is homotypical. The phenomena of the two divisions differ in some of their details from those of ordinary cell divisions, therefore a short account of them is necessary.

In the prophase of the **first maturation division**, the centrosome, the nucleolus, and the nucleus vanish, and an achromatic spindle appears at one pole of the oocyte, where it lies, at first, parallel with the surface; and the chromosomes are gathered around its equator. The number of the chromosomes is only half the typical number, and they are probably twin chromosomes (p. 11). There are no centrosomes at the poles of the spindle. After a short time the spindle rotates until it lies at right angles to its original position, and one pole, surrounded by a small amount of the cytoplasm, forms a projection, the **first polar projection**, on the surface of the oocyte (Fig. 14).

During the metaphase the twin chromosomes divide. In the anaphase the daughter chromosomes travel to the opposite poles of the spindle, and at the end of the anaphase one-half of the daughter chromosomes lies in the first polar projection and the other half in the body of the oocyte (Fig. 16).

In the telophase the first polar projection is separated from the body of the oocyte and oocyte I ceases to exist, being converted into an **oocyte of the second order**, or oocyte II, and the **first polar body**, each of which contains half the typical number of chromosomes.

The **second maturation division** occurs without the intervention of a resting stage, *i.e.* without the reappearance of a nucleus in oocyte II. A new achromatic spindle appears with the daughter chromosomes at its equator; it rotates, and one pole, surrounded by a small amount of cytoplasm, projects on the surface of the oocyte as the **second polar projection** (Fig. 17). In the metaphase the daughter chromosomes divide homotypically into equal parts, and during the anaphase the grand-daughter chromosomes move towards the poles of the spindle, one-half entering the second polar projection and the other half remaining in the body of the oocyte. During the telophase the second polar projection is separated as the **second polar body** and the larger remaining part of the oocyte II becomes the **mature ovum** (Figs. 17 and 18).

FIG. 15.—SCHEMA OF MATURATION OF OVUM IN METAPHASE OF FIRST DIVISION. One pole of the spindle projects into the first polar bud, and the maternal and paternal parts of the chromosomes are separating from each other.

FIG. 16.—SCHEMA OF MATURATION OF OVUM AT END OF THE ANAPHASE OF THE FIRST DIVISION. Two chromosomes (paternal or maternal) lie in the first polar bud and two in the larger part of the ovum which becomes oocyte II.

FIG. 17.—SCHEMA OF MATURATION OF OVUM AT THE COMMENCEMENT OF THE METAPHASE OF THE SECOND DIVISION.

Simultaneously with the division of the oocyte II into the second polar body and the mature ovum, the first polar body may divide into two parts. When this occurs four cells are present within the oolemma at the end of the maturation, *i.e.* the relatively large mature ovum and the three polar bodies (Fig. 19).

The details of the maturation of the human ovum are unknown, and the above account is based upon the phenomena which occur in other mammals. In some animals only one polar body is formed, and in others the first does not divide into two parts simultaneously with the formation of the second. The significance of these differences is not at present fully understood.

Each of the four descendants of the oocyte I contains half the typical number of chromosomes, and those in the mature ovum soon become enclosed in a new-formed nucleus, which is called the **female pronucleus**.

When the process of maturation is completed, the mature ovum differs from a typical animal cell, inasmuch as it possesses no centrosome and its nucleus contains the chromatic substance of only half the typical number of chromosomes.

The first maturation division usually occurs whilst the oocyte is still in the ovary and before the spermatozoon has entered it. The second division takes place in the upper part of the uterine tube, and frequently after the spermatozoon has entered the oocyte.

If the mature ovum does not meet with a spermatozoon it passes through the genital passages and is cast off and lost; or it breaks down, whilst still in the genital passages, into a detritus which disappears; but if it meets and unites with a spermatozoon a **zygote** is formed, from which a new individual may arise, and in that case the polar bodies persist until the zygote has undergone one or two divisions; but sooner or later they disappear, probably breaking down into fragments which are absorbed by the cells of the zygote.

Spermatocytes.—When the male germ cells reach the period of growth they are called **spermatocytes of the first order**, or spermatocytes I, which correspond, morphologically, with oocytes I (Fig. 10).

The spermatocytes lie in the walls of the tubules of the testes or male sex glands, where their descendants become converted into spermatozoa.

They differ from the oocytes I in three important respects: (1) they have no protective membrane corresponding with the oolemma of the oocyte; (2) they are not enclosed in follicles; (3) the spermatocytes are not surrounded by definite encircling layers of cells similar to the cells of the stratum granulosum.

As the spermatocytes lie in the walls of the tubules of the testes they are intermingled with other cells, the supporting and nurse cells, amidst which they undergo their maturation divisions, and their descendants become embedded in the nurse cells, where they are converted into spermatozoa. To a certain extent, therefore, the nurse cells may be looked upon as corresponding with the cells of the ovular cumulus which surround the growing oocyte.

After it has reached its full growth each spermatocyte I, like each oocyte I, can produce only four descendants, and the descendants, as in the case of the oocyte I,

FIG. 18.—SCHEMA OF MATURATION OF OVUM AT END OF ANAPHASE OF SECOND DIVISION. The chromosomes of oocyte II have separated into equal parts which have passed to the opposite poles of the spindle.

FIG. 19.—SCHEMA OF MATURATION OF OVUM. END OF TELOPHASE OF SECOND DIVISION where the four descendants of oocyte I are the mature ovum, with half the original number of chromosomes, and three polar bodies.

are formed by two successive mitotic divisions, of which the first is heterotypical and produces reduction of the chromosomes, and the second is homotypical.

The two divisions differ from the corresponding divisions of the oocytes in three important respects: (1) centrosomes are present; (2) the four grand-daughter cells produced are of equal size and presumably of equal value, so far as capability of uniting with a mature ovum to form a zygote is concerned; (3) each of the four grand-daughter cells possesses two centrosomes.

In the prophase of the first or heterotype division the nucleus and nucleolus disappear in the ordinary way. The centrosome divides, and an achromatic spindle appears, which has the daughter centrosomes at its poles and half the typical number of chromosomes at its equator. The chromosomes are twin chromosomes. During the metaphase the two segments of each twin chromosome separate from each other. In the anaphase they travel to the opposite poles of the achromatic spindle, and consequently, when the cell divides in the telophase, each daughter cell or **spermatocyte II** contains a centrosome and half the typical number of chromosomes.

The second maturation division, which takes place without the intervention of a resting stage, is of the homotype form. The centrosome divides, a new achromatic spindle appears, and the daughter chromosomes gather at its equator. In the metaphase the chromosomes divide into equal parts, which travel to the opposite poles of the spindle during the anaphase, and when the telophase is completed the granddaughter cells, which are called **spermatids**, possess a centrosome and half the typical number of chromosomes. In the resting stage which follows, the chromatic particles become enclosed in a new-formed nucleus, and the centrosome, if it has not already divided, separates into two parts, one which lies nearer the nucleus and is called the *anterior centrosome*, and another, farther from the nucleus, termed the *posterior centrosome* (Fig. 22). Numerous mitochondria are present, and an indefinite structure, called the accessory body, is also found in the cell protoplasm. A spermatid, therefore, differs from a typical animal cell not only because it possesses the chromatic substance of only half the typical number of chromosomes, but also because it possesses an accessory body and two centrosomes.

From Spermatid to Spermatozoon.—The reader will have noted that the female gametes become mature and ready for conjugation with male gametes directly after the second maturation division is completed. In the case of the male germ cells, however, the spermatids which result from the second maturation division have still to undergo a complicated process of transformation before they become converted to spermatozoa or mature male gametes. The process of transformation takes place in association with the nurse cells in which the developing spermatozoa become embedded.

The details of the process of transformation are difficult to follow, and the knowledge regarding them is still to some extent indefinite. Certain points, however, are well established; but before they are considered it is necessary that the reader should be acquainted with the anatomy of an adult spermatozoon.

THE SPERMATOZOON.

A spermatozoon is a minute organism consisting of a head, a neck, a body, a tail, and an end-piece. Its total length is about 50μ , that is, its length is about the same as the diameter of the nucleus of the ovum.

The **head** has the form of a laterally compressed ovoid. It is separable into anterior and posterior portions, and the anterior portion is more or less completely covered by a head-cap, which culminates in a sharp ridge. The length of the head is about 4.5μ .

The **neck** is an extremely short constricted region which intervenes between the head and the body. At its anterior end, where it joins the head, there is a deeply staining **anterior centrosome**, and at its posterior end a similarly deep-staining **posterior centrosome**, from which a deep-staining **axial filament** extends posteriorly through the body and tail into the end-piece (Fig. 21).

The Body.—The body is a little longer than the head, and its constituent parts are: (1) a portion of the axial filament; (2) a portion of the axial sheath; (3) the spiral sheath; (4) the mitochondrial sheath; (5) the end-ring.

The **axial sheath** is a thin layer of protoplasm immediately surrounding the **axial filament**.

The **spiral sheath** consists of a **spiral fibril** embedded in indifferent protoplasm, and the **mitochondrial sheath**, which surrounds the spiral sheath, is formed by protoplasm containing numerous mitochondria.

The **end-ring** closes the posterior ends of the spiral and mitochondrial sheaths, and it is perforated by the axial filament and its sheath as they pass from the body into the tail.

FIG. 20.—HUMAN SPERMATOOA (after Retzius).

A, Side view; B, Front view.

The **tail** is 28-29 μ long. It consists of prolongations of the axial filament and its sheath, and it ends in the short thin *end-piece*.

The Transformation of the Spermatid into the Spermatozoon.—As the transformation progresses the nucleus of the spermatid becomes the head of the spermatozoon. The axial filament grows out from the posterior centrosome of the spermatid, which divides into two parts, one of which becomes the posterior centrosome of the neck of the spermatozoon, whilst the other becomes the end-ring of the body of the spermatozoon.

The anterior centrosome of the spermatid becomes

FIG. 22.—SCHEMA OF TRANSFORMATION OF SPERMATID INTO SPERMATOOA (after Meeves, modified).

FIG. 21.—STRUCTURE OF A HUMAN SPERMATOOA (after Meeves).

the anterior centrosome of the neck of the spermatozoon. The cytoplasm of the spermatid forms the axial sheath, the indifferent protoplasm of the spiral sheath and mitochondrial sheath. The origin of the spiral filament and the origin of the head-cap are uncertain, but it is stated that, in some animals, the head-cap is formed from the accessory body, which is not shown in Fig. 22.

The Object of the Reduction of the Chromosomes.—The most striking phenomenon of the process of the maturation of the gametes is the reduction of the chromosomes. The constancy of the reduction tends to emphasise its importance, but, as we have no definite knowledge of the functions of the chromatic substance, the object of the reduction

can only be surmised. The evidence which has been accumulated tends to the

conclusion that the particles of the chromatic substance are the bearers of hereditary tendencies and capabilities.¹ If this is the case, then they are the means by which ancestral possessions, in the morphological sense, are transmitted from generation to generation. There is evidence also, first ascertained by Mendel and substantiated and increased in recent years by his followers, which lends probability to the belief that the tendency carriers form two main groups: (1) those which carry certain tendencies; (2) those which carry opposite tendencies. The bearers of tendencies and the bearers of their opposites are allelomorphic or alternative to each other, and are called allelomorphs. Thus the particles which bear tallness and dwarfness respectively are allelomorphs, that is, they are alternative to each other.

Further, the facts which are known suggest the idea that in the primitive germ cells, and their descendants which contain the typical number of chromosomes, the character-bearing particles are arranged in pairs of which both elements may bear the same tendencies, or one may bear one tendency and the other the opposite.

For example, if red and blue be supposed to be opposite tendencies carried by different particles or allelomorphs, then the germ cells of any given animal, male or female, may contain either a pair of red-bearing particles, a pair of blue-bearing particles, or a red and a blue bearing particle associated together as a pair.

The reduction of the chromosomes during the maturation divisions of the germ cells is an admitted fact, and it is believed that the reduction is a necessary preliminary to the union of a male and a female gamete to form a zygote from which a new individual may arise. It is assumed that the purpose of the reduction is the segregation of the different tendency bearers from each other in order that they may enter into new combinations. If this assumption is correct, then every mature germ element or gamete contains only one element of any given pair of tendency bearers, in the supposititious case under consideration, either the red or the blue bearer, but not both; and the object of the reducing division is the segregation of the allelomorphs in order that they may enter into new and possibly into different combinations, producing new and possibly varied results.

If, in the case of any given group of animals, the mature germ cells of some of both sexes contain the blue-bearing particles and others the red-bearing particles, it necessarily follows that three possible results may ensue when impregnation occurs, that is when two mature germ cells unite to form a zygote.

(1) A female gamete bearing red tendency particles may fuse with a male gamete bearing red tendency particles; (2) a female gamete bearing blue tendency particles may meet and fuse with a male gamete bearing blue tendency particles; (3) a female gamete bearing red tendency particles may meet and fuse with a male gamete bearing blue tendency particles. The constitution of the zygotes formed may be stated as follows:—

RR BB RB,

and the character of the individual developed from the zygote will vary according to the combination. If two red tendency bearing gametes meet, the individual will be red; if two blue tendency bearing gametes meet, the individual produced will be blue; but when a gamete bearing red tendency particles unites with a gamete bearing blue tendency particles the individual will be either red or blue or a combination of the two, the result depending upon the relative potency or dominance of the two tendencies.

Further exposition of this interesting subject would be out of place in a text-book of anatomy, but it is of such great importance in association with the transmission of hereditary characteristics and hereditary diseases that every medical student should make himself familiar with its possibilities by consulting the works of Bateson, Punnett, and other writers and observers who are attempting to solve the complicated problems which it presents.

¹ It must be understood that this function, if it exists, does not prevent the chromatic particles possessing other functions, and that there is no evidence that the potency of a tendency depends upon amount of chromatic substance.

FERTILISATION.

Fertilisation is the term applied to the union of the male with the female gamete to form a zygote which contains the typical number of chromosomes (Fig. 23).

The meeting of the gametes and their union take place, normally, in the upper part of the uterine tube.

The details of the process are unknown in the case of the human subject, but in many animals it has been noted that as the spermatozoon approaches the ovum the latter shows signs of excitement, and a small prominence, called the **cone of attraction**, appears on its surface. At the same time its pronucleus undergoes changes of form. As the two gametes meet the spermatozoon pierces the oolemma which surrounds the ovum and passes through the cone of attraction into the body of the ovum.

In some cases apparently only the head, neck, and body of the spermatozoon effect an entrance, but in others the whole spermatozoon enters the body of the ovum.

If the entrance occurs before the second polar body is formed, the parts of the

FIG. 23.—SCHEMA OF THE FERTILISATION OF THE MATURE OVUM AND THE FORMATION OF THE ZYGOTE.

spermatozoon which have entered remain quiescent till that event has occurred, then they disappear and are replaced by a nucleus which contains half the typical number of chromosomes and is accompanied by two centrosomes. At this period the impregnated ovum contains two pronuclei, both of which contain half the typical number of chromosomes; but the female pronucleus has no accompanying centrosomes.

Shortly after the appearance of the male pronucleus the two pronuclei unite and then the **zygote**, formed by the union of the male and female gametes, consists of a cell body enclosing a nucleus called the **first segmentation nucleus**; and two centrosomes.

The first segmentation nucleus is the product of the union of the male and the female pronuclei. It contains the typical number of chromosomes, half being derived from the male and half from the female gamete; and it is accompanied by two centrosomes, both of which appear to be derived from the male gamete, though their exact origin has not yet been definitely established. The zygote and the polar bodies which are still present are enclosed within the oolemma.

SEGMENTATION.

Immediately after its formation the zygote is separated, by a series of consecutive mitotic divisions, into a large number of cells which are grouped together in the form of a solid spherical mass, called a **morula** on account of the mulberry-like appearance of its surface. This period of division is called the period of segmentation (Figs. 24-27).

The segmentation divisions are of the homotype form, and there is evidence which tends to the conclusion that the earliest divisions, by which the zygote is divided first into two and then into four parts, are quantitatively and qualitatively equal. After a time, however, the divisions result in the formation of cells of different sizes and different capabilities, definite and circumscribed functions being allocated to certain groups of cells and their descendants. It is probable that at this time cells are set apart which are the progenitors of the germ cells of the next generation, and which therefore retain all the capabilities of their ancestors. These cells are the means by which the species is reproduced and the hereditary tendencies are transmitted from generation to generation. At the same time other cells are set apart for the production of the tissues and organs of the individual which will be produced from the zygote, and in which the germ cells and their descendants will be lodged and protected till they attain their maturity.

After the morula is established one of the first definite changes which occurs in its constitution is the differentiation of its cells into an outer layer and an inner mass (Fig. 26).

In the human subject, as in many other mammals, the cells of the outer layer constitute the **trophoblast** or trophoblastic ectoderm, which plays a most important part in the nutrition of the embryo and fetus. They enter into the formation of the **chorion**, or outermost envelope of the growing zygote, which is subsequently differentiated into a placental and a non-placental portion and which serves, in the first instance, both as a protective and a nutritive covering.

In many mammals the cells of the inner mass soon separate into two main groups, the ecto-mesoderm and the entoderm; but it appears probable that, in the human subject, they differentiate into three groups, **ecto-mesoderm**, **primary mesoderm**, and **entoderm**.

In the majority of mammals, immediately before or as the differentiation of the inner mass occurs, a cavity appears in the zygote. As soon as the cavity appears the morula is converted into a **blastula** and the cavity enlarges until it separates the inner mass from the outer layer, except at one pole of the zygote, where the inner mass and the outer layer remain in contact. The cavity is called the **segmentation cavity**. It would appear, however, from the evidence at present available, that this primitive cavity never exists in the human subject, for as the main part of the inner mass separates from the outer layer the cells of the primary mesoderm segment of the inner mass proliferate rapidly and form a jelly-like tissue which completely fills the space which would otherwise become the segmentation cavity. At the same time the ecto-mesodermal and entodermal segments of the

FIG. 27.—DIFFERENTIATION OF
ZYGOTE AND CELLS (Hypothetical).

inner mass become converted into hollow vesicles by the appearance of cavities in their interiors (Fig. 29).

When the above-mentioned changes have occurred the zygote consists of three spheres, one large and two small. The large sphere is bounded by the trophoblast, and it contains the two small spheres and the jelly-like mass of primary mesoderm derived from the primary mesoderm segment of the inner mass (Fig. 29).

FIG. 28.—FURTHER DIFFERENTIATION OF ZYGOTE (Hypothetical).

The two small vesicles lie ex-centrally in the interior of the larger vesicle. The larger and more external of the two is the ecto-mesodermal vesicle. It is separated from the trophoblast, peripherally, and the entodermal vesicle, centrally, by the surrounding mesoderm.

The early appearance of the mesoderm in the zygote and its insinuation at so early a period between the ectoderm and the entoderm are peculiarities limited to the human subject. In most mammals the mesoderm does not appear until the embryonic area and its primitive streak are defined.

The Embryonic Area.—The area where the two inner vesicles lie in apposition with each other is the region of the zygote from which the embryo will be formed; it is called, therefore, the **embryonic area**, and at the time of its definition it consists of three layers, ectoderm, primary mesoderm, and entoderm. It is uncertain whether the mesoderm which is present in the area at this period takes part in the formation of the embryo or is replaced at a later period by mesoderm derived from the cells of the

ecto-mesodermal vesicle; the latter certainly forms a large part of the mesoderm of the embryo.

The Extra-Embryonic Cœlom.—The extra-embryonic cœlom is a space which appears as two clefts, one on either side of the embryonic area, in the primary mesoderm (Fig. 30). The clefts fuse together round the periphery of the embryonic area, and the single space so formed expands rapidly until the mesoderm which originally filled the greater part of the larger vesicle becomes converted into a thin layer which lines the inner surface of the trophoblast and covers the outer surfaces of the epithelial walls of the extra-embryonic parts of the two inner vesicles (Fig. 32).

FIG. 29.—SCHEMA OF DIFFERENTIATION OF ZYGOTE (Bryce's Ovum).

FIG. 30.—SCHEMA OF DIFFERENTIATION OF ZYGOTE (Peter's Ovum).

The extra-embryonic cœlom does not extend into the embryonic area, and it never completely separates the ecto-mesodermal vesicle from the inner surface of the trophoblast; on the contrary, the primary mesoderm on the outer surface of the ecto-mesodermal vesicle retains its continuity with the mesoderm on the inner surface of the trophoblast until the termination of intrauterine life, and

it takes part, as will be seen later, in the formation of the umbilical cord, which connects the foetus with the placenta.

The Differentiation of the Embryonic Area.—As the embryonic area is the area of contact between the ecto-mesodermal and the entodermal vesicles it is, at first, circular in outline. As growth continues the area becomes oval, and a linear streak, the **primitive streak**, appears in that part of the oval which becomes the posterior part of the area (Fig. 31).

At the same time the position of the mesodermal elements of the wall of the ecto-mesodermal vesicle is revealed, for the primitive streak is a thickened ridge of cells which grows from the ecto-mesoderm and projects against the entoderm in the posterior part of the embryonic area, pushing aside the primitive mesoderm which intervened between the adjacent parts of the walls of the ecto-mesodermal and the entodermal vesicles. The deeper cells of the ridge, those next the entoderm, are the mesodermal elements of the primitive ecto-mesoderm, and, by proliferation, they form the larger part, if not the whole, of the embryonic mesoderm and also an organ, called the **notochord**. The mesoderm produced from the primitive streak may be termed the **secondary mesoderm**.

Immediately after the formation of the primitive streak a groove, the **neural groove**, appears in the anterior part of the embryonic area. It is formed by the longitudinal folding of a thickened plate of ectoderm, the **neural plate**, which is the rudiment of the whole of the central and peripheral portions of the nervous system, except perhaps the olfactory nerves, and the end organs of the sensory nerves. From it also are derived the cells of the primitive sheaths of the nerve-fibres and the chromaffin cells of the supra-renal glands and other chromaffin bodies.

The lateral walls of the neural groove are called the **neural folds**.

Almost from the first the anterior ends of the neural folds are united together a short distance posterior to the anterior end of the embryonic area. Their posterior ends, which remain separate for a time, embrace the anterior part of the primitive streak. In the meantime, however, a groove, the **primitive groove**, has appeared on the surface of the primitive streak. The anterior end of the primitive groove deepens until it forms a perforation which passes through the anterior end of the streak and the subjacent entoderm into the cavity of the entodermal vesicle. As this perforation passes from the floor of the posterior part of the neural groove into that part of the entodermal vesicle which afterwards becomes the primitive enteron or alimentary canal, it is called the **neurenteric canal**. This canal is but a transitory passage, and it disappears before the neural groove is converted into a neural tube.

After the appearance of the primitive groove and the neurenteric canal the posterior ends of the neural folds converge across the anterior part of the primitive streak and groove and fuse together posterior to the neurenteric canal. The primitive streak is thus divided into two portions. (1) An anterior portion which lies at first in the floor of the neural groove, and, later, in the floor or ventral wall of the posterior end of the spinal medulla; and (2) a posterior portion which remains on the surface and afterwards takes part in the formation of the median portion of the posterior end of the body, forming the perineum, and the median part of the ventral wall of the body, from the perineum posteriorly to the umbilicus

FIG. 31.—SCHEMA OF DORSAL SURFACE OF EMBRYONIC AREA OF ZYGOTE AFTER THE REMOVAL OF PART OF THE CHORION AND PART OF THE AMNION.

anteriorly. It is through the perineal section of the posterior part of the primitive streak that, at a later period of embryonic life, the anal and urogenital orifices of the body are formed.

FIG. 32.—SCHEMA OF SAGITTAL SECTION OF ZYGOTE ALONG LINE A IN FIG. 31.

FIG. 33.—SCHEMA OF TRANSVERSE SECTION OF ZYGOTE ALONG LINE B IN FIG. 31.

FIG. 34.—SCHEMA OF TRANSVERSE SECTION OF ZYGOTE ALONG LINE C IN FIG. 31.

The Formation of the Notochord and the Secondary Mesoderm.—The notochord and the secondary mesoderm are formed from the primitive streak; thenotochord from its anterior extremity and the secondary mesoderm from its lateral margins and posterior end.

As soon as the primitive streak is established its anterior end becomes a node or centre of growth by means of which the length and, to a certain extent, the breadth of the body are increased. The portions of the body formed by the activity of the anterior end of the streak are (1) the dorsal portion, from the back part of the roof of the nose, anteriorly, to the posterior end of the trunk, (2) the perineum, (3) pelvis, and (4) the ventral wall of the body from the perineum to the umbilicus. Nevertheless, the primitive streak undergoes little or no increase in length; indeed, as growth continues, it becomes relatively shorter as contrasted with the total length of the embryonic region, for the new material, formed by its borders and its anterior extremity, is transformed into the tissues of embryo as rapidly as it is created.

The Notochord.—The notochord or primitive skeletal axis is formed by the proliferation of cells from the anterior end of the primitive streak. On its first appearance it is a narrow process of cells, the **head process**, which projects forwards from the anterior boundary of the neurenteric canal, between the ectoderm and the entoderm. Shortly after its appearance the head process wedges its way between the entoderm cells, and from that period onwards, as the posterior parts are formed,

by continued proliferation from the front end of the primitive streak, they are at once intercalated in the dorsal wall of the entodermal sac, where they remain, forming a part of the dorsal wall of the entodermal cavity (Fig. 33), for a

considerable time. At a later period the notochordal cells are excalated from the entoderm, and then they form a cylindrical rod of cells which occupies the median plane, lying between the floor of the ectodermal neural groove and the entodermal roof of the primitive alimentary canal, which, in the meantime, has been more or less moulded off from the dorsal part of the entodermal sac (Fig. 37). For a still longer time the caudal end of the notochord remains connected with the anterior end of the primitive streak and its cephalic end is continuous with the entoderm of a small portion of the embryonic area, which lies immediately in front of the anterior end of the neural groove, and becomes bilaminar by the disappearance of the primary mesoderm. This region, because it afterwards forms the boundary membrane between the anterior end of the primitive entodermal canal and the primitive buccal cavity or stomatodæum, is called the **bucco-pharyngeal membrane** (Fig. 55, p. 42). It disappears about the third week of embryonic life, and immediately afterwards the anterior end of the notochord separates from the entoderm, but the posterior end remains continuous with the primitive streak until the formation of the neural tube is completed.

After a time the cylindrical notochordal rod is surrounded by secondary mesoderm which becomes converted into the vertebral column of the adult, and as the vertebral column is formed the notochord is enlarged in the regions of the intervertebral fibro-cartilages and for a time assumes a nodulated appearance (Fig. 60).

Ultimately it disappears as a distinct structure, but remnants of it are believed to exist as the pulpy centres of the intervertebral fibro-cartilages. The extension of the notochord into the region of the head is of interest from a morphological, and possibly also from a practical point of view. It extends through the base of the cranium from the anterior border of the foramen magnum into the posterior part of the body of the sphenoid bone. Its presence in this region suggests that the posterior part of the skull was primitively of vertebral nature. As it passes through the occipital portion of the skull it pierces the basilar portion of the occipital region first from within outwards and then in the reverse direction. It lies, therefore, for a short distance, on the ventral surface of the rudiment of the occipital bone, in the dorsal wall of the pharynx, and it is possible that some of the tumours which form in the dorsal wall of the pharynx are due to the proliferation of remnants of this pharyngeal portion of the notochord.

The Differentiation of the Secondary Mesoderm.—It has already been noted that a portion of the inner mass of the human zygote becomes converted directly into mesoderm which may be called, for convenience, *primary mesoderm*. It was stated also that the wall of the larger of the two inner vesicles of the zygote consists of ecto-mesoderm, that term being intended to convey the idea that the cells of the wall of the larger inner vesicle were the progenitors of both ectodermal and mesodermal cells.

As soon as the larger of the two inner vesicles is formed two areas of its wall are defined: (1) the part in contact with the smaller inner or entodermal vesicle and (2) the remainder. As future events prove, the cells of the larger area, which is not in contact with the entodermal vesicle, simply produce ectodermal descendants which line the inner surface of a sac-like covering of the embryo termed the amnion; they are, therefore, the predecessors of the *amniotic ectoderm*.

The cells of the larger inner vesicle, which lie adjacent to the smaller entodermal vesicle, and are merely separated from the entoderm by a thin layer of primary mesoderm, take part in the formation of the embryo; forming, with the entoderm, the embryonic area from which the embryo is evolved. These cells are the forerunners of both ectoderm and mesoderm, and as the mesoderm developed from them is differentiated after the formation of the primary mesoderm it may be termed **secondary mesoderm** or **primitive streak mesoderm**: the latter term being applied because it is differentiated in a linear region called the primitive streak (p. 23). It is the formation and fate of this primitive streak mesoderm which is now to be considered.

At first the embryonic area is circular in outline, at a later period it becomes ovoid, and in the narrower or caudal portion of the ovoid area a linear thickening

FIG. 35.—TRANSVERSE SECTION OF A ZYGOTE, showing early stage of embryonic secondary mesoderm before the appearance of the embryonic parts of coelom.

FIG. 37.—TRANSVERSE SECTION OF A ZYGOTE, showing union of intra- and extra-embryonic parts of coelom and separation of embryonic mesoderm into paraxial bars, intermediate tracts, and lateral plates, with separation of lateral plates into somatic and splanchnic layers by the intra-embryonic part of the coelom.

appears; this is the **primitive streak** (Figs. 31, 34). It is formed by the proliferation of the ecto-mesodermal cells of the wall of the larger inner vesicle. The deeper cells of the streak, which displace the primary mesoderm from the median plane, and thus come into contact with the entoderm, are the rudiments of the secondary or primitive streak mesoderm (Fig. 34). The superficial cells form part of the surface ectoderm of the embryo.

At the anterior end of the primitive streak the mesodermal elements of the streak fuse with the subjacent entoderm and through the fused mass a perforation, the **neurenteric canal** (p. 23), is formed (Fig. 32).

The canal itself soon disappears, but the cells of its walls form a nodal growing point, and by their proliferation the length and breadth of the embryonic area are increased. The mesoderm cells proliferated from the cephalic border of the nodal point are the rudiments of the notochord, which has already been considered (p. 24).

It is uncertain whether or not the mesodermal cells budded off from the nodal point blend with the cells of the primary mesoderm, but there can be little doubt that they form by far the greater part, if not the whole, of the permanent mesoderm of the embryo.

Either by displacement or by union with the primary mesoderm the secondary mesoderm forms a continuous sheet of cells, in the embryonic area, on each side of the median plane.

Each of the lateral sheets is thickest where it abuts against the notochord and the wall of the neural groove, and thinnest at its peripheral margin, where it is continuous with the primary mesoderm of the extra-embryonic area (Fig. 35).

At the cephalic end of the embryonic area the medial margins of the mesodermal sheets fuse together across the median plane, forming a transverse bar of mesodermal cells which may be called the **pericardial mesoderm** (Fig. 48), because the pericardial sac, which envelops the heart, is afterwards developed from it. The area in which this mesoderm lies may be named the pericardial region of the embryonic area (Fig. 48).

Between the bar of pericardial mesoderm, the cephalic end of the neural groove, and the medial margins of the mesodermal plates lies a small segment of the embryonic area from which the primary mesoderm entirely disappears, leaving the ectoderm and entoderm in contact. This is the **bucco-pharyngeal area**. It afterwards becomes the **bucco-pharyngeal membrane** (Figs. 50, 55), which separates the primitive mouth or stomatodæum from the cephalic end of the primitive entodermal alimentary canal. As already stated, the bucco-pharyngeal membrane disappears during the third week, when the stomatodæum and the primitive alimentary canal become continuous with each other.

Between the bucco-pharyngeal area and the cephalic end of the primitive streak the medial margins of the mesodermal plates are separated from one another by the notochord and the neural groove (Fig. 36), and still more caudally they are united with the sides of the streak (Fig. 34).

After the permanent mesodermal plates are definitely established a series of clefts appear in their peripheral margins. The clefts on each side soon fuse together to form the bilateral rudiments of the **embryonic cœlom** (Fig. 36).

The septum of cells at the lateral border of the embryonic area on each side, which, for a time, separates the embryonic from the extra-embryonic cœlom, soon disappears, and the cœlom then forms a continuous cavity (Fig. 37).

The embryonic cœlom also extends medially, but the medial extension ceases whilst the cavity is still at some distance from the median plane, except at the cephalic end of the embryonic area, where the two lateral halves of the embryonic cœlom become continuous with each other through the interior of the pericardial mesodermal bar (Figs. 49, 55).

As the embryonic cœlom is forming and extending, a longitudinal constriction appears in each lateral half of the mesoderm, a short distance from its medial border. This constriction separates each plate into three parts: (1) a medial bar, the **paraxial mesoderm**, which lies at the side of the neural groove and the notochord (Fig. 37); (2) the constricted portion, which is called the **intermediate cell tract**; and (3) the part lateral to the constriction, which is called the **lateral plate** (Fig. 37).

The embryonic cœlom is confined, as a rule, in the human subject, to the lateral plate, which it divides into a superficial layer, next the ectoderm, the **somatic mesoderm**, and a deeper layer, next the entoderm, the **splanchnic mesoderm**.

The medial borders of the somatic and splanchnic mesoderm are continuous

FIG. 38.—SCHEMA OF DORSAL ASPECT OF EMBRYO, showing partial closure of neural groove.

Portions of the chorion and amnion have been removed. The neural folds have fused, except in the cephalic and caudal regions, both the cephalic and the caudal ends of the embryo have been bent ventrically and thirteen mesodermal somites have been formed.

with each other round the medial border of the coelom. The lateral border of the somatic mesoderm is continuous, at the margin of the embryonic area, with the mesoderm which covers the outer surface of the amnion, and the lateral border of the splanchnic layer is continuous with the mesoderm on the wall of the extra-embryonic or yolk-sac portion of the entodermal sac.

The Paraxial Mesoderm.—Each paraxial mesodermal bar soon assumes the form

FIG. 39.—TRANSVERSE SECTION OF THE ZYGOTE SHOWN IN FIG. 38, showing the differentiation of the mesoderm.

of a triangular prism with the apex directed ventro-medially, towards the notochord, and the base dorso-laterally, towards the surface ectoderm.

The cephalic portion of each paraxial bar, as far caudalwards as the middle of the hind-brain, remains unsegmented, but the remainder is cut into a number of

FIG. 40.—SCHEMA OF A TRANSVERSE SECTION OF A ZYGOTE, showing differentiation of mesoderm and extension of amnion.

segments, the **mesodermal somites**, by a series of transverse clefts (Fig. 38). The first cleft appears in the region of the hind-brain, and the others are formed successively, each caudal to its predecessor. Only three or four somites lie in the

region of the head; the remainder are in the body area of the embryonic region. The segmentation of the paraxial bars commences before their elongation is completed, and the posterior somites are separated off as the paraxial bars are extended by the continued proliferation from the nodal point at the anterior end of the primitive streak.

When they are first defined the somites are solid masses of cells, but in a short time a cavity—the coelom of the somite or *myocœle*—is developed in each mass.

FIG. 41.

A. Transverse section of a zygote, showing the constituent parts.

B. Diagram of embryonic area showing parts of neural plate and primitive streak.

The apical portion of the hollow mesodermal somite is its **sclerotogenous segment**. The cells of the sclerotogenous section of the somite undergo rapid proliferation. Some of the newly formed sclerotogenous cells invade the *myocœle*; others migrate towards the notochord; finally, the sclerotogenous cells separate from the remainder of the somite, and as they increase in number they migrate along the sides of

FIG. 42.

A. Diagram of a transverse section of a zygote, showing the formation of a neural groove in the embryonic area.

B. Diagram of a surface view of the embryonic area of the same zygote.

the notochord and the neural tube, which has been formed in the meantime from the neural groove, and join with their fellows of the opposite side, and with their cephalic and caudal neighbours. In this way is formed, around the neural tube and the notochord, a continuous sheath of mesoderm, the **membranous vertebral column**, from which are differentiated, in later stages, the vertebral column and its ligaments, and the membranes of the brain and the spinal medulla.

After the separation of the scleratogenous segments of the mesodermal somites, the remainders of the somites, each of which consists of a flat plate with incurved dorsal and ventral margins, constitute the muscle plates from which the striped muscle fibres are derived.

In the opinion of some observers the outermost portion of each of the above-described plates is developed into subcutaneous connective tissue cells; consequently it is spoken of as the *cutis lamella*. According to this view the muscle cells are formed from their innermost cells and the incurved margins of the plates.

The Intermediate Cell Tracts.—The intermediate cell tracts are the rudiments of the internal organs of the genital system and the temporary and permanent urinary system, with the exception of the urinary bladder and the urethra.

The Lateral Plates.—From the cells of the lateral plates are formed the lining endothelial cells of the great serous cavities of the body—the pleuræ, the pericardium, and the peritoneum; the majority of the connective tissues, with the exception of those of the vertebral column and the head, the greater part or all the mesoderm of the limbs, and, probably, the unstriped muscle fibres of the walls of the alimentary canal and the blood-vessels.

FIG. 43.

A. Diagram of a transverse section of a zygote, in which the neural tube has formed but has not separated from the surface ectoderm.

B. Diagram of embryonic area of same zygote. Compare with surface view of embryo in Fig. 38.

The Cephalic Mesoderm.—It has already been noted that the mesoderm of the head becomes segmented only in the region of the caudal part of the hind-brain, where four cephalic mesodermal somites are formed on each side. From the scleratogenous portions of these somites are developed the occipital part of the skull and the corresponding portions of the membranes of the brain, and from their muscle plates the intrinsic muscles of the tongue.

The unsegmented part of the cephalic mesoderm gives rise to the remaining muscles and connective tissues of the head region.

Early Stages of the Development of the Nervous System.—No definite trace of the nervous system is present until the primitive streak has formed and the embryonic area has passed from a circular to an elongated form. Then an area of thickened ectoderm, the **neural plate**, appears in the anterior part of the area. It commences a short distance posterior to the anterior end of the area, and its posterior extremity embraces the anterior end of the primitive streak. Its lateral margins fade gradually into the surrounding ectoderm, and in the earliest stages cannot be definitely defined; but, as the elongation of the plate continues coincidentally with the elongation of the embryonic area, the lateral margins of the plate are elevated as the mesoderm beneath them thickens, and so they become distinct.

As the lateral margins of the neural plate are raised the plate is necessarily folded longitudinally, and the sulcus so formed is called the **neural groove**. Each side wall of the neural groove, formed by the corresponding half of the neural plate, is a **neural fold**. At a very early period the neural folds unite anteriorly to form the anterior boundary of the neural groove, and somewhat later they unite posteriorly, caudal to the neurenteric canal and across the anterior end of the primitive streak. After the lateral boundaries and the anterior and posterior extremities of the neural groove are defined, the lateral margins of the neural folds converge until they meet and fuse in the median plane, and the neural groove is thus converted into the **neural tube**, which possesses a floor or ventral wall, formed by the central part of

FIG. 44.—DIAGRAMS illustrating the formation of (1) the rudiments of the primitive ganglion from the neural crest. (2) The differentiation of different parts of the primitive ganglion into permanent ganglion root, sympathetic ganglion, and masses of chromaffin cells. (3) The formation of the anterior and posterior nerve-roots. (4) The differentiation of the walls of the neural tube into ependymal matter and peripheral layers.

The cells of the primitive ganglion which form the primitive sheaths of the nerves are not shown in the diagrams.

the original neural plate and called the **basal plate** or **floor-plate**, a dorsal wall or **roof-plate**, formed by the lateral parts of the neural plate, and two lateral walls.

The fusion of the lateral margins of the neural plate to form the dorsal wall of the neural tube commences in the cervical region, and from there extends anteriorly and posteriorly, therefore the last parts of the dorsal wall which are formed are its anterior and its posterior extremities; consequently, for a time, the **neural canal**, which is the cavity of the tube, opens on the surface at its anterior and posterior ends; the anterior opening being called the **anterior neuropore**, whilst the open part at the posterior end is termed the **posterior neuropore** (Fig. 43). Eventually, however, about the third week of embryonic

life both apertures are closed and, for a time, the neural canal becomes a completely closed cavity.

As the margins of the neural groove rise and converge they carry with them the adjacent ectoderm to which they are attached, and which forms part of the surface covering of the embryo; consequently, when the lateral margins of the folds meet and unite, the tube, which is completed by their fusion, is embedded in the body of the embryo, but, for a time, its dorsal wall is attached to the surface ectoderm by a ridge of cells, formed by the fused lateral margins of the neural plate. This ridge is called the **neural crest** (Figs. 41-44).

The neural crest is the rudiment of the cerebral and spinal nerve ganglia, the sympathetic ganglia, the chromaffin cells of the chromaffin organs, and the cellular sheaths of the peripheral nerves; whilst the walls of the neural tube become transformed into the various constituent parts of the central nervous system, the brain and spinal medulla, the retinae of the eye-balls, and the optic nerves.¹

The Formation of the Nerve Ganglia, the Chromaffin Tissues, and the Primitive Nerve Sheaths.—The primitive ganglia grow as cell buds from the neural crest which, for a time, connects the dorsal wall of the neural tube with the surface ectoderm. In the body region they correspond in number with the spinal nerves and with the primitive segments into which the mesoderm becomes divided, but in the cephalic region their arrangement is more irregular, and some of the ganglia of the cerebral nerves receive additional cell elements from the surface ectoderm.

Simultaneously with the appearance of the cell buds which form the primitive ganglia, the neural crest disappears, and directly after the ganglia are formed they lose their connexion with both the neural tube and the surface ectoderm and become isolated cell clumps. At this period, therefore, the nervous system consists of the neural tube and the primitive ganglia.

After the primitive ganglia have lost their connexion with the neural tube they increase in size by the proliferation of their constituent cells, and they migrate ventrally along the sides of the neural tube, but the migration ceases before the ventral ends of the ganglia reach the level of the ventral wall of the tube. As the migration proceeds, clumps of cells are budded off from the ventral ends of the ganglia. These secondary cell buds are the rudiments of the sympathetic ganglion cells and of the chromaffin tissue which is found in the sympathetic nerve plexuses, the medulla of the suprarenal glands, and in the carotid glands. In the first instance the secondary cell buds which form the sympathetic ganglia wander ventrally and medially, from the ventral ends of the primitive ganglia, until they attain the positions afterwards occupied by the ganglia of the sympathetic trunks on the ventro-lateral aspects of the vertebral column. From the primary sympathetic ganglia, buds of cells are given off which wander still further ventrally to become the cells of the ganglia of the cardiac, coeliac, and other great ganglionic nerve plexuses, as well as to form the chromaffin cells of the chromaffin organs.

The exact manner in which the cells of the primitive sheaths of the nerves originate from the primitive ganglia is not known, but it has been shown by Harrison, in the case of the frog, that if the primitive ganglia are destroyed, the primitive sheaths of the nerves are not formed. Presumably, therefore, in the frog the cellular sheaths of the nerves are derived from cells produced by the primitive ganglia, and it may be assumed that they have a similar origin in the human subject.

After the rudiments of the sympathetic system, the chromaffin cells, and the cellular sheaths of the nerves have separated, the remains of the primitive ganglia become the permanent spinal and cerebral nerve ganglia.

In the early stages these ganglia are completely isolated structures which lie along the sides of the neural tube between the lateral walls of the tube medially, and the mesoderm somites laterally.

Some time after the ganglia of the cerebral and spinal nerves become isolated,

¹ It is stated that some of the sympathetic nerve-cells are derived from the ventral parts of the lateral walls of the neural tube, but the evidence on this point is not entirely satisfactory.

their cells give off processes which become nerve-fibres. These fibres grow out both from the dorsal and the ventral ends of the ganglia, and, together with the ganglia, they form, in the cranial region, certain of the cerebral nerves, and, in the spinal region, the posterior roots of the spinal nerves.

The fibres which grow out of the dorsal ends of the ganglia enter the walls of the neural tube, and by their means the ganglia regain connexion with the tube.

The fibres which grow out from the ventral end of each spinal ganglion unite with the fibres of the corresponding anterior nerve-root, which, in the meantime, has grown out from the cells of the ventral part of the lateral wall of the spinal portion of the neural tube, and form with them a spinal nerve-trunk.

The Differentiation of the Neural Tube.—Before the neural groove is converted into a closed tube, an expansion of its anterior part indicates the separation of the neural rudiment into cerebral and spinal sections, the dilated portion being the rudiment of the brain and undilated part the rudiment of the spinal medulla.

Whilst the cerebral portion is still unclosed, three secondary dilatations of its walls indicate its separation into three sections, the primitive **fore-brain**, the **mid-brain**, and the **hind-brain**; the primitive fore-brain being the most cephalward or anterior and the hind-brain the most caudal or posterior of the three (Fig. 38).

Shortly after the three segments of the brain are defined, and before it becomes a closed tube, a vesicular evagination forms at the cephalic end of each lateral wall of the primitive fore-brain region. These evaginations are the **primary optic vesicles**, and they are the rudiments of the **optic nerves**, the **retinæ**, and the **posterior epithelium of the ciliary body**, and the **iris** of the eye-ball.

When the cerebral portions of the neural folds meet and fuse dorsally the cerebral dilatations become the primitive brain vesicles, each vesicle possessing its own cavity and walls, but the cavities of the three vesicles are continuous with one another, and the cavity of the hind-brain vesicle is continuous, caudally, with the central canal of the spinal part of the neural tube.

After the primitive brain vesicles are formed, a diverticulum grows out from the cephalic end of the primitive fore-brain vesicle. This is the rudiment of the secondary fore-brain. Its cephalic end soon divides into two lateral halves, which are the rudiments of the cerebral hemispheres of the adult brain (Fig. 45).

After their formation the cerebral hemispheres expand rapidly in all directions. They soon overlap the primitive fore-brain and mid-brain (Fig. 63), and, eventually, the hind-brain also, and each gives off from the cephalic end of its ventral wall a secondary diverticulum, the **olfactory diverticulum**, which becomes converted later into the olfactory bulb and olfactory tract.

When they first appear the rudiments of the cerebral hemispheres are connected together, across the median plane, by a part of the cephalic end of the wall of the **secondary fore-brain dilatation**, which is called the **lamina terminalis**. This primitive connexion between the two cerebral hemispheres persists throughout the whole of life, and it is supplemented, at a later period, by the formation of two secondary commissures, the **corpus callosum** and the **foruix**, which grow across the space between the cerebral hemispheres and connect their medial walls together.

The Fate of the Walls of the Primitive Brain Vesicles.—The primitive hind-brain, which is also called the rhombencephalon, is separated in the later stages of development into two parts. (1) A caudal portion which is connected with the medulla spinalis, and which becomes the **medulla oblongata** or **myelencephalon** of the adult brain. (2) A cephalic portion called the metencephalon, which is continuous at one end with the medulla oblongata and at the other with the mid-brain. The ventral wall of this portion of the primitive hind-brain is ultimately converted into the **pons**, and its dorsal wall differentiates into two parts—a caudal part which becomes the **cerebellum**; and a cephalic part which is converted into the **anterior medullary velum** and the **brachia conjunctiva**. The brachia conjunctiva connect the cerebellum with the corpora quadrigemina, which are developed from the dorsal part of the mid-brain. The pons and cerebellum form the metencephalon of the adult, whilst the brachia conjunctiva and the

anterior medullary velum constitute parts of the isthmus rhombencephali (Figs. 45, 63).

The ventral portion of the primitive mid-brain is converted into the two peduncles of the cerebrum of the adult brain, and the dorsal portion, as already mentioned, is transformed into four rounded elevations, the *corpora quadrigemina*.

The transformations which take place in the region of the primitive fore-brain or prosencephalon are numerous and complicated; therefore its ventral, lateral, and dorsal walls require separate consideration.

By the expansion of its cephalic (anterior) extremity is formed the **secondary fore-brain**, which becomes divided, as already explained, into the two secondary vesicles which are the rudiments of the **cerebral hemispheres** of the completed brain.

After the formation of the rudiments of the cerebral hemispheres, which

constitute the **telencephalon** of the adult, the primitive fore-brain and the undivided stalk of these secondary fore-brain diverticulum become the **diencephalon**.

The cephalic or anterior end of the diencephalon is closed by the lamina terminalis (see p. 33), in association with which are subsequently developed two columns which run dorso-ventrally, the **columns of the fornix** (O.T. **anterior pillars**), and two transverse commissures, one of which connects together the two

FIG. 45.—DIAGRAMS TO ILLUSTRATE THE ALAR AND BASAL LAMINÆ. In both cases the embryonic brain is represented in mesial section (His).

A. The different subdivisions of the brain are marked off from each other by dotted lines, and the dotted line running in the long axis of the neural tube indicates the separation of the alar from the basal lamina of the lateral wall.

B. Medial section through the brain of a human embryo at the end of the first month. Dotted lines mark off the different regions and also the alar and basal laminae from each other.

cerebral hemispheres and is called the **anterior commissure**, whilst the other is the **optic chiasma** in which the medial fibres of the optic nerves decussate.

From the cephalic or anterior end of the ventral wall of the diencephalon a diverticulum is projected ventrally towards the dorsal wall of the primitive mouth. The ventral end of this diverticulum becomes the posterior lobe of the **hypophysis** (O.T. **pituitary body**) of the adult, the dorsal end becomes the *tuber cinereum*, and the intermediate part is the *infundibulum* which connects the *tuber cinereum* of the adult brain with the posterior lobe of the hypophysis.

Caudal to the hypophyseal diverticulum a single elevation appears in the ventral wall of the diencephalon. It is the **corpus mamillare**, which afterwards separates into the paired **corpora mamillaria** of the adult brain.

Still more caudally the ventral wall of the diencephalon takes part in the formation of the **substantia perforata posterior**, which lies between the two peduncles of the cerebrum and is partly developed from the cephalic or anterior end of the ventral wall of the primitive mid-brain.

The greater part of the dorsal wall of the diencephalon is ultimately reduced to a single layer of epithelial cells, but near its caudal end a diverticulum is projected dorsally. This is the **epiphysis** or **pineal body**, which remains quite

rudimentary in man as contrasted with many other animals. At a later period two transverse bands of fibres appear in the dorsal wall of the diencephalon, one in front of and the other immediately behind the root of the epiphyseal recess. The anterior band is the **dorsal** or **habenular commissure**, and the posterior is the posterior commissure of the adult brain.

These structures, collectively, together with a small diverticulum of the epithelial roof, which appears anterior to the dorsal commissure, and is called the **supra-pineal recess**, constitute the so-called **epithalamus**.

Each lateral wall of the diencephalon is differentiated into a dorsal and a ventral part. The dorsal part forms a large gray mass called the **thalamus**, and on the posterior end of the thalamus are developed two rounded elevations, the **medial** and the **lateral geniculate bodies**, which constitute the **meta-thalamus** of the adult brain.

The ventral or basal portion of the lateral wall of the diencephalon, together with the adjacent part of the ventral wall, forms the **hypothalamus** of the fully developed brain.

The Fate of the Spinal Portion of the Primitive Neural Tube.—The spinal portion of the neural tube, during the first three months of intra-uterine life, develops equally in its whole extent, but after that period a longer cephalic or anterior (superior in the erect posture) and a shorter caudal portion are recognisable. The cephalic portion undergoes still further development and is converted into

the spinal medulla of the adult, but in the smaller caudal or posterior portion retrogressive changes occur, and it is transformed into the non-functional **filum terminale** of the completed medulla spinalis.

Histological Differentiation of the Walls of the Neural Tube.

—In the earliest stages of its development the walls of the neural tube consist of a mass of nucleated protoplasm more or less distinctly differentiated into cell areas of columnar form which extend between and are connected with an **internal limiting membrane**, bounding the neural canal, and an **external limiting membrane**, which surrounds the whole tube. At

FIG. 47.—SHOWING ELEMENTS OF CENTRAL NERVOUS SYSTEM.

at this time the outline of a transverse section of the primitive neural tube is somewhat ovoid. The cavity of the tube is compressed laterally into a dorso-ventral cleft, which is bounded by dorsal, ventral, and lateral walls. In the dorsal and ventral walls, called respectively the roof- and floor-plates, the columnar character of the primitive epithelial elements of the medulla spinalis is retained throughout the whole of life, but the peripheral parts of the cells are converted into fibrils.

In the lateral walls of the embryonic medulla spinalis some of the cells soon

FIG. 46.

A. Diagram of a transverse section of a spinal medulla which has not differentiated into groups of cells.

B. Diagram of a transverse section of a spinal medulla showing positions of germinal cells.

assume a spherical form. These spherical cells have large deeply staining nuclei, and they are termed **germinal cells**.

For many years it was believed that the germinal cells were the predecessors of the primitive nerve elements or **neuroblasts**, and that the remaining cells, called **spongioblasts**, became transformed into the reticular sustentacular tissue of the central nervous system. It appears, however, from the results of more recent researches, that some of the descendants of the germinal cells become spongioblasts whilst others become neuroblasts or primitive nerve-cells. Moreover, there appear to be two groups of primitive germ cells; the descendants of one group are directly transformed into the ependymal or lining cells of the central canal, whilst those of the other group form in the first instance **indifferent cells**, some of whose descendants become neuroblasts and others spongioblasts. The fate of the cells present before the germinal cells appear is uncertain, but they probably take part in the formation of the spongioblastic tissue.

It is believed, therefore, that all the nerve-cells are the descendants of the germinal cells, and that the spongioblasts which become developed into the cells of the neuroglia or sustentacular reticulum are derived partly from the non-germinal cells of the primitive neural tube and, partly, they are descendants of the germinal cells.

As differentiation proceeds three layers and two membranes are gradually defined in the walls of the neural tube: (1) a central layer of columnar ependyma cells immediately surrounding the central canal; (2) an intermediate or mantle layer consisting of neuroblasts and their processes, the nerve-fibres, intermingled with spongioblasts; (3) a peripheral reticular layer consisting, at first, of processes of the bodies of the spongioblasts. The membranes are an external limiting membrane, surrounding the exterior of the tube, formed by the fused outer ends of the spongioblastic cells, and an internal limiting membrane bounding the central canal and continuous with the inner ends of the ependyma cells. Throughout the whole of the spinal medulla and the brain, the ependyma cells become transformed into the columnar ciliated cells which line the cavities of the adult brain and spinal medulla. The mantle layer becomes converted into the gray matter of the adult central nervous system.

The peripheral reticular layer, in the spinal region, becomes permeated by nerve-fibres, which are merely processes of the nerve-cells, and it is thus converted into the white matter of the adult spinal medulla. In the brain region it is either transformed in the same way into white matter, or it remains in a more rudimentary condition as a thin peripheral layer of neuroglia on the surface of the gray matter. On the other hand, in the brain region white matter is formed internal to the gray matter by the growth of nerve-fibres which insinuate themselves between the mantle layer externally and the bodies of the ependyma cells internally.

As the histological differentiation of the walls of the neural tube is proceeding each lateral wall is divided into a dorsal part, the **alar lamina**, and a ventral part, the **basal lamina**, by a sulcus-like dilatation of the central canal called the *sulcus limitans*. After the limiting sulci are formed the parts of the walls of the neural tube are a roof-plate, a floor-plate, and two lateral walls, each of which consists of an alar lamina, essentially sensory in function, and a basal lamina, essentially motor in function (Fig. 44).

The Fate of the Cavities of the Primitive Brain.—The cavity of the spinal portion of the primitive neural tube becomes the central canal of the spinal medulla of the adult. The cavities of the primitive brain vesicles are transformed into the ventricles, foramina, and aqueduct of the adult brain. The cavities of the telencephalic divisions of the secondary fore-brain become the **right and left lateral ventricles** of the adult brain. The cavity of the undivided portion of the secondary fore-brain vesicle, together with the cavity of the primary fore-brain, become the **third ventricle** or cavity of the diencephalon, and the apertures of communication between the third ventricle and the cerebral hemispheres are the **interventricular foramina** (O.T. **foramina of Monro**).

The cavity of the hind-brain vesicle becomes the **fourth ventricle**, and the

cavity of the primitive mid-brain is converted into the *aqueductus cerebri*, which connects the third with the fourth ventricle.

After the anterior and posterior neuropores (p. 31) are closed, the cavity of the neural tube is, for a time, a completely enclosed space. Subsequently the mesoderm, which in the meantime has surrounded the tube, becomes differentiated, in its immediate neighbourhood, into three membranes. The innermost of the three is closely connected with the walls of the neural tube and is called the *pia mater*. The outermost, known as the *dura mater*, is dense and resistant, and the intermediate membrane is a thin lamella called the *arachnoid*.

As the membranes are formed, spaces are differentiated between them. The space between the *dura mater* and the *arachnoid* is the *subdural space*, and that between the *arachnoid* and the *pia mater* is the *subarachnoid space*.

After a time a median perforation, the *median aperture of the fourth ventricle* (O.T. *foramen of Magendie*), and two lateral perforations pierce the dorsal wall of the fourth ventricle and the *pia mater* which covers it, and thus the fourth ventricle becomes connected with the subarachnoid space. It is stated also that a perforation passes through the medial wall and the covering *pia mater* of a portion of each lateral ventricle which is called its inferior horn, throwing those portions of the lateral ventricles also into communication with the subarachnoid space.

THE FORMATION OF THE EMBRYO.

The transformation of the relatively flat embryonic area into the form of the embryo is due, in the first instance, to the rapid extension of the median part of the area, as contrasted with the slower growth of its margins, and the later modelling of the various parts of the embryo is due to different rates of growth in different parts of the embryonic region.

By the rapid proliferation of cells from the nodal growing point, at the cephalic end of the primitive streak, the cephalo-caudal length of the area is increased, whilst the cephalic and caudal ends of the area remain relatively fixed, consequently the area becomes folded longitudinally. At the same time, the cephalic end of the neural groove is pushed away from the nodal point until it lies at first dorsal and then cephalad to the cephalic border of the area. As a result of this movement the bucco-pharyngeal and the pericardial areas become reversed in position, and a *cephalic fold* is formed. This is bounded dorsally by what is now the cephalic portion of the embryo, ventrally by the reversed pericardial region, and its cephalic end is formed by the extremity of the head region and the bucco-pharyngeal membrane.

FIG. 48.—SCHEMA OF SAGITTAL SECTION OF EMBRYONIC AREA AND AMNION BEFORE THE FOLDING OF THE AREA HAS COMMENCED.

FIG. 49.—SCHEMA OF SAGITTAL SECTION OF EMBRYONIC AREA SHORTLY AFTER THE FOLDING HAS COMMENCED. The pericardial mesoderm is carried into the ventral wall of the fore-gut and the coelom has extended through it. The cephalic end of the neural tube and the caudal part of the primitive streak are bent ventrally, and the latter now forms the cloacal membrane.

The growth at the nodal point not only produces a head fold, but at the same time it forces the cephalic end of the primitive streak caudally over the caudal end of the embryonic area, thus forming a **tail fold**.

As the head and tail folds of the embryo are produced by the longitudinal increase of the embryonic area, transverse growth of the area results in the formation of right and left **lateral folds** (Figs. 37, 39), and as the various folds are formed the embryo rises like a mushroom into the interior of the amnion cavity.

The portion of the entodermal sac which is enclosed within the hollow embryo, formed by the folding of the embryonic area, is the **primitive entodermal alimentary canal**. The part which remains outside the embryo is the **yolk sac**, and the passage of communication between the two is the **vitello-intestinal duct**.

That portion of the primitive entodermal alimentary canal which lies in the head fold is termed the **fore-gut**, the part in the tail fold is the **hind-gut**, and the intermediate portion which is in free communication with the yolk-sac is the **mid-gut**.

As the extension of the embryonic area and its folding proceed the margin of the area which remains relatively stationary becomes the margin of an orifice, on

FIG. 50.—SCHEMA OF SAGITTAL SECTION OF EMBRYO AFTER THE FOLDING HAS DEFINED BOTH THE FORE-GUT AND HIND-GUT AREAS.

the ventral aspect of the embryo, through which the primitive alimentary canal of the embryo and the intra-embryonic part of the coelom communicate, respectively, with the yolk sac and the extra-embryonic portion of the coelom. This orifice is the **primitive umbilical orifice**.

Not only does the primitive alimentary canal communicate with the yolk sac, and the intra-embryonic with the extra-embryonic coelom, at the margin of the umbilical orifice, but also the body walls of the embryo, formed by the somatopleure, becomes continuous, at the same margin, with the wall of the amnion.

The young embryo is connected also with the inner surface of the chorion by a band of tissue formed by the median portion of the caudal part of the wall of the amnion sac. The mesoderm in this region is thickened, and contains in its interior a diverticulum, **allantoic diverticulum**, which is primarily derived from the entodermal sac, but is afterwards connected with the hind-gut. This strand, which contains the blood-vessels passing between the embryo and the chorion, was called by His the **body stalk**. The term is not altogether fortunate, for it appears that the stalk takes no direct part in the formation of the body of the embryo. On the other hand, its mesodermal and entodermal constituents represent a diverticulum from the wall of the hind-gut, known as the **allantois** which, in many animals, attains a large size, and it might with advantage be termed the **allantoic stalk**.

At first the umbilical orifice is relatively large as contrasted with the total size

of the embryo, but as the embryo rapidly extends in all directions from the margin of the orifice, the latter soon becomes relatively small. Ultimately the various parts of the margin of the orifice are approximated until they fuse together, closing the opening and forming a cicatrix on the ventral wall of the abdomen which is known as the **umbilicus** or **navel**.

THE EMBRYO.

Whilst the embryonic area is being folded into the form of the embryo, the neural groove on the surface of the area is being converted into the neural tube. After the neural tube is completely closed and separated from the surface, during the third week, the embryo is an elongated organism possessing a larger cephalic end, a smaller caudal end attached by the body stalk to the chorion (Fig. 49), a continuous and unbroken dorsal surface, a ventral surface separated into cephalic and caudal portions by the umbilical orifice, two lateral surfaces right and left, and it contains within its interior three cavities: (1) The cavity of the neural tube, which becomes the cavities of the brain and the spinal medulla (Fig. 50); (2) the primitive alimentary canal, which is a portion of the entodermal vesicle constricted off during the folding of the embryonic area (Figs. 37, 40); (3) the embryonic **cœlom**. The **cœlom** consists of right and left portions which communicate at the margin of the umbilicus with the extra-embryonic **cœlom**, and with each other through the pericardial portion of the **cœlom** in the ventral wall of the fore-gut of the embryo (Figs. 49, 90).

At this period the embryo is easily distinguished from the remainder of the zygote, and it is so far developed that indications of its general plan of organisation are discernible.

It has, as yet, no limbs, but the general contour of the head and body are defined. It possesses a notochord or primitive skeletal axis, afterwards replaced by the permanent vertebral column. On the dorsal aspect of the notochord lies the neural tube, which is the rudiment of the future brain and the spinal medulla.

At the sides of the neural tube and the notochord are the mesodermal somites and the nerve ganglia (Figs. 40, 43).

Ventral to the notochord is the primitive alimentary canal (Fig. 50), closed at its cephalic end by the bucco-pharyngeal membrane, and at its caudal end by what was originally the caudal portion of the primitive streak, but which is now called the **cloacal membrane** because it separates the caudal end of the hind-gut, which becomes the **entodermal cloaca**, from the amniotic cavity (Fig. 50).

At the sides of the primitive alimentary canal are the right and left lateral parts of the **cœlom**, and between the dorsal angle of each half of the **cœlom** and the mesodermal somites of the same side lies the intermediate cell tract which is the rudiment of the greater part of the genito-urinary system (Figs. 39, 40).

Ventral to the fore-gut is the pericardial mesoderm, traversed by the pericardial portion of the **cœlom**, which is connected dorsally, on each side with the corresponding lateral portions of the **cœlom**; and ventral to the hind-gut is the cloacal membrane. Between the pericardial region at the one end and the cloacal membrane at the other lies the umbilical orifice, through which the mid-gut communicates with the yolk sac, the intra-embryonic part of the **cœlom** with the extra-embryonic **cœlom**, and the allantoic diverticulum with the cloaca (Figs. 39, 50).

THE LIMBS.

When it is first defined the embryo is entirely devoid of limbs (Fig. 51). During the third week a superficial ridge appears on each side, along the line of the intermediate cell tract in the interior. This is the **Wolffian ridge**, and upon it the rudiments of the fore and hind limbs, the **limb buds**, are formed, as secondary elevations, the fore-limb buds preceding the hind-limb buds in time of appearance (Fig. 52).

Shortly after it has appeared, each limb bud assumes a semilunar outline; it projects at right angles from the surface of the body, and it possesses dorsal and ventral surfaces, and cephalic or preaxial, and caudal or postaxial borders. The

FIG. 51.—VIEW OF DORSAL ASPECT OF A HUMAN EMBRYO—1.38 mm. LONG, before the appearance of the limbs. (From Keibel and Elze, *Normaltafeln*.)

FIG. 52.—DORSAL LATERAL VIEW OF A HUMAN EMBRYO—2.4 mm. LONG. The Wolfian ridge is seen at the lateral border of the mesodermal somites. (Keibel and Elze, *Normaltafeln*.)

bud is the rudiment of the distal segment of the future limb, the hand in the case of the fore-limb, and the foot in the case of the hind-limb.

As the limb-rudiment increases in length the more proximal segments of the limb are differentiated, the forearm and arm in the case of the fore-limb, and the

FIG. 53.—LATERAL VIEW OF A HUMAN EMBRYO—2.1 mm. greatest length, showing limb buds projecting from the Wolfian ridge. (Keibel and Elze, *Normaltafeln*.)

leg and the thigh in the case of the hind-limb. At the same time the limbs are folded ventrally, so that their original ventral surfaces become medial and their original dorsal surfaces lateral, and the convexities of the elbows and knees are directed laterally. At a later period, on account of a rotation which takes place in opposite directions in the fore- as contrasted with the hind-limbs, the convexity of the elbow is turned towards the caudal end of the body and that of the knee towards the cephalic end. It is only at much later periods of development, as the erect posture is assumed, that the convexity of the elbow is directed dorsally and the convexity of the knee ventrally.

The terminal or distal segment of each limb is, at first, a flat plate with a rounded margin, but it soon differentiates into a proximal or basal part and a more flattened marginal portion. It is along the line where these two parts are continuous that the rudiments of the digits appear. They become evident as small elevations on the dorsal surface of the limb bud about the fifth week; they extend peripherally, and by the sixth week the fingers project beyond the margins of the hand segment, but the toes do not attain to a corresponding stage of development until the early part of the seventh week.

The **nails** are later developments. They appear at the third month and reach the ends of the digits at the sixth month.

Each limb bud is essentially an extension of a definite number of segments of the body. It consists, at first, of a core of mesoderm covered by ectoderm. As it grows the anterior branches of the spinal nerves of the corresponding segments are prolonged into it, together with a number of blood-vessels. The nerves remain as the nerves of the fully developed limb, but the blood-vessels are reduced in number and are modified until a smaller number of permanent main trunks is established.

The greater part, if not the whole, of the mesodermal core of the primitive limb-rudiment seems to be produced by the somatic mesoderm of the lateral plate. As the development proceeds it is differentiated into the cartilaginous, muscular, and other connective tissue elements which are the rudiments of the skeletal framework and the muscles and fasciæ of the adult limb.

It is not yet decided whether or not the muscle elements of the mesodermal core are derived from the lateral plate mesoderm or from muscle cells which have migrated into the limb, from the muscle plates of the segments from which the limb is formed and from which muscles of the body wall are developed; and although it is generally believed that the bone which replaces the cartilaginous skeletal rudiments is produced by mesodermal cells, it has been asserted that the bone-producing cells originate in the ectoderm and migrate from the surface into the interior.

FIG. 54.—LATERAL VIEW OF A HUMAN EMBRYO—9.5 mm. LONG. (Keibel and Elze, *Normaltafeln*.)

Note that the limb rudiments no longer project at right angles from the side of the body but that they are bent ventrally.

THE EARLIER MODIFICATIONS OF THE PRIMITIVE ENTODERMAL ALIMENTARY CANAL AND THE FORMATION OF THE STOMATODÆUM AND PROCTODÆUM.

The greater part of the permanent alimentary canal is derived from the entodermal sac and is therefore lined by entoderm cells. This part is enclosed in the embryo as the latter is folded off from the remainder of the zygote (Fig. 50), but its cephalic and caudal portions are formed by the enclosure of part of the external space and are, therefore, lined by ectoderm.

The cephalic part is a portion of a space called the **stomatodæum** which lies, at first, between the ventrally bent extremity of the head and the bulging pericardial region (Fig. 50). At a later period it is enclosed laterally by the rudiments of the maxillæ or upper jaws, and caudally by the mandibular rudiments.

When it first appears the stomatodæum is separated from the cephalic end of the entodermal portion of the primitive canal by the bucco-pharyngeal membrane, but when that septum disappears, during the third week, the stomatodæum communicates with the fore-gut. Subsequently it is separated into nasal and oral portions, and the latter forms that portion of the mouth in which the gums and teeth are developed.

The caudal part of the permanent canal is formed by the elevation of a surface

fold round a pit-like hollow called the **proctodæum** (Fig. 60), which is separated

FIG. 55.—SAGITTAL SECTION OF ZYGOTE SHOWN IN FIG. 38.

the cephalic extremity, the rudiment of the **thyroid gland**, and a second situated more caudally, which is the germ of the **respiratory system**, that is, of the larynx, the trachea, the bronchi, and the epithelial lining of the lungs. The eighth pouch, **Seessel's pouch**, is formed in the dorsal wall, immediately caudal to the dorsal end of the bucco-pharyngeal membrane, and it projects into the floor of the primitive cranium.

FIG. 56.—SCHEMA showing the branchial pouches, the branchial clefts, the branchial bars, and the thyreo-glossal duct and some of their derivatives. I., II., III., IV., and V., the five branchial bars.

Simultaneously with the formation of the pharyngeal pouches internally a series of clefts appear externally. They correspond in position with the first four pharyngeal pouches, and they are called the **pharyngeal** or **branchial clefts**.

By means of the pharyngeal pouches and clefts the lateral boundary of the cephalic part of the fore-gut, on each side, is divided into a series of bars, the **pharyngeal** or **branchial bars**, five in number, but the fifth is distinctly visible only in the inner aspect of the pharynx.

from the caudal part of the entodermal portion of the alimentary canal, until about the fourth week, by a membrane called the **anal membrane**, a portion of the more extensive cloacal membrane mentioned on p. 39.

Differentiation of the Fore-gut.

Derivatives of the Lateral Wall.—Shortly after the fore-gut is enclosed, and whilst it is still separated from the stomatodæum by the bucco-pharyngeal membrane, its cephalic extremity dilates to form the primitive pharynx and thereafter, a series of eight pouches are formed in its walls, five in each lateral wall; the **pharyngeal** or **branchial pouches**; two in its ventral wall, one near

The first of these bars is the rudiment of the maxillary and mandibular regions. It is called the **mandibular arch**. The second is the **hyoid arch**, and the remainder are the branchial arches proper.

When they first appear the arches extend from the level of the dorsal wall of the fore-gut to the pericardium but, as growth proceeds, and the neck is developed between the head and the pericardium, the ventral ends of the arches of opposite sides meet in the ventral wall of the primitive pharynx. The growth of the mandi-

FIG. 57.—SCHEMA OF A LONGITUDINAL SECTION OF AN EMBRYO. (After Mall, modified.) Showing dorsal and ventral diverticula for alimentary canal. The heart is not shown.

bular and the hyoid arches soon greatly exceeds that of the branchial arches proper, and the latter gradually recede from the surface until, on each side, they lie at the bottom of a depression, the **precervical sinus**, which is overlapped by the caudal border of the hyoid arch. As the overgrowth of the hyoid arch continues the opening of the precervical sinus on the surface is reduced to a narrow channel, the **precervical duct**. Afterwards this is obliterated, the sinus becomes the **precervical vesicle**,

FIG. 58.—SCHEMA showing the formation of the precervical sinus, the branchial ducts, and the precervical sulcus.

and the position of the original aperture of the precervical duct is indicated by a sulcus, the **precervical sulcus** which soon disappears. The precervical vesicle lies at the side of the third pharyngeal pouch, and it is associated with the second and fourth pouches by narrow canals, the **branchial ducts**, which are the remains of the branchial clefts. Ultimately the precervical vesicle and the branchial ducts disappear, but it has been suggested that before the vesicle disappears a part of the lobe of the thymus of the same side is formed from its wall.

The portion of the wall of the primitive pharynx which lies between each pair of visceral arches and separates the clefts externally from the pouches internally is called the **separating membrane**. In the earliest stages it consists of ectoderm, mesoderm, and entoderm; then, for a time, the mesoderm disappears to re-appear again between the two epithelial strata at a still later period.

Round the margins of the dorsal part of the first pharyngeal or mandibular cleft are formed a series of tubercles which develop into the **auricle** of the external ear, and the cavity of the cleft becomes the **external acoustic meatus** (see p. 52). The first pharyngeal pouch and the adjacent part of the cavity of the primitive pharynx becomes the **tympanic cavity** and the **auditory** (O.T. **Eustachian**) **tube**. A part of the cavity of the second pharyngeal or hyoid pouch is represented in the adult by the supra-tonsillar recess, which lies in the side wall of the pharynx above the palatine tonsil (Fig. 56).

The third pharyngeal pouch opens like the first and second directly into the cavity of the fore-gut, but the fourth and fifth pouches lie in the lateral wall of a common recess which opens by a single aperture, the **pharyngo-branchial duct**, into the cavity of the primitive pharynx (Fig. 56).

The cavities of the third, fourth, and fifth pouches ultimately disappear, but before the disappearance takes place diverticula which at first are hollow but afterwards become solid are given off from the ventro-lateral parts of each, and solid epithelial outgrowths are formed from the dorso-lateral walls of the third and fourth pouches (Fig. 56).

The ventral diverticulum from the third pouch, on each side, forms the main part of the corresponding lobe of the **thymus**, and the ventral diverticulum of the fourth pouch either takes part in the formation of the thymus or it entirely disappears. The rudiment of the thymus is formed in the neck, but as the gland differentiates it extends and it migrates caudally, until its cephalic end lies near the caudal end of the thyroid gland, at the level of the sixth ring of the trachea, and its caudal end is in the thorax at the level of the fourth costal cartilage.

The epithelial bodies derived from the third and fourth pharyngeal pouches form the structures known in the adult as the **parathyreoid bodies**. That derived from the third pouch migrates caudally more rapidly than its fellow formed from the fourth pouch; consequently the parathyreoid derived from the fourth pharyngeal pouch lies at the middle of the dorsal border of the lateral lobe of the adult thyroid gland, and the parathyreoid formed from the third pharyngeal pouch is situated at the caudal end of the lateral lobe of the thyroid gland and close to the cephalic end of the thymus.

The diverticulum formed from the ventral part of the fifth pharyngeal pouch is the **ultimo-branchial body**. After it separates from the pouch it becomes solid and is associated with the corresponding lobe of the thyroid gland, but, apparently, in the human subject, it takes no part in the formation of that gland.

Derivatives of the Ventral Wall.—The diverticulum from the ventral wall of the primitive fore-gut, which is situated nearest the cephalic or anterior end of the gut, is the rudiment of the thyroid gland. It commences in the median plane, between the ventral ends of the mandibular and hyoid arches, and grows ventrally into the substance of the neck, then turns caudally, ventral to the cartilages which form in the second, third, and fourth arches, from which the hyoid bone and the cartilages of the larynx are developed. When the caudal end of the diverticulum reaches the region where the cephalic or anterior portion of the trachea will be formed it becomes bilobed, and thus is differentiated into the isthmus and the lateral lobes of the permanent gland. The stalk of the diverticulum, which extends from what becomes the oral part of the primitive pharynx to the isthmus of the gland, is the **thyreoglossal duct**. Its cephalic end remains as the **foramen cæcum**, which is situated in the dorsum of the tongue at the junction of the ventral two-thirds with the dorsal third. The caudal end sometimes persists and is transformed into the third or pyramidal lobe of the thyroid gland, which is attached to the dorsal border of the isthmus (Figs. 56, 61).

The more caudally situated diverticulum from the ventral wall of the fore-gut is the **rudiment of the respiratory system** (Figs. 59, 60). When it first appears

it has the form of a longitudinal groove bounded at its cranial end and laterally by an elevated ridge, named by His the *furcula* (Fig. 59). The caudal end of the groove soon dilates into a pouch, and then the pouch and groove are separated by a constriction, which passes from the caudal towards the cranial end, from the more dorsal part of the fore-gut, which becomes the *œsophagus*. The constricting process ceases before the separation reaches the cranial extremity of the respiratory rudiment, which remains, therefore, in communication with the pharynx and forms the permanent laryngeal aperture. The tube formed by the separation of the groove is differentiated into the larynx and the trachea, and the caudal terminal dilatation soon divides into two lateral lobes, each of which is the rudiment of the bronchi and the lung of the corresponding side.

FIG. 59.—VIEW OF FLOOR OF PRIMITIVE PHARYNX, showing the furcula with the groove, from which arise the cavities of the larynx, the trachea, the bronchi, and the alveoli of the lungs.

The Tongue.—The tongue is formed by *four separate rudiments* which lie in the ventral part of the cranial end of the primitive pharynx. Two of these are elevations formed on the caudal surfaces of the ventral ends of the mandibular arches,

FIG. 60.—FURTHER DEVELOPMENT OF THE ALIMENTARY CANAL, AS SEEN IN A HUMAN EMBRYO ABOUT FIVE WEEKS OLD (Diagrammatic).

The tongue is well formed, the trachea and œsophagus are separated, the bronchi have commenced to branch: the duodenal curve is well formed, and the cæcum has appeared in the loop of the mid-gut. The cloaca is partially separated into genito-urinary and rectal portions.

one on each side. The third is a median elevation, the *tuberculum impar*, which is situated immediately caudal to the conjoined ventral ends of the mandibular arches,

and the fourth, called the **copula**, formed by the conjoined ventral ends of the second arches, is separated from the tuberculum impar by the orifice of the thyroid rudiment (Fig. 61).

The two lateral elevations on the mandibular arches unite to form the greater part of the ventral or anterior two-thirds of the tongue, upon which all the papillæ

FIG. 61.—SCHEMA showing stages in the development of the tongue.

are developed. The tuberculum impar either disappears or it forms the median part of the anterior two-thirds of the organ. The posterior or dorsal third of the tongue, which lies in the ventral or anterior wall of the permanent pharynx, is formed from the copula of the second arches. It follows from what has been said

FIG. 62.—SCHEMA showing further stages in the development of the diverticula from the primitive gut and modifications of the mid-gut and the mid-gut regions. The heart is not shown. (After Mall, modified.)

that the commencement of the thyroid rudiment, which persists in the adult as the foramen cæcum of the tongue, must lie at the junction of the dorsal third with the ventral two-thirds. In many cases it appears to lie in the dorsal end of the ventral two-thirds, a position which may be associated with the fact that in some cases the rudiment of the thyroid passes through the substance of the tuberculum

impar and not from between the tuberculum impar and the ventral ends of the hyoid arches.

Derivative of the Dorsal Wall (Seessel's Pouch).—The dorsal diverticulum from the cranial end of the fore-gut, to which the above term is applied, enters the base of the occipital region of the primitive head. The ultimate fate of the pouch is unknown in the human subject, but it has been suggested that it is represented by a depression in the mucous membrane of the cranial part of the pharynx, close to the pharyngeal tonsil, which is known as the pharyngeal bursa.

The reader who has followed this description will have noted that from the cranial portion of the fore-gut are formed the caudal or inferior part of the mouth (with the exception of the lips, teeth, and gums), the pharynx, the thyroid gland, the thymus, the parathyroids, the respiratory organs, and the œsophagus. The more caudally situated portion of the fore-gut is differentiated into the stomach and the first and second parts of the duodenum.

The stomach is formed from the part of the fore-gut immediately adjacent to

FIG. 63.—SCHEMA showing complete separation of cloaca into dorsal and ventral parts and the temporary ventral hernia of a portion of the gut through the umbilical orifice. The heart is not shown. (After Mall, modified.)

the œsophagus, and the duodenum from the more caudally placed portion, which is directly continuous with the mid-gut.

The Liver and Pancreas.—When the embryo is about three weeks old and has attained a length of 2.5 mm. a ventral diverticulum appears in the ventral wall of the duodenal part of the fore-gut, and when the age of the embryo is about four weeks and its length increased to about 4 mm. a diverticulum is formed in the dorsal wall a little nearer the cranial end. The ventral pouch is the rudiment of the *liver*, the *gall bladder*, the *bile-ducts*, and a portion of the *pancreas*, and the remainder of the pancreas is formed from the dorsal diverticulum (Figs. 57, 62, 63).

The Derivatives of the Mid-Gut.—The mid-gut is transformed into small intestine and part of the large intestine. The exact amount of intestine formed from this portion of the primitive gut is not definitely known, but it is generally believed that it is the rudiment of the terminal part of the duodenum, the jejunum, the ileum, the cæcum and its vermiform process, the ascending colon, the right colic flexure, and the transverse colon. It is possible that the left colic flexure and a portion if not the whole of the descending colon may also be developed from this part of the gut.

It has already been noted that the mid-gut is simply that part of the entodermal

portion of the primitive alimentary tract which lies between the more definitely enclosed fore-gut and hind-gut, and that it is in free communication with the yolk-sac.

As development proceeds this portion of the alimentary canal becomes converted into a U-shaped tube which possesses a cranial and a caudal limb, and a ventral extremity which is connected with the yolk-sac by a narrowed and elongated canal, the **vitello-intestinal duct** (Fig. 57).

Upon the caudal limb of the loop, about the middle of its dorso-ventral height, an enlargement appears which is the rudiment of the **cæcum** and **vermiform process** of the adult. After this rudiment has formed the caudal limb of the loop undergoes rotation, being carried first to the left, then cranially, and finally to the right. As it is carried to the right it crosses the cranial (later ventral) aspect of the cranial limb of the loop, and when the rotation is completed the regions of the jejunum and ileum, the cæcum, the ascending and the transverse colon are defined.

After the rotation has occurred the tubular intestine formed from the mid-gut undergoes rapid elongation and is thrown into a number of coils.

When the embryo has attained the length of 10 mm., and is a little over a month old, the greater portion of the coiled gut passes through the umbilical orifice into an expansion of the coelom formed in the proximal part of the umbilical cord (see p. 47), (Fig. 63), which has replaced the allantoic or body-stalk as the medium by which the embryo is attached to the chorion. The herniated coils remain in the root of the umbilical cord until the embryo is about 40 mm. long, and about ten weeks old, when they return to the abdomen, and the coelomic space in the umbilical cord disappears.

The Derivatives of the Hind-Gut.—When the caudal portion of the hind-gut is first enclosed its terminal extremity and its ventral wall are bounded by the caudal portion of the primitive streak, which is bent ventrally during the folding-off of the embryo.

The terminal part of this portion of the gut becomes expanded, forming a chamber called the **entodermal cloaca**, into the ventral parts of which the ducts of the primitive kidneys, the pronephric or **Wolffian ducts**, open, one on each side.

The ventral part of the cephalic end of the cloaca is continuous with the allantoic diverticulum, and the dorsal part with a tubular portion of gut which forms the descending and possibly also the iliac and pelvic portions of the colon. The exact origin of the latter part of the primitive gut is uncertain, but it must be formed either from the mid- or hind-gut. As the temporary tail is formed and projected first caudally and then ventrally, by the growth energy of the nodal point situated at the caudal end of the neural tube, a diverticulum of the caudal end of the dorsal part of the cloaca is prolonged into it, forming the **tail gut**. This soon becomes shut off from the cloaca. But it entirely disappears before the temporary tail is absorbed into the caudal end of the body (Figs. 57, 62, 63).

At a later period the cloaca itself is separated into a dorsal part, the rectum, and a ventral part, the urino-genital chamber, by the formation of a septum, which commences in the angle between the allantoic diverticulum and the ventral wall of the cloaca, and is prolonged caudally till it reaches and fuses with the internal surface of the cloacal membrane, which thus becomes separated into urino-genital and anal portions, both of which disappear about the eighth week.

In both sexes the urino-genital section of the cloaca is separable into three parts: (1) a cranial part, which is converted into the urachus or middle umbilical ligament; (2) an intermediate part, which becomes the urinary bladder; and (3) a caudal part, which, in the female, is transformed into the urethra and the vestibule of the vagina, and in the male it is developed into the urethra.

Derivatives of the Stomatodæum.—When the stomatodæum is first definitely established, it is bounded cranially by the caudal surface of the ventrally bent terminal part of the head, caudally by the conjoined ventral ends of the mandibular arches, and laterally by the dorsal parts of the mandibular arches and the maxillary processes, which grow ventrally from the dorsal parts of the mandibular arches. The space is open ventrally, and it is closed dorsally by the bucco-pharyngeal membrane, which separates it from the fore-gut (Fig. 55).

The bucco-pharyngeal membrane disappears about the third week, and about the twenty-first day a diverticulum from the stomatodæum is projected into the caudal surface of the head, from the angle immediately ventral to the point where that surface originally joined the external surface of the bucco-pharyngeal membrane. The diverticulum is **Rathke's pouch**. The cranial extremity of the pouch comes into relation with the hypophyseal diverticulum from the floor of the third ventricle, and dilates. The stalk which connects the dilated terminal part of the diverticulum with the stomatodæum disappears, and the terminal vesicle becomes the anterior lobe of the hypophysis (O.T. pituitary body) (Figs. 57, 62, 63).

The Separation of the Stomatodæum into Nose and Mouth.—In the cephalic boundary of the stomatodæal space lies the ventral end of the head, which is called the **fronto-nasal process**.

Upon the fronto-nasal process, on either side of the median plane, is situated a shallow pit, the **olfactory pit**, and by the pits the process is divided into a median part, the **median nasal process**, and two lateral parts, the **lateral nasal processes**. Further, the margin of the median process is divided by a median cleft into right and left **globular processes** (Fig. 64).

The orifices of the olfactory pits are directed laterally, therefore the lateral nasal processes lie dorsal to the median nasal process in the cranial boundary of the stomatodæal space, and as their margins increase in height the pits deepen (Fig. 69).

At this period the cranial boundary of the stomatodæum is divided by the median sulcus and the olfactory pits into four projections—the two globular processes, each of which lies between the median sulcus and an olfactory pit, and the two lateral nasal processes, which form the dorso-lateral borders of the olfactory pits. The lateral boundaries are formed by the maxillary processes and the dorsal parts of the mandibular bars, and the caudal boundary is formed by the medially turned and conjoined ventral parts of the mandibular bars. Immediately cranial to the maxillary process, on each side, is the projecting eye: and leading from it, between the maxillary process and the lateral nasal process, is the **naso-lacral sulcus**.

As growth proceeds and each maxillary process grows ventrally, its extremity fuses with the caudal or posterior border of the lateral nasal process, and then, carrying the lateral nasal process with it, it fuses with the globular process of the same side.

After the fusion of the maxillary processes, and the posterior or caudal borders of the lateral nasal processes, with the globular processes has occurred, the olfactory pits are completely separated, for a time, from the stomatodæum, and they lie in the ledge which now forms the cranial boundary of the stomatodæum. This ledge consists of the two globular processes, fused into a single mass, and the two maxillary processes, the caudal or posterior¹ edges of the lateral nasal

FIG. 64.—ANTERIOR VIEW OF BOUNDARIES OF STOMATODÆUM BEFORE COMPLETION OF PRIMITIVE UPPER LIP.

FIG. 65.—SCHEMA OF ANTERIOR VIEW OF THE HEAD OF A HUMAN EMBRYO SHOWING THE COMPLETION OF THE PRIMITIVE UPPER LIP.

¹ Inferior in erect posture.

processes being shut off from the margin of the ledge by the maxillary processes (Fig. 65).

After the ledge is completed the dorsal ends of the olfactory pits are separated from the stomatodæum by a thin membrane, but this soon disappears, and the pits open again into the stomatodæal space, through apertures which are called the **primitive choanæ**.

After the formation of the primitive choanæ a ledge grows from the medial surface of each maxillary process towards the median plane, caudal to the choanæ. These ledges, the **palatine processes**, meet and fuse during the third month of foetal life, the fusion commencing ventrally and being completed dorsally in the region of the uvula. As the ledges meet and fuse, the stomatodæum is separated into a

FIG. 66.—PORTION OF THE HEAD OF A HUMAN EMBRYO ABOUT 2½ MONTHS OLD (His). The lips are separated from the gums, and the line of the common dental germ is visible in the latter. The palatine processes are growing inwards from the maxillary processes.

Urino-genital System.—The formation of the intermediate cell tract, the urino-genital chamber, and the differentiation of the external genitals in the region of the cloacal membrane are described in the account of the urino-genital system.

The development of the auditory organ is so intimately associated with the development of the pharyngeal portion of the primitive gut that a short consideration of the chief phenomena may with advantage be introduced here; but for the details of the development of the internal, middle, and external portions of the ear the student must refer to the account of the development given in association with the description of the auditory organ.

THE INTERNAL EAR, THE TYMPANUM AND AUDITORY TUBE, AND THE EXTERNAL EAR.

In the human subject, as in other mammals, the auditory organ consists of the **internal ear** or labyrinth, the middle ear or **tympanum**, with which is associated the **auditory tube** (O.T. **Eustachian**); and the **external ear**, which consists of the **external acoustic meatus** with the **auricle** at its lateral end.

The **internal ear** itself consists of two parts—the **cochlea**, which is the true organ of hearing, and the **vestibule** and the **three semicircular canals** connected with it, which are associated with the recognition of alterations in the position of the head, and, therefore, with the recognition and maintenance of equilibrium.

The whole of the internal ear is lined with ectodermal epithelium, the **auditory epithelium**, which is derived from the surface of the head of the embryo. It is recognisable in embryos of about 2.6 mm. (Fig. 67) as a thickened and slightly depressed plate of ectodermal cells which lies on the surface of the head, in the region of the hind-brain, dorsal to the second branchial cleft. As development

cranial and a caudal portion. The cranial part is the **nasal cavity**; it is soon divided into two lateral halves by a septum which passes caudally from the base of the cranium. The caudal portion of the stomatodæum blends with the ventral part of the primitive pharynx to form the vestibule of the mouth and its derivatives, and the gums and teeth.

The details of the process by which the primitive lips are separated into the permanent lips, and the gums are defined, are described in the section dealing with the digestive system.

The Derivative of the Proctodæum.

—The proctodæum is a surface depression which owes its origin to the elevation of the surface round the margin of the anal membrane. It forms the lower portion of the pars analis recti of the adult.

proceeds the plate is gradually invaginated into the substance of the head, and is

transformed into a pear-shaped vesicle, the **otic vesicle**, which remains for a time in communication with the exterior by means of a short tubular stalk, the **recessus labyrinthi**, which is subsequently converted into the **ductus endolymphaticus**.

After it is separated from the surface the otic vesicle alters its position until its ventral end lies in close relation to the dorsal wall of the pharynx, and, at the same time, it undergoes alteration of shape. The ventral part of the vesicle grows towards the median plane, along the ventral wall of the hind-brain. It forms the cavity and the lining epithelium of the **cochlea**; but it remains in connexion with the dorsal part by means of a narrow tube, the **canalis reuniens**, and as it grows in length it becomes converted into a spiral tube.

The portion of the dorsal section of the primitive vesicle, which lies to the lateral side of the **ductus endolymphaticus**,

first expands and then becomes compressed and

constricted into the form of three flat purse-like diverticula which, by the partial obliteration of their cavities, become converted into the three **semicircular canals** (see Sense Organs). The more ventral part of the dorsal section of the vesicle is divided, by a constriction of its lateral wall, into a dorsal part, the **utricle**, which remains in connexion with the semicircular canals, and a ventral part, the **saccule**, which is united to the cochlea by the **canalis reuniens**. The apex of the constriction which separates the utricle from the saccule passes gradually into the mouth of the **ductus endolymphaticus**, which is thus transformed into a Y-shaped tube connecting the utricle with the saccule. At a later period the closed extremity of the **ductus endolymphaticus**, which was originally connected with the surface of the head, becomes dilated and forms the **saccus endolymphaticus**. This is found,

in the adult, in the posterior fossa of the skull, lying in relation with the posterior surface of the petrous part of the temporal bone.

The **tympanum** and the **auditory tube** (O.T. **Eustachian**) are developed from the first visceral pouch.

The ventral part of the pouch disappears at an early stage. The dorsal extremity expands and is converted into the cavity of the **tympanum**, whilst the stalk of connexion with the pharynx is gradually constricted off from its lateral to-

wards its medial end, and is converted into the auditory tube. The constriction commences when the embryo has attained a length of about 20 mm., that is about the beginning of the eighth week, and is completed about the end of the week when the embryo is about 25 mm. long.

After the auditory tube is defined it grows rapidly in length, and cartilage appears in its walls during the fourth month.

As the tympanic cavity increases in size the auditory ossicles—*stapes*, *incus*, and *malleus*, which are differentiated from the dorsal ends of the cartilages of the first and second branchial arches, are invaginated into it.

The **membrana tympani**, which separates the tympanum from the external acoustic meatus, is formed from the separating membrane which intervenes between the first branchial pouch and the first cleft. It consists, therefore, of an external covering of ectoderm, an internal lining of entoderm, and an intervening layer, of fibrous tissue, derived from the mesoderm.

The **external ear** is developed from the cavity and the boundaries of the first branchial cleft. The cavity of the cleft is transformed into the cavity of the external acoustic meatus, and on the mandibular and on the hyoid margins of the

cleft three eminences appear. From the eminences on the two arches, and the skin immediately posterior to the eminences on the hyoid arch, are formed the various parts of the auricle, but the exact part played by the individual eminences in the human subject is as yet a matter of some doubt.

THE PROTECTION AND NUTRITION OF THE EMBRYO DURING ITS INTRA-UTERINE EXISTENCE.

Whilst it is passing down the uterine tube, and for a brief period after it enters the uterus, the zygote, or impregnated ovum, depends for its nutrition upon the yolk granules (deutoplasm) embedded in its cytoplasm, and upon the fluid medium surrounding it which is secreted by the walls of the uterine tube and the uterus.

As the human ovum is very small, and as it contains but little deutoplasm, its nutrition is practically dependent, almost from the first, upon external sources of supply. The urgent necessity for the formation of adequate arrangements whereby the external sources may be utilised leads to the early establishment of an intimate connexion between the zygote and the mother, which is one of the characteristic features of the development of the human embryo.

During the third week after fertilisation, as the embryo is beginning to be moulded from the embryonic region, and before the paraxial mesoderm commences to separate into mesodermal somites, a primitive heart and the rudiments of some well-defined blood-vessels are distinguishable in the embryo; but the details of the development of the vascular system and the establishment of the embryonic circulation cannot be well understood until the formation and structure of a group of closely associated extra-embryonic organs or appendages, derived from the zygote, has been considered.

This group includes the chorion, the placenta, the amnion, the umbilical cord, and the yolk-sac.

THE MEMBRANES AND APPENDAGES.

The Chorion.—It has already been noted that when the zygote becomes a blastula it consists of three vesicles, a large vesicle enclosing two smaller vesicles and a mass of primary mesoderm (Fig. 29).

The wall of the large vesicle is composed of trophoblast (trophoblastic ectoderm), and its inner surface is in direct contact with the primary mesoderm.

A little later a cavity, the **extra-embryonic coelom**, appears in the primary mesoderm, separating it into two layers, one lining the inner surface of the trophoblast and the other covering the outer surfaces of the two inner vesicles (Figs. 70, 71).

As soon as the extra-embryonic coelom is established the **chorion** is formed; it consists of the trophoblast and its inner covering of mesoderm.

In the meantime the trophoblast has differentiated into two layers, an inner cellular layer, and an outer plasmodial layer. In the plasmodial layer cell territories are not defined, and it consists, therefore, of nucleated protoplasm.

The differentiation of the trophoblast into two layers occurs after the zygote has become embedded in the mucous membrane of the uterus which is modified for its reception and, after the modification has occurred, is called the **decidua**.

As development proceeds the trophoblast increases in thickness and it invades the decidua. As this invasion occurs the plasmodial layer of the trophoblast becomes permeated with spaces which are continuous with the lumina of the maternal blood-vessels in the decidua, and are filled with maternal blood.

By means of the spaces the plasmodial trophoblast is separated into branching processes which intervene between the blood-filled spaces. The processes are the **primary chorionic villi**, and they soon develop cellular interiors (Fig. 72).

After a time the primary villi are invaded by the chorionic mesoderm, and are thus converted into the **secondary chorionic villi**, which become vascularised by the

growth of foetal vessels into the foetal mesodermal cores. The secondary villi, therefore, consist of a mesodermal core covered by a layer of cellular trophoblast and a layer of plasmodium, the latter lying outside the former. Still later the

secondary villi send out numerous branches into the blood spaces, and thus increase greatly in complexity (Figs. 75, 76, 77).

As development progresses still further a part of the chorion is converted into the foetal portion of an organ called the **placenta**, and thus the chorion is divided into placental and non-placental regions. Upon the placental part the villi continue to increase, but they disappear entirely from the non-placental part, which is then called the **chorion laeve** (Fig. 77).

The Amnion, the Body-Stalk (Allantoic Stalk), and the Umbilical Cord.—The amnion is formed from that portion of the wall of the larger of the two inner vesicles of the zygote, the ecto-mesodermal vesicle (p. 22), which does not take part in the formation of the embryo. It consists of ectoderm cells covered externally by a layer of extra-embryonic mesoderm, and it is continuous with the margin of the embryonic area (Figs. 70, 71).

The cavity of the ecto-mesodermal vesicle, enclosed between the amnion and the embryonic area, is the **cavity of the amnion**; it is filled with fluid, which raises the amnion in the form of a cupola over the embryonic region (Fig. 70).

The Body-Stalk (Allantoic Stalk).—It has been noted already that the mesoderm of the median part of the posterior portion of the amnion becomes thickened.

FIG. 72.—SCHEMA OF THREE STAGES IN THE FORMATION OF A CHORIONIC VILLUS.

In the thickened strand lies the allantoic diverticulum of the entodermal vesicle (Fig. 70), whilst through it, on either side of the allantoic diverticulum, pass the umbilical arteries and veins, by means of which blood is conveyed between the embryo and the chorion.

This strand of the wall of the amnion vesicle, with its contents, was termed by His the **body-stalk**. Apparently it takes no direct part in the formation of the

FIG. 70.—SCHEMA OF SAGITTAL SECTION OF ZYGOTE ALONG LINE A.

FIG. 71.—SCHEMA OF TRANSVERSE SECTION OF ZYGOTE ALONG LINE B (Fig. 31).

embryo, and as it contains the rudimentary allantoic diverticulum and represents the much more highly developed allantois of other forms, it might, with advantage, be named the **allantoic stalk**. For the present purpose it is important to note that the blood-vessels which pass through the body-stalk enter or leave the body through the umbilical orifice, which is, at first, a relatively large aperture (Fig. 50).

As the embryonic area is folded into the form of the embryo the amnion increases in extent, filling more and more of the extra-embryonic coelom, and the embryo rises into the interior of its cavity. In other words, the walls of the amnion bulge ventrally round the cranial and caudal extremities and the lateral borders of the embryo (Figs. 75, 76, 77). As the distension of the amnion still continues, the ventral bulging round the margin of the umbilical orifice becomes more pronounced, the yolk-sac is forced farther and farther away from the embryo, the vitello-intestinal duct is elongated, and it is surrounded by a hollow tube. The cavity of the tube is an elongated part of the extra-embryonic coelom, and its walls are formed by the amnion (Figs. 57, 62, 63).

The caudal wall of the tube necessarily consists of the elongated body-stalk (allantoic stalk).

As the distension of the amnion still continues, the walls of the tube are forced against the vitello-intestinal duct, and the amniotic mesoderm fuses with the mesoderm of the vitello-intestinal duct.

When the fusion is completed, a solid cord, the **umbilical cord**, is formed (Figs. 77, 78, 80). It consists of an external covering of amniotic ectoderm, and a core of mesoderm in which lie the two umbilical arteries of the body-stalk, a single umbilical vein formed by the fusion of the two primitive veins, and the remains of the vitello-intestinal duct and the vitelline vessels. The proximal end of the umbilical cord is connected with the embryo; the distal end is attached to the chorion, and in its neighbourhood lies the now relatively small vesicular yolk-sac (Fig. 62).

As the amnion grows still larger, all that part of its outer surface which does not take part in the formation of the umbilical cord is ultimately pressed into contact with the inner surface of the chorion, with which it fuses, and the cavity of the extra-embryonic part of the coelom is obliterated (Fig. 78).

The outer wall of the zygote now consists of the fused chorion and amnion, and it contains in its interior the amniotic cavity and the embryo, which is attached to the chorion by the umbilical cord.

When it is first formed the umbilical cord is comparatively short, but as the amniotic cavity increases the cord elongates, until it attains a length of from 18 to 20 inches, a condition which allows the embryo to float freely in the fluid in the amniotic cavity, whilst its nutrition is provided for by the flow and return of blood, through the umbilical cord, to and from the placenta, where interchanges take place between the maternal and the foetal blood.

The Yolk-Sac or Umbilical Vesicle.—When the embryonic area is folded into the form of the embryo, the entodermal vesicle is differentiated into three parts: (1) a part enclosed in the embryo, where it forms the **primitive entodermal alimentary canal**; (2) a part which lies external to the embryo in the extra-embryonic coelom—this is the **yolk-sac or umbilical vesicle**; (3) the third portion is the **vitello-intestinal duct**, which connects the primitive alimentary canal and the yolk-sac together (Figs. 40, 62).

The walls and the cavity of the yolk sac are, therefore, continuous with the walls of the primitive alimentary canal, and the structural features of the two are identical, each consisting of an internal layer of entodermal cells and an external layer of splanchnic mesoderm.

Free communication between the yolk-sac and the primitive alimentary canal

FIG. 73.—SCHEMA OF A TRANSVERSE SECTION OF A SECONDARY CHORIONIC VILLUS. A loop of the afferent vessel has been cut at two points.

appears to exist in the human subject till the embryo is three weeks old and about 2.5 mm. long. During the fourth week the vitello-intestinal duct is elongated into a relatively long narrow tube, which is lodged in the umbilical cord, and the yolk-sac, which has become a relatively small vesicle, is placed between the outer surface of the amnion and the inner surface of the chorion, in the region of the placenta (Fig. 62). During the latter part of the fourth or the early part of the fifth week, when the embryo has attained a length of about 5 mm., the vitello-intestinal duct separates from the intestine and commences to undergo atrophy, but remnants of it may be found in the umbilical cord up to the third month.

The yolk-sac itself persists until birth, when it is, relatively, a very minute object which lies either between the amnion and the placenta or between the amnion and the chorion lve.

At a very early period, before the paraxial mesoderm has commenced to divide into mesodermal somites, a number of arteries, the **primitive vitelline arteries**, are distributed to the yolk-sac from the primitive arterial trunks of the embryo, the primitive aort, and the blood is returned from the yolk-sac to the embryo by a pair of **vitelline veins** (Fig. 81).

After a time the arteries are reduced to a single pair, and after the two primitive dorsal aort have fused into a single trunk, the pair of vitelline arteries also becomes converted into a single trunk, which passes through the umbilical orifice along the vitello-intestinal duct to the yolk-sac (Fig. 83).

The vitelline veins also pass through the umbilical orifice on their way to the heart of the embryo, and they become connected together, in the interior of the body of the embryo, by transverse anastomoses, which are described in the account of the development of the vascular system.

After the umbilical cord is formed, the extra-embryonic parts of the vitelline veins disappear, and can no longer be traced in the cord. The same fate overtakes the extra-embryonic and a portion of the intra-embryonic part of the vitelline artery, and the remainder of the artery persists as the superior mesenteric.

THE PLACENTA.

The placenta is an organ developed for the purpose of providing first the embryo and later the ftus with food and oxygen, and for removing the effete products produced by the metabolic processes which take place in the growing organism. It is formed partly from the zygote and partly from the mucous membrane of the uterus of the mother.

In the placenta the blood-vessels of the embryo of the earlier stages and the ftus of the later stages and the blood of the mother are brought into close relationship with one another, so that free interchanges may readily take place between the two blood streams; and the modifications and transformations of the uterine mucous membrane and the chorion of the zygote, by which this intimate relationship is attained, constitute the phenomena of the development of the placenta.

The details of the development of the human zygote for the first ten or twelve days after the fertilisation of the ovum are not known, but the knowledge of what happens in other mammals justifies the belief that during that time the zygote is formed, in the uterine end of the uterine tube, by the union of a spermatozoon with the mature ovum. During the first ten to fourteen days after its formation it passes along the uterine tube, towards the uterus, whilst, at the same time, it undergoes the divisions which convert it into a morula.

The Formation of the Placenta.—Before the zygote reaches the uterus the mucous membrane which lines the cavity of that organ undergoes changes, in preparation for its reception and retention, and when the changes are completed the modified mucous membrane is known as the **uterine decidua**.

The changes which take place are, for the most part, hypertrophic in character; the vascularity of the mucous membrane is increased, mainly by the dilatation of its capillaries; the tubular glands of the membrane are elongated, they become

tortuous, and dilatations form in their walls a short distance from their outer closed extremities. At the same time the interglandular tissue increases in amount, and as a result of the various processes the decidua is thicker, softer, more spongy, and more vascular than the mucous membrane from which it was evolved.

Partly on account of the dilatation of the deep part of the glands and partly on account of differences in texture of the internal as contrasted with the external part of the decidua, the membrane may be looked upon as consisting of three layers. (1) An internal layer, next the cavity, the **stratum compactum**. (2) An intermediate layer, the **stratum spongiosum**, formed largely by the dilated parts of the glands. (3) An external layer, the **unchanged layer**, in which lie the comparatively unaltered outer ends of the glands.

When the zygote, in the morula stage, reaches the uterus, from the tenth to the fourteenth day, it acts as a parasite, eats its way through the epithelium on the surface of the decidua, and implants itself in the stratum compactum.

The zygote may penetrate the decidua at any point of the wall of the uterine cavity, but it usually enters at some point of the dorsal or the ventral wall. The entrance generally takes place between the mouths of adjacent glands, which are pushed aside, and the zygote becomes at once surrounded by the interglandular tissue of the stratum compactum of the decidua. The aperture through which it passes may be closed by a fibrinous plug or its margins may converge rapidly and fuse together.

The portion of the decidua in which the zygote is embedded is thicker than the other parts of the membrane, and it is separated by the zygote into an internal part, the **decidua capsularis**, and an external part, the **decidua basalis**. The junction of the decidua capsularis with the decidua basalis is the **decidua marginalis**, and the remainder of the decidua, by far the larger portion, is the **decidua vera**.

As soon as the zygote becomes embedded in the decidua its trophoblast undergoes rapid proliferation. The superficial part of the growing trophoblast becomes converted into a mass of nucleated protoplasm, the plasmodial or syncytial layer, but the inner part remains more or less distinctly cellular.

The plasmodial portion of the trophoblast invades and destroys the surrounding maternal tissue, and at the same time spaces appear in its substance. As the plasmodium destroys the walls of the dilated maternal blood-vessels, channels are made through which the maternal blood flows into the spaces in the plasmodium, and thus maternal blood begins to circulate in the tissue of the zygote.

In the meantime the extra-embryonic coelom has appeared in the primary mesoderm of the zygote, and the outer layer of the mesoderm has associated itself with the trophoblast to form the chorion.

The spaces in the plasmodium enlarge rapidly after the maternal blood

FIG. 74.—SCHEMA OF A FRONTAL SECTION OF THE UTERUS, showing the various parts of the decidua and a zygote embedded in the decidua.

FIG. 75.—SCHEMA OF A SECTION OF A PREGNANT UTERUS AFTER THE FORMATION OF THE INTERVILLOUS SPACES.

ates into a cellular core and plasmodial periphery, and thereafter the villi are invaded by the mesoderm of the chorion and are thus converted into **secondary villi** (Fig. 76).

The first-formed villi are non-vascular, but by the time the secondary villi have developed the umbilical arteries have grown through the body-stalk (allantoic stalk) into the mesoderm of the chorion, and branches from them enter the mesodermal cores of the villi, which thus become vascular.

When the secondary villi are fully developed each consists of a vascular mesodermal core continuous with the mesoderm of the chorion. The mesodermal core is covered

FIG. 76.—SCHEMA OF A FRONTAL SECTION OF A PREGNANT UTERUS AT THE PERIOD OF THE FORMATION OF THE EMBRYO. Note extension of amnion as contrasted with stage shown in Fig. 75.

by a layer of cellular trophoblast, *Langhan's layer*, which lies next the mesoderm, and a layer of plasmodium external to the cellular layer. The proximal end of each villus is continuous with the chorion plate of the intervillous spaces, formed by the chorion, and the distal extremity is connected by the plasmodial basal layer of the trophoblast, which forms the outer boundary of the intervillous spaces and which is fused with the maternal decidual tissue.

After a time branches are projected from the sides of the secondary villi into the intervillous spaces. In this way two sets of secondary villi are differentiated, (1) the **anchoring villi** (Fig. 79), which cross from the chorion to the

FIG. 77.—SCHEMA OF A SECTION OF A PREGNANT UTERUS AFTER THE FORMATION OF THE UMBILICAL CORD. Note that the expanding amnion has almost obliterated the extra-embryonic coelom which lies between it and the chorion.

basal layer of trophoblast and are attached to the latter by cell columns, which are the remains of the primary villi which have not been penetrated by the foetal mesoderm, and (2) **free or absorbing villi** (Fig. 76), which extend from the sides of the original secondary villi into the blood, in the intervillous spaces.

Whilst the trophoblastic invasion of the compact layer of the decidua is proceeding, not only are the interglandular elements of the decidua destroyed, but the walls of the glands also, and, as a consequence, some of the glands in the decidua basalis open for a time into the intervillous spaces, and become filled with blood which passes from the spaces into the gland cavities. In many cases, however, before the glands are destroyed their walls are converted into solid strands of cells, and thus the cavities of their more external undestroyed portions are converted into closed spaces.

In the early stages the trophoblast is differentiated in a similar manner over

the whole of the surface of the zygote, and thus, for a time, the whole of the surface of the chorion is covered with villi. As the embryo grows, and the amnion and the extra-embryonic cœlom are distended, the zygote increases in size, and the capsular portion of the decidua is stretched till its vascular supply is interfered with and the villi associated with it undergo atrophy and disappear. When these degenerative changes have occurred, the portion of the chorion in association with the thinned decidua capsularis presents a relatively smooth surface, and is known as the **chorion læve**. Whilst the decidua capsularis is being stretched and thinned, and the associated portion of the chorion is being reduced to the condition of a non-villous region, the decidua basalis increases in thickness; at the same time the villi associated with it increase in size and in the complexity of their branches. The portion of the chorion from which these large villi spring is termed the **chorion frondosum**. It is this portion of the chorion which takes

FIG. 78.—SCHEMA OF A SECTION OF A PREGNANT UTERUS AFTER FUSION OF AMNION AND CHORION.

part in the formation of the so-called **fœtal portion** of the placenta, the **maternal part** of that organ being formed by the decidua basalis.

The placenta, therefore, is formed partly by the zygote and partly by maternal tissues, but the interchanges between the fœtal and the maternal blood take place in the tissue of the zygote through the trophoblast which covers the surfaces of the villi.

As the growth of the embryo and the distension of the amnion continue, the outer surface of the amnion is gradually forced against the inner surface of the chorion, with which it fuses. When this fusion is completed the extra-embryonic cœlom is obliterated and the zygote contains only one extra-embryonic cavity, the amniotic cavity, in which the fœtus floats in the amnion fluid (Fig. 78).

At this period the amnion cavity is bounded by a wall formed by the fused amnion chorion and decidua. In the meantime the chorion has differentiated into the chorion læve, fused with the decidua capsularis, and the chorion frondosum, fused with the decidua basalis. As the distension of the amnion proceeds to a still greater extent, the part of the wall of the cavity formed by the fused amnion chorion læve and the decidua capsularis projects more and more into the cavity

of the uterus, until it is forced against the surrounding wall of the uterine cavity, where it fuses with the decidua vera, and thus the cavity of the uterus is obliterated. This fusion takes place towards the end of the second month, and as soon as it has occurred the discoid mass of placental tissue is continuous at its margin with the fused amnion, chorion, and decidua vera (Fig. 78).

After the second month the foetus lies in the amnion cavity, which is bounded by the fused chorion and uterine wall, except at the lower end of the uterus, where, over the orificium internum, the cavity of the body of the uterus communicates with the cavity of the neck of the uterus; there the amniotic cavity is bounded by a membrane formed by the fused amnion chorion laeve and the decidua capsularis only.

And at the end of pregnancy this portion of the membrane is ruptured by the increased pressure of the amnion fluid produced by the contraction of the muscular wall of the uterus (Fig. 88).

FIG. 79.—SCHEMA OF STRUCTURE OF COMPLETED PLACENTA.

Completion of the Placenta.—It has already been stated that each secondary villus consists of a vascular mesodermal core covered by a cellular and a plasmodial layer of trophoblast, the latter lying next the maternal blood in the intervillous spaces. As development proceeds and the intervillous spaces become larger, the villi become longer and more complicated, and at the same time the cellular layer of the trophoblast largely disappears, until in the majority of the villi the plasmodial layer alone covers the vascular mesodermal core.

In still later stages, degenerative changes occur not only in the villi, but also in the chorionic plate of the intervillous spaces and in the basal trophoblast which closes the spaces externally. One of the results of the degenerative processes is the deposit of fibrinoid material in the place originally occupied by the trophoblast; the object of this process is still unknown: another is the adhesion of the fibrinous layers on the surfaces of adjacent villi, and the fusion of the villi thus connected into masses of intermingled fibrinous and vascular tissue.

When the chorionic part of the placenta is completed it consists of (1) the

chorion plate closing the intervillous spaces internally; (2) the villi; (3) the intervillous spaces; and (4) the basal layer of the trophoblast, which closes the intervillous spaces externally, and is perforated by the maternal vessels passing to and from the spaces.

The maternal portion of the completed placenta consists from within outwards of (1) the basal layer of the decidua; (2) the remains of the spongy layer of the decidua; and (3) the unchanged layer.

FIG. 80.—SCHEMA OF PREGNANT UTERUS IMMEDIATELY AFTER BIRTH OF THE CHILD, showing commencing separation of the placenta. Part of the umbilical cord is shown in section and part in surface view. The blue streaks in the former part indicate the position occupied by the vitello-intestinal duct in earlier stages.

The basal layer of the decidua is the remains of the compact part of the decidua basalis of earlier stages. It is fused internally with the basal plate of the trophoblast, and is continuous externally with the spongy layer. The spongy layer consists of a series of cleft-like spaces. These spaces are the compressed remains of the earlier dilated portions of the glands of the stratum spongiosum from which the epithelial lining has, to a great extent, disappeared. The spongy layer is continuous externally with the unchanged layer, in which lie the unaltered outer parts of the glands and the intervening interglandular tissue.

The maternal blood-vessels pass from the muscular wall of the uterus into the sub-mucous tissue, and thence into the placenta, where they traverse the maternal portion and the basal plate of the decidua and open into the intervillous spaces. The arteries usually open on or near the septa and the veins in the intermediate areas.

In addition, however, to the constituent parts already described, the chorionic part of the placenta contains some strands of maternal tissue, and in the maternal part there are portions of trophoblast.

The parts of the decidua found in the chorionic part of the placenta are a series of fibrous strands, the remains of parts of the stratum compactum which were not destroyed by the trophoblastic invasion. They are continuous externally with fibrous strands of the maternal part of the placenta, and serve to separate the placenta into a series of lobes, from 15 to 20 in number.

The portions of trophoblast met with in the maternal part of the placenta are variable pieces of plasmodium which appear to have wandered from the general mass. They may be found in any of the strata of the maternal part, and even in the submucous tissue.

At the end of pregnancy, when intra-uterine life terminates, the fused amnion chorion and decidua capsularis are ruptured in the region of the internal orifice of the uterus, and the amniotic fluid is expelled through the vagina. Next the foetus is extruded, and as soon as it is born it becomes a child. After the child is born it remains attached to the placenta by the umbilical cord (Fig. 80), which is usually ligatured in two places and then divided, between the ligatures, by a medical man or an attendant. Afterwards the placenta is expelled from the uterus.

Detachment of the placenta is probably caused by contraction of the muscular substance of the uterus, and it takes place by rupture of the strands of the spongy layer of the decidua (Fig. 80). As the detached placenta is expelled the decidua vera is torn through along the line of the spongy layer, and the fused amnion and chorion leave and the inner part of the decidua vera, which are attached to the margin of the placenta and which constitute the membranes, are expelled with it.

At birth the placenta weighs about 500 grm., it has a diameter of about 16 to 20 cm., and is about 3 cm. thick. Its inner surface is covered with the amnion which fused with the chorion towards the end of the second month of pregnancy. Its outer surface is rough, it is formed by the remains of the spongy layer of the decidua, and is divided into a number of areas by a series of fissures which correspond in position with the septa by which the organ is divided into lobes.

THE PRIMITIVE VASCULAR SYSTEM AND THE FETAL CIRCULATION.

As the zygote travels along the uterine tube, from the ovarian towards the uterine end, it exists either upon the yolk granules derived from the ovum or upon substances absorbed from the fluids by which it is surrounded. After it enters the uterus it must depend, for a time, upon the same sources of nutriment, but as it penetrates the decidua it is probable that the cells of the trophoblast actually devour the cells of the decidua which they invade. This source of food is only sufficient for a short period, whilst the zygote remains relatively small, and substances absorbed by its surface cells can be transmitted easily to all parts.

Whilst the period exists, however, not only are the decidual tissues utilised as a food-supply, but fluids are absorbed from them and transmitted into the interior of the zygote to fill the expanding cavities of the amnion and the coelom.

In all probability the fluids passed into the zygote contain nutritive materials which suffice for the requirements of the embryonic and non-embryonic parts of the zygote so long as both consist of comparatively thin layers of cells, but when the embryonic area increases in thickness, and begins to be moulded into the embryo, its association with adjacent fluids becomes less intimate, and as the development of its various parts progresses, a supply of food and oxygen is required which is greater than can be provided by osmosis from the adjacent fluid media. Thus an imperative necessity arises for a method of food-supply adequate to meet the increasing requirements upon which the continued development and growth depend.

To meet this necessity the **blood vascular system** is formed. The system is essentially an irrigation system. In its earliest stages it consists of a series of vessels, the blood-vessels, all of which contain a corpuscle-laden fluid, called blood. The blood is kept circulating, in the early stages, by the rhythmical contraction of the walls of the vessels, but, after a short time, parts of the vessels are developed into a muscular organ called the heart. After the heart is established the continuance of the circulation of the blood depends upon the regular contractions of the muscular substance of its walls.

The corpuscular portions of the blood and the walls of the blood-vessels are formed from the cells of the zygote, but it is obvious, in the early stages at all events, that the fluid portion of the blood must be obtained from the mother. It is necessary, therefore, both for this purpose and for the facilitation of interchanges between the foetal and maternal blood streams, that the foetal blood-vessels should be brought into close association with the maternal blood at an early period. It is for this purpose, among others, that large spaces appear in the trophoblast, become filled with blood from maternal vessels which have been opened up by the destructive action of the trophoblast cells, and are afterwards invaded by the chorionis villi, which carry in their interiors branches of the blood-vessels of the embryo. As soon as the intimate relationship between the chorionic villi and the maternal blood is established fluids can readily pass from the maternal to the foetal vessels, and there can be no doubt that both food and oxygen pass from the maternal to the foetal blood through and by the agency of the trophoblastic epithelium, whilst, at the same time, waste products of foetal metabolism pass from the foetal to the maternal blood.

The germs of the vascular system are a series of cells arranged in strands which constitute, collectively, the **angioblast**. They appear between the entodermal and the mesodermal layers of the wall of the yolk-sac, and, therefore, entirely outside the embryo; but it is not certain whether they are derived from the mesoderm or from the entoderm.

Origin of Blood Corpuscles.—After a time the angioblast separates into two parts, (1) the peripheral cells of the strands which form the endothelial walls of the primitive blood-vessels, and (2) the central cells which become the primitive blood corpuscles or **mesamœboids** (Minot).

The mesamœboids are colourless cells with large nuclei and a relatively small amount of protoplasm; from them are formed, either by transformation or division, the **erythrocytes**, which are coloured blood corpuscles, and also **nucleated colourless corpuscles**. The erythrocytes are nucleated cells with a homogeneous protoplasm which contains the substance, called **hæmoglobin**, upon which the yellowish-red colour of the cells depends, and from them are derived the fully developed **red corpuscles**.

The primitive erythrocytes, the **ichthyoid cells** of Minot, are transitory structures in mammals, but they are the permanent red blood cells of the ichthyopsida (fishes and amphibia). They are succeeded by the **sauroid blood cells** (Minot), which represent the permanent corpuscles of reptiles and birds, and which are distinguishable from the ichthyoid cells by their smaller size and more deeply-staining nuclei.

The sauroid blood cells are replaced by the **blood plastids**, which are young non-nucleated red corpuscles. According to some observers the blood plastids are sauroid cells which have lost their nuclei, whilst other investigators believe the blood plastids to be the nuclei of sauroid cells. Whatever their origin, they become converted into permanent red blood corpuscles by transformation from the spherical to a cup-shaped and later to a biconcave form.

The young red blood cells are therefore the ichthyoid cells, those progressively older are sauroid cells, blood plastids, and blood corpuscles.

The colourless, nucleated corpuscles—white blood corpuscles—are much less numerous than the coloured corpuscles in the adult blood. They appear to be derived from the mesamœboids, though it is possible that they are also formed by ordinary mesoderm cells, and as regards those formed from mesamœboids it is not certain whether a mesamœboid cell can by division produce both erythrocytes and white corpuscles, or whether it must produce one or the other.

The primitive mesamœboids are formed in the wall of the yolk-sac, and there some of them produce erythrocytes; many, however, migrate into the embryo, where some of them take part in the formation of the walls of the embryonic blood-vessels, and others become enclosed in the liver, the lymph glands, and the bone marrow, where they become foci for the formation of blood corpuscles.

During the first two months the primitive forms of red blood cells predominate. In the second month the sauroid cells increase considerably in number, and from the third month the blood plastids become more and more numerous, until, at the eighth month (Minot), the majority of the blood cells are blood plastids undergoing conversion into blood corpuscles. At this time the colourless cells are present in a very distinct minority.

FIG. 81.—SCHEMA OF CIRCULATION OF AN EMBRYO, 1.35 MM. LONG, WITH SIX SOMITES. (After Felix, modified.)

Formation of the Primitive Blood Vascular System of the Embryo.—The earliest stage of the formation of the heart and blood-vessels in the human subject are not known, but, judging by what occurs in other mammals, it is probable that the first-formed vessels appear in the splanchnic mesoderm of the pericardial region before the embryonic area begins to fold. It is presumed that they are formed by angioblastic cells which have migrated into the embryonic area from the walls of the yolk-sac. From their seat of origin they extend towards the caudal end of the embryonic area, one on either side of the notochord, and from the caudal end of the embryonic region they pass along the body-stalk into the chorion.

FIG. 82.—SCHEMA OF VASCULAR SYSTEM OF AN EMBRYO, 2.6 MM. LONG, WITH FOURTEEN SOMITES. (Arteries after Felix, modified.)

As the cephalic end of the embryonic area is folded to enclose the fore-gut, the corresponding parts of the primitive arteries are bent into a C-shaped form. The ventral limb of the C, which lies in the dorsal wall of the pericardium and the ventral wall of the fore-gut, is the **primitive ventral aorta**. The bend of the C is the **first aortic arch**, which passes along the lateral margin of the bucco-pharyngeal membrane. The dorsal limb of the C is the cranial part of the primitive dorsal aorta. The primitive dorsal aorta passes posteriorly into the tail and gives off in the region of the tail fold the **primitive umbilical artery**, which runs along the body-stalk to the chorion.

The caudal parts of the primitive ventral aortae are the rudiments of the heart. At first they lie, quite separate from each other, in the dorsal wall of the pericardium, but soon they approach one another and fuse together to form a single tubular

heart. The more cranially situated parts of the primitive ventral aortæ remain separate and take part in the formation of ventral roots of the aortic arches. Before the single heart is formed other blood-vessels have appeared, which return blood from the chorion and the yolk-sac to the heart. These vessels are the primitive veins. Two veins pass from the chorion into the body-stalk, where they fuse together to form the *vena umbilicalis impar*. This divides, at the caudal end of the embryo, into the two lateral umbilical veins, which run to the heart one along each lateral margin of the embryo. In an embryo 1.3 mm. long (Eternod), in which the paraxial mesoderm had not yet commenced to segment into mesodermal somites, each lateral umbilical vein received, as it entered the embryo, a large

FIG. 83.—SCHEMA OF VASCULAR SYSTEM OF AN EMBRYO WITH TWENTY-THREE SOMITES. (Arteries after Felix, modified.)

effluent vein from the yolk-sac. This condition, if regular, is very transitory. After a very short time the connexion of the vitelline veins with the caudal ends of the lateral umbilical veins is lost, and the blood is returned from the yolk-sac directly to the heart by two vitelline veins, one on each side, which run along the sides of the vitello-intestinal duct and receive the lateral umbilical veins close to the heart (Fig. 81).

In the meantime a number of branches have been developed from both the dorsal and the ventral walls of the primitive dorsal aortæ; the former are the somatic **pre-segmental** and **segmental arteries**, and the latter are the **primitive vitelline arteries**.

In a human embryo which has developed six distinct mesodermal somites the vitelline arteries form a plexus on the sides of the hind-gut area of the wall of the entodermal vesicle, from which the umbilical arteries appear to spring (Felix). The plexus is represented in Fig. 81 by the bulbous dilations. The vessels which enter this plexus arise from the ventral aspects of the primitive dorsal aortæ, some distance from their caudal ends. It is probable, however, that the caudal ends of the primitive dorsal aortæ are connected with the caudal part of the plexus at the points of origin of the umbilical arteries, though the connexions are not visible in the sections of the embryo mentioned (Fig. 81).

Practically the same condition is present in an embryo 1.6 mm. long possessing fourteen distinct somites, except that the main rootlets of the umbilical artery, on each side, are situated farther caudalwards than in the younger embryo, and lie in the region of the most caudal somites (Fig. 82).

Further Development of the Arterial System.—When the embryo possesses twenty-three mesodermal somites, but is still devoid of limbs, the arterial system has

FIG. 84.—DIAGRAM showing stage of five aortic arches.

advanced considerably in development. Two aortic arches, on each side, now connect the cephalic end of the heart with the primitive dorsal aorta. The umbilical artery and vitelline arteries are quite separate, and each umbilical artery springs, by a number of roots which anastomose together, from the caudal part of the corresponding dorsal aorta. The vitelline arteries are still numerous, but that which rises opposite the twelfth mesodermal somite is becoming the main artery of the yolk-sac; eventually its proximal part is transformed into the superior mesenteric artery of the fetus.

When the embryo has attained a length of 5 mm., and is about five weeks old, it possesses about thirty-eight mesodermal somites, and five aortic arches are present on each side. Commencing from the cranial end, they are the first, second, third, fourth, and sixth; the fifth arch appears subsequently between the fourth and the sixth.

All five arches pass to the corresponding dorsal aorta, but the three most caudal, on each side, spring from the cranial end of the heart, which is now called the **aortic trunk**, whilst the two most cranial rise from a common stem which constitutes their ventral roots, and which springs, also, from the aortic trunk (Fig. 84). A little later the aortic trunk gives off only two branches on each side, (1) a stem common to the first five arches, for the fifth has now appeared, and (2) the sixth arch (Fig. 85). The fifth arch is very transitory. Whilst it is present

FIG. 85.—SCHEMA OF AORTIC ARCHES OF AN EMBRYO, 9 MM. LONG. (After Tandelin, modified.) The second and third arches have atrophied and the transitory fifth has appeared.

FIG. 86.—SCHEMA OF PART OF THE ARTERIAL SYSTEM OF A FETUS SEEN FROM THE LEFT SIDE. Parts of the first and second arches, the dorsal roots of the third arches, the dorsal part of the right sixth arch, and the dorsal roots of the right fourth and fifth arches have atrophied. The position of the fifth arch is not indicated; see Fig. 84.

arch, and the parts of the primitive dorsal aortæ which lie caudal to the dorsal ends of the arches are called their **dorsal roots**.

The first two arches, on each side, disappear, and their ventral roots become the **external carotid arteries** of the adult. The ventral root of the third arch becomes the **common carotid**, whilst the third arch and the dorsal roots of the first and second arches are transformed into the **internal carotid**. The ventral root of the fourth arch on the right side becomes the **innominate artery**, and the right fourth arch forms the proximal part of the **right subclavian artery**. The remainder of the

it runs from the common ventral stem, caudal to the fourth arch, to the dorsal part of the sixth arch. It soon disappears, and no traces of it are left in the adult (Fig. 85).

The portion of the common ventral stem which lies caudal to each of the arches is called the **ventral root** of the

right subclavian is developed from the seventh right somatic segmental artery. The ventral root of the left fourth arch and the arch itself form the **arch of the aorta**. The fifth arch, as already stated, is quite transitory; it leaves no remains, therefore it is not necessary to speak of any part of the ventral stem as its ventral root. The ventral part of the sixth arch on the right side becomes the extra-pulmonary part of the corresponding pulmonary artery. On the left side it disappears. On the right side the dorsal part disappears, but on the left side it persists, till birth, as the **ductus arteriosus**, which connects the pulmonary artery with the aorta, and after birth it is converted into the **ligamentum arteriosum**. The truncus arteriosus is cleft into two parts by a spiral septum; one part, which remains continuous with the ventral roots of the fourth arches and therefore with the innominate artery and the aortic arch, becomes the **ascending aorta**, and the other, which remains associated with the sixth arches, becomes the **stem of the pulmonary artery**.

Whilst the changes mentioned have been taking place in the cephalic part of the arterial system, the primitive dorsal aortæ have fused together from a point immediately caudal to their seventh dorsal branches to a point immediately cranial to the origins of the umbilical branches from their ventral aspects, and their ventral branches have fused together into single stems, some of which have been converted into the celiac, the superior mesenteric, and the inferior mesenteric arteries. The fusion of the dorsal aortæ commences in embryos about 2·5 mm. long. When the embryo has attained a length of 5 mm. the fusion has extended to the caudal ends of the aortæ and the single stem is continued into the rudimentary tail as the caudal artery, which afterwards becomes the middle sacral artery. After the fusion is completed the umbilical arteries spring from the ventral aspect of the single dorsal aorta. (For the further history of the arterial system, see under Vascular System.)

FIG. 87.—SCHEMA OF PART OF THE VASCULAR SYSTEM OF A FETUS SEEN FROM THE FRONT. Showing the origin of the positions of the first and second arches, the dorsal roots of the third arches on both sides, and the dorsal roots of the fourth and fifth arches on the right side are shown in dotted lines. The positions of the fifth arches are not shown.

veins, which convey the blood from the yolk-sac.

Two umbilical veins enter the body-stalk and unite to form the **vena umbilicalis impar** (Fig. 81). This divides, at the posterior margin of the umbilicus, into the **right** and **left lateral umbilical veins**, which run round the lateral margins of the umbilical orifice, in the lateral margins of the body wall of the embryo. At the cranial margin of the umbilicus they turn medially, enter a transverse bar of mesoderm which forms the caudal boundary of the pericardium and is known as the **septum transversum**, and pass through it into the caudal end of the heart (Figs. 81, 82).

The blood from the yolk-sac passes, for a short time, into the lateral umbilical veins at the posterior margin of the umbilicus. This is a very transitory arrangement, and it is soon replaced by the formation of two proper vitelline veins, one on each side, which ascend, along the vitello-intestinal duct, to the cranial margin

The Primitive Venous System.—The first definite venous trunks to appear are the umbilical veins, returning blood from the chorion, and the vitelline

of the umbilicus, where they enter the septum transversum, in which each vitelline vein joins the corresponding umbilical vein, forming a common vitello-intestinal trunk, which enters the sinus venosus (Fig. 81).

This trunk also receives the **primitive head vein**, or **anterior cardinal vein**, which returns the blood from the cranial part of the embryo (Fig. 82).

FIG. 88.—DIAGRAM OF THE FETAL CIRCULATION.

A little later two veins are formed, one on each side, which return blood from the body wall and the primitive limbs. They are the **posterior cardinal veins**, and as soon as they are established they join the caudal ends of the anterior cardinal veins to form the ducts of Cuvier, which then open directly into the posterior part of the heart which is called the sinus venosus (Fig. 83). Shortly afterwards the common stems of the vitello-umbilical veins are absorbed into the sinus venosus, forming its right and left horns. When this has happened six veins open into

the sinus venosus, three on each side—the two ducts of Cuvier, the two vitelline veins, and the two lateral umbilical veins (Fig. 83).

The anterior cardinal veins and their tributaries, and cross anastomoses which form between them, are transformed into some of the cranial blood sinuses, the internal jugular veins, the innominate veins, and the cephalic (upper) part of the superior vena cava. The right duct of Cuvier becomes the caudal part of the superior vena cava, and the left is converted into the oblique vein of the left atrium (O.T. oblique vein of Marshall) (Fig. 88).

A portion of the abdominal part of the right posterior cardinal vein is replaced by the right **subcardinal vein**, and from this and a transverse anastomosis between it and the opposite subcardinal vein is formed that part of the inferior vena cava which extends from the renal veins to the liver, and a part of the left renal vein. From the remains of the cardinal veins and transverse anastomoses between them are formed (1) the azygos, the hemiazygos, and the accessory hemiazygos veins; (2) the inferior vena cava, caudal to the renal veins; (3) the common iliac veins; (4) the hypogastric veins; and (5) the parts of the left lumbar veins which pass dorsal to the aorta (Fig. 88).

The cephalic end of the inferior vena cava is formed from the cephalic extremity of the right vitelline vein and a caudal outgrowth from it which unites with the right subcardinal vein (Fig. 88).

Details of the history of the transformations of the cardinal veins, the vitelline and umbilical veins, and the formation of the cranial part of the inferior vena cava are given in the account of the further stage of the development of the vascular system.

The Primitive Heart.—The primitive heart is formed in the dorsal wall of the pericardium, ventral to the fore-gut, by the fusion of the caudal parts of the primitive ventral aortæ, and shortly after its formation it is divided into five primitive chambers. The most caudal of the five, which receives the main primitive veins, is the **sinus venosus**, the second is the **atrium**, the third the **ventricle**, the fourth is the **bulbus cordis**, and the fifth and most cranial is the **truncus aorticus**, which discharges its contents into the ventral roots of the aortic arches (Fig. 84).

During the period which intervenes between the time when the embryo is 8 mm. and 17 mm. long, that is between the fifth and the eighth weeks, the greater part of the sinus venosus is absorbed into the atrium; the ventricle and the atrium are each divided into right and left chambers by the formation of an interatrial and an interventricular septum; the bulbus cordis is absorbed partly into the ventricle and partly into the truncus aorticus, and the truncus aorticus is separated into the ascending part of the aorta and the stem of the pulmonary artery. When these changes are completed the heart consists of right and left atria and right and left ventricles. The ventricles are entirely separated from one another by the interventricular septum, but there is an orifice of communication between the right and left atria (Fig. 88).

The right atrium receives blood from the superior and inferior venæ cavæ, and from the walls of the heart, by the coronary sinus, which is a remnant of the transverse part and left horn of the sinus venosus. The blood which enters through the superior vena cava and by the coronary sinus, passes through the right atrio-ventricular orifice into the right ventricle, but the whole, or the greater part, of the blood which enters by the inferior vena cava passes through the foramen ovale, which lies in the interatrial septum, into the left atrium.

The blood which enters the right ventricle is ejected into the pulmonary artery. A small portion of it passes by the right and left branches of the artery into the lungs, and is returned to the left atrium by the pulmonary veins, but by far the greater part passes through the ductus arteriosus into the aorta, which it enters at a point immediately beyond the origin of the left subclavian artery (Fig. 88).

The blood which passes into the left atrium, through the foramen ovale, mixes, in the left atrium, with a small amount of blood which is returned by the pulmonary veins; then it passes through the left atrio-ventricular orifice into the left ventricle, by which it is forced into the aorta. Some of this blood passes into the innominate artery, and so, by its right subclavian branch, to the right upper

extremity, and by its right common carotid branch to the right side of the head and neck; another part enters the left common carotid artery and is distributed to the left side of the head and neck, and some passes through the left subclavian artery to the left upper limb. The remainder mixes with the blood which enters the aorta, from the right ventricle, through the pulmonary artery and the ductus arteriosus. Part of this mixed blood is distributed to the body and the viscera, and the remainder passes through the umbilical arteries to the placenta (Fig. 88).

The Fœtal Circulation.—When the fœtal circulation is thus fully established, purified oxygenated blood, returning from the placenta, enters the body of the fœtus by the umbilical vein and passes to the liver. Some of it enters the liver, but the greater part passes, through a channel called the **ductus venosus**, to the inferior vena cava, where it mixes with the venous blood returning from the lower limbs and the abdominal region, including the liver. This mixed, but, as contrasted with the blood in the superior vena cava, comparatively pure blood enters the right atrium and passes through it and through the foramen ovale into the left atrium, thence to the left ventricle and through the left ventricle into the aorta. A portion of this comparatively pure blood is distributed to the head and neck and the upper limbs. The remainder unites with the stream of venous blood poured into the aorta through the ductus arteriosus. Part of it is distributed to the body and the lower limbs, and part is sent to the placenta to be purified and oxygenated (Fig. 88).

The remaining part of the blood stream is formed by the blood returned from the head and neck, the upper part of the body and the upper limbs, by the superior vena cava, and from the walls of the heart by the coronary sinus. It is the most venous and impure blood in the body. After entering the right atrium it passes into the right ventricle, and thence into the pulmonary artery. A very small part of it is passed to the lungs, by the right and left branches of the pulmonary artery; the remainder goes through the ductus arteriosus into the aorta, where, beyond the origin of the left subclavian artery, it mixes with the much purer blood which entered the aorta from the left ventricle.

At birth, when the placental circulation ceases, the lungs become the organs through which oxygen enters and carbonic acid leaves the blood; the foramen ovale in the interatrial septum closes, and the ductus arteriosus is obliterated. The course of the circulation and the condition of the blood in the different regions is, therefore, considerably altered.

On account of the cessation of the placental circulation all the blood which enters the right atrium is entirely venous, and, as the foramen ovale is closed, it all passes into the right ventricle, which forces it into the pulmonary artery. As the ductus arteriosus is closed, all the blood which enters the pulmonary artery must now pass through the lungs, where it is ærated, and whence it is returned, by the pulmonary veins, as oxygenated blood, to the left atrium. It passes from the left atrium to the left ventricle, which forces it through the aorta and its branches to all parts of the head, neck, body, and limbs; and now, for the first time, all parts receive blood of the same quality.

THE CŒLOM.

It has already been pointed out that there are two parts of the cœlom, the extra-embryonic and the intra-embryonic. Both are clefts separating an outer from an inner layer of mesoderm.

The Extra-embryonic Cœlom.—The extra-embryonic cœlom appears in the primary mesoderm and separates it into a parietal and a visceral layer. The parietal layer covers the inner surface of the trophoblast and forms with it the chorion. It covers also the outer surface of the amnion. The visceral layer covers the outer surface of the extra-embryonic portion of the wall of the entodermal cavity.

The extra-embryonic and intra-embryonic parts of the cœlom are at first separate from one another (Fig. 36), then they become continuous, for a time, in the region of the umbilical orifice (Fig. 37), but are separated from one another again

when the umbilical orifice closes. The extra-embryonic portion is entirely obliterated when the outer surface of the expanding amnion fuses with the inner surface of the chorion (compare Figs. 77 and 78).

The Intra-embryonic Cœlom.—The intra-embryonic cœlom appears as a series of cleft-like spaces in the margin of the embryonic mesoderm. The spaces fuse together to form a $\cap$ -shaped cavity (Fig. 89) which separates the peripheral part of the embryonic mesoderm into a parietal or somatic, and a visceral or splanchnic, layer. The bend of the $\cap$ -shaped cavity lies in the margin of the cephalic part of the embryonic region, and it has no direct communication with the extra-embryonic cœlom, but the caudal part of each stem of the cavity, on account of the disappearance of its lateral wall, soon opens, laterally, into the extra-embryonic cœlom.

FIG. 89.—SCHEMA OF INTRA-EMBRYONIC CŒLOM SEEN FROM ABOVE BEFORE THE FOLDING OF THE EMBRYONIC AREA.

The transverse portion of the $\cap$ -shaped cavity, which extends across the cephalic end of the embryonic area and connects the two limbs together, is the **pericardial cavity**. The adjacent part of each lateral limb of the cavity, the **pleuro-pericardial canal**, becomes a *pleural cavity*, and the lateral parts of the remaining portions unite ventrally, as the umbilical orifice closes, to form the single **peritoneal cavity**.

As the head fold forms, the pericardial part of the cavity is carried ventrally and caudally into the ventral wall of the fore-gut (Fig. 90). The mesoderm which originally formed its peripheral boundary, but which now lies in the cephalic boundary of the umbilical orifice, becomes thickened, and forms the *septum transversum* (Figs. 90, 91, 93).

FIG. 90.—SCHEMATA OF EMBRYONIC CŒLOM AFTER FOLDING OF EMBRYONIC AREA BUT BEFORE THE SEPARATION OF THE VARIOUS PARTS. D from above; A, B, and C at levels of line A, B, and C in Fig. D.

At the cephalic end of its dorsal wall, on each side, the pericardial cavity is still continuous with the two lateral parts of the cœlom; and each lateral part, which

lies dorsal to the pericardium, and between the fore-gut medially and the body laterally, is still a pleuro-pericardial canal.

The Separation of the Pericardial, Pleural, and Peritoneal Parts of the Cœlom.

In the lateral wall of each pleuro-pericardial canal, near its cephalic end, lies the duct of Cuvier, passing towards the heart; and a lung bud containing a primitive bronchial tube grows from the medial wall into the cavity of each pleuro-

FIG. 91.—SCHEMA OF LATER STAGE OF DIFFERENTIATION OF CÆLOM. A, from above. B, transverse section cut level of lung bud in A.

FIG. 92.—SCHEMA OF A TRANSVERSE SECTION AT THE LEVEL OF THE LUNG BUD IN FIG. 91.

pericardial canal (Fig. 91). As the lung buds grow the cavities of the pleuro-pericardial canals increase in size, and each passes ventrally, round the side of the pericardium towards the ven-

tral wall of the body, until it is separated from its fellow of the opposite side only by a median mesoderm-filled interval, which becomes the anterior mediastinum and the anterior part of the superior mediastinum (Fig. 94). At the same time the cavity of each pleuro-pericardial canal, and the growing lung bud in its interior, grow towards the cephalic end of the embryo (Fig.

FIG. 93.—SCHEMA OF STILL LATER STAGE OF CÆLOM DIFFERENTIATION. The pleuræ are separated from the pericardia, but still communicate with the peritoneum.

FIG. 94.—SCHEMA OF TRANSVERSE SECTION OF EMBRYO AT LEVEL OF LINE B, Fig. 93, showing ventral extension of the pleuræ.

93). As it passes cephalwards the growing lung lies to the lateral side of the duct of Cuvier, which is thus forced against the cephalic end of the pleuro-pericardial canal, compressing it towards the median plane, against the sides

of the trachea and the oesophagus, until its cavity is obliterated. When this occurs the pericardial cavity is entirely shut off from the remainder of the coelom, and becomes a completely closed space (Fig. 93).

As the closure of the pericardial cavity is taking place two wing-like folds of mesoderm, connected ventrally with the septum transversum and laterally with the body walls, appear, caudal to the lungs (Figs. 91, 93). These folds are the rudiments of the lateral parts of the diaphragm, and each passes medially until it fuses with the mesoderm of the side wall of the fore-gut and its dorsal mesentery. When this fusion is completed the cavity of the portion of the coelom surrounding the lung, the original pleuro-pericardial canal, is separated from the more caudal part of the coelom, which now becomes the peritoneal cavity.

Only the broad outlines of the processes by which the pleuro-peritoneal canals are separated from the pericardium and the peritoneum are mentioned in the preceding paragraphs. The details of the processes are too complicated for description in an ordinary text-book of anatomy.

The Formation of the Diaphragm.—There are four main parts of the diaphragm, a ventral, a dorsal, and a right and a left lateral.

The ventral part is formed from the septum transversum, which is gradually differentiated into a caudal, an intermediate, and a cephalic part. The caudal part is transformed into (1) the mesodermal tissue of the liver, which grows towards the abdomen, (2) the falciform and coronary ligaments, and (3) the small omentum. The cephalic part becomes the caudal or diaphragmatic wall of the pericardium. The intermediate part is transformed into the ventral portion of the diaphragm.

The dorsal part of the diaphragm is developed from the mesoderm of the dorsal mesentery of the fore-gut. Each lateral part is derived from a lateral ingrowth which springs ventrally from the septum transversum and laterally from the body wall. The two lateral portions grow towards the median plane till they fuse with the dorsal portion; but in some cases, especially on the left side, the fusion is not completed. In such cases an aperture of communication remains, between the pleural and the peritoneal cavities, through which a portion of the abdominal contents may pass into the pleural sac, constituting a diaphragmatic hernia.

SUMMARY OF THE EXTERNAL FEATURES OF THE HUMAN EMBRYO AND FÆTUS AT DIFFERENT PERIODS OF DEVELOPMENT.

During the first **fourteen** days after the impregnation of the ovum the human zygote descends through the uterine tube, assumes the morula condition, enters the uterus, penetrates into the decidua compacta, and differentiates into three vesicles and a mass of primitive mesoderm; but, probably, it is not until the beginning of the third week, if Bryce's calculations are correct, that a definite embryonic area is present. By that time the zygote is an ovoid vesicle measuring 2.4 by 1.8 mm. Its wall is formed by the trophoblast, and it contains two inner vesicles, the ecto-mesodermal and the entodermal vesicles. The inner vesicles are surrounded by a mass of primary mesoderm in which the extra-embryonic portion of the coelom is beginning to appear. At this period the embryonic area is the region where the walls of the two inner vesicles lie in relation with one another, and it is .19 mm. long (Fig. 30).

By the **eighteenth** or **nineteenth** day the area has attained a length of 1.17 mm. and it is .6 mm. broad. It is pierced, about the centre of its length, by the neurenteric canal; the primitive streak has appeared on the dorsal surface of the area; the primitive groove is distinct, and the neural groove is indicated. The body-stalk is bent dorsally, at right angles with the area, and it contains the allantoic diverticulum, which has already been projected from the wall of the entodermal vesicle (Fig. 95).

During the next twenty-four hours the length of the embryonic area increases to 1.54 mm.; the neurenteric canal is moved caudally, to a point well behind the middle of the length of the area, and the posterior part of the area is bent ventrally, forming the posterior boundary of the hind-gut region and indicating the position of the future cloacal membrane. The head fold has begun to form, and the pericardial region lies in the ventral wall of the rudimentary fore-gut (Fig. 96).

By the middle of the **third week** the head and tail folds are distinctly formed and

the length of the embryo is 1.9 mm., the neural folds are well developed, the neural groove is still completely open, and six pairs of mesodermal somites are visible (Fig. 97).

In the next few days the length increases to 2.5 mm., the neural groove closes except in the cranial and caudal regions, the number of mesodermal somites is increased to fourteen pairs, and the cranial region begins to bend ventrally as the cervical flexure forms (Fig. 98).

By the end of the **first month** the greatest length of the embryo is about 2.6 mm., the head is bent at right angles to the body, the Wolffian ridges have appeared along the ventral margins of the mesodermal somites and indications of the limb rudiments

FIG. 95.—FRASSI'S ZYGOTE. Estimated to be 18-19 days old (Bryce). The embryonic area is 1.17 mm. long and .6 mm. broad. Copied from *Normaltafeln*, Keibel and Elze, representing a reconstruction. The chorion is not shown. The upper part of the amnion is cut away, and the dorsal aspect of the embryonic area is seen from above. In the centre of the area is the neurenteric canal and caudal (inferior in the Fig.) to it is the primitive groove. Cephalwards of the neurenteric canal is the neural groove, in the middle of the neural plate. At the lower (caudal) end of the Fig. is seen a section of the body stalk containing the allantoic diverticulum, and the nodulated area seen at the upper and right lateral part of the Fig. is a portion of the yolk-sac.

FIG. 96.—SPEE'S ZYGOTE. (From Keibel and Elze's *Normaltafeln*.) Length of embryonic area 1.54 mm. Estimated age 19-20 days (Bryce). At the lower end of the Fig. (caudal end of the embryo) is seen a portion of the chorion attached to the embryo by the body stalk. A portion of the amnion is still attached to the margin of the embryonic area, and the dorsal surface of the embryonic area is exposed. In the median plane of the area is the neural groove, and at the caudal end of the groove is the neurenteric canal. The caudal part of the area is bent ventrally, and upon it is the remains of the primitive groove. The yolk-sac is seen at the upper and right part of the Fig.

are present. The rudiments of the otic vesicles have appeared as slight depressions in the region of the hind-brain. The anterior and posterior neuropores are still open (Fig. 99).

In the latter part of the fourth or the beginning of the fifth week the embryo attains a length of about 5 mm., when measured from the vertex of the head to the base of the tail, the mesodermal somites increase to thirty-five; the rudiments of the fore- and hind-limbs become quite distinct; the otic vesicles sink into the interior of the head but remain connected with the surface by the ductus endolymphaticus, the tail becomes a very definite appendage, and the bulgings caused by the otic vesicles are quite obvious on the surface of the head. The cervical flexure remains acute, and the head bends at right angles upon itself in the region of the hind-brain, forming the cephalic flexure, with the result that the frontal extremity of the head is turned caudally (Fig. 100).

By the end of the **fifth week** the length of the embryo has increased to 11 mm. (CR)¹

¹ CR indicates the crown-rump or crown-breech measurement which corresponds with the sitting height (Mall).

(Mall). Forty-three mesodermal somites are present, but only about twenty-one are visible on the surface. During the fifth week the lens of the eye appears as a thickening of the surface ectoderm: sinks into the interior of the eyeball: becomes a vesicle and separates from the surface. The three segments of the fore-limb become visible, and the rudiments of the fingers appear. The hind-limb is less advanced: the thigh segment is not distinct, and the rudiments of the toes are not yet visible. The third and fourth visceral arches disappear from the surface and lie in the depths of the **precervical sinus**, a depression between the neck and the anterior part of the body; this is overlapped, superficially, by the caudal margin of the second arch, which grows tailwards and forms the operculum of

FIG. 97.—KROEMER-PFANNENSTIEL ZYGOTE. (From Keibel and Elze's *Normaltafeln*.) The embryonic region is folded into the form of an embryo, which is 1.9 mm. long, and it is possibly about three weeks old. At the lower end of the Fig. (the caudal end of the embryo) are seen portions of the chorion and body-stalk. The cerebral portion of the neural rudiment is defined. Six pairs of mesodermal somites are present, but there are no signs of limbs.

FIG. 98.—BALLE'S EMBRYO. (From Keibel and Elze's *Normaltafeln*.) Length after hardening in alcohol 2.5 mm. The neural groove is closed from the sixth somite to within a short distance of the caudal end, but it is open anteriorly. The hind-, mid-, and fore-brain regions and the optic vesicle can be distinguished. At the lower end of the Fig. is the body-stalk, and at the right side a part of the yolk-sac.

FIG. 99.—PFANNENSTIEL'S EMBRYO. (From Keibel and Elze's *Normaltafeln*.) Length of embryo about 2.6 mm. The rudiment of the otic vesicle is seen in the Fig. above the second branchial cleft. The heart and pericardium from the bulging eminence below the head and the Wolffian ridge is seen at the lateral border of the mesodermal somites.

the sinus (Figs. 101, 102). During the fifth week the head grows rapidly, and becomes relatively very large as contrasted with the body.

During this week also the olfactory pits appear, and grow dorsally in the roof of the stomatodæum, separating the median from the lateral nasal processes; the median process is divided into the two globular processes; and the maxillary processes of the mandibular arches, growing towards the median plane, fuse with the lateral nasal and the globular processes, so completing the lateral parts of the primitive cranial lip (Figs. 64, 65, 66).

The nodular outgrowths which form the rudiments of the auricles appear on the margins of the hyo-mandibular cleft and fuse together, and by the end of the week traces of the tragus, the helix, and the antitragus are visible (Fig. 103).

By the seventh week the embryo has attained a length of 17 mm. (CR). The cervical flexure has begun to unfold. The rudiments of the eyelids have appeared. The globular processes have fused together, but there is still a distinct notch in the middle of the cephalic on upper lip. The margins of the auricles are now well defined; the hands are

FIG. 100.—SIDE VIEW OF AN EMBRYO, measuring about 5 mm. from the root of the neck to the base of the tail, and about 47 mm. from the crown or mid-brain region to the base of the tail, that is to the breech or rump. (From Keibel and Elze's *Normaltafeln*.) The neural tube is closed. The limb buds are quite distinct, and the maxillary process of the mandibular bar has grown forward below the eye (dorsal to the eye in the Fig.).

FIG. 101.—EMBRYO OF 7.2 MM., CR MEASUREMENT. 8.5 mm. greatest length. (From Keibel and Elze's *Normaltafeln*.) The fore-limb is distinctly in advance of the hind-limb. The second branchial arch has begun to overlap the third and fourth and to enclose the precervical sinus. The tip of the maxillary process is in contact with the lateral and medial nasal processes at the margins of the olfactory pit.

FIG. 102.—EMBRYO, 7.2 mm. (CR), and 8 mm. greatest length. (From Keibel and Elze's *Normaltafeln*.) The limbs have begun to fold ventrally. The second arch has completely overlapped the third and fourth which now lie in the precervical sinus, and the sinus still opens on the surface at the posterior border of the second arch. The lens of the eyeball is very evident, and rudiments of the auricle of the external ear have appeared on the mandibular or first, and the hyoid or second arch.

FIG. 103.—EMBRYO, 10.9 mm. (CR) and 11.5 mm. greatest length. (From Keibel and Elze's *Normaltafeln*.) The precervical sinus is closed and additional rudiments of the auricle of the external ear are present on the first and second arches. The anterior nares are no longer visible from the side.

folded medially; the tips of the fingers are free, and the palms rest on the cranial part of the distended abdomen. The thighs and the toes have appeared, and the tail has begun to fuse with the caudal end of the body (Fig. 104).

At the end of the **eighth week**, when the embryo becomes a fœtus, it has attained a length of about 25 mm. (CR). The auricles project from the sides of the head, the tail has almost disappeared from the surface, and the toes are free from one another. The cervical flexure is now very slight, and although the head is still relatively large, the disproportion between it and the body has begun to decrease (Fig. 105).

Third Month.—The head grows less rapidly, and, though it is still large, it is relatively smaller in proportion to the whole body. The eyelids close, and their margins fuse

FIG. 104.—EMBRYO (CR) greatest length 18.5 mm. Probably between seven and eight weeks old. (From Keibel and Elze's *Normalatfeln*.) The abdomen is very prominent on account of the rapid increase of the liver. The digits of the hand and foot are distinct but not separated from one another. The margin auricle of the external ear is completed. The eyelids have begun to form.

FIG. 105.—HUMAN FŒTUS EIGHT AND A HALF WEEKS OLD. (After His.)

GE. Genital eminence; UC. Umbilical cord.

together. The neck increases in length. The various parts of the limbs assume their definite proportions, and nails appear on the fingers and toes. The proctodæum is formed and the external generative organs are differentiated, so that the sex can be distinguished on external examination. The skin is a rosy colour, thin and delicate, but more consistent than in the preceding stages. By the end of the third month the total length of the fœtus, excluding the legs, is 7 cm. ($2\frac{4}{5}$ in.), including the legs, 9-10 cm. ($3\frac{3}{5}$ -4 in.), and it weighs from 100-125 grammes ($3\frac{1}{2}$ -4 $\frac{1}{2}$ oz.).

Fourth Month.—In the fourth month the skin becomes firmer, and fine hairs are developed. The disproportion between the fore- and hind-limbs disappears. If the fœtus is born at this period it may live for a few hours. Its total length from vertex to heels is 16-20 cm. ($6\frac{2}{5}$ -8 in.), from vertex to coccyx 12-13 cm. ($4\frac{3}{5}$ -5 $\frac{1}{5}$ in.), and it weighs from 230-260 grammes ($8\frac{1}{8}$ -9 $\frac{1}{8}$ oz.).

Fifth Month.—The skin becomes firmer, the hairs are more developed, and sebaceous matter appears on the surface of the body. The legs are longer than the arms, and the umbilicus is farther from the pubis. At the end of the month the total length of the

fœtus, from vertex to heels, is 25-27 cm. ($10-10\frac{4}{5}$ in.), from vertex to coccyx 20 cm. (8 in.), and its average weight is about half a kilogramme ($1\frac{1}{10}$ lbs.).

Sixth Month.—The skin is wrinkled and of a dirty reddish colour. The hairs are stronger and darker. The deposit of sebaceous matter is greater, especially in the axillæ and groins. The eyelashes and eyebrows appear. At the end of the month the total length of the fœtus, from vertex to heels, is from 30-32 cm. ($12-12\frac{2}{5}$ in.), and its average weight is about one kilogramme ($2\frac{1}{5}$ lbs.).

Seventh Month.—The skin is still a dirty red colour, but it is lighter than in the previous month. The body is more plump on account of a greater deposit of subcutaneous fat. The eyelids re-open, and the fœtus is capable of living if born at this period. Its total length at the end of the month, measured from vertex to heels, is 35-36 cm. ($14-14\frac{2}{5}$ in.), and its weight is about one and a half kilogrammes ($3\frac{1}{3}$ lbs.).

Eighth Month.—The skin is completely covered with sebaceous deposit, which is thickest on the head and in the axillæ and groins, and its colour changes to a bright flesh tint. The umbilicus is farther from the pubis, but it is not yet at the centre of the body. The total length of the fœtus, from vertex to heels, is 40 cm. (16 in.), and its weight varies from 2 to $2\frac{1}{2}$ kilogrammes ($4\frac{1}{2}-5\frac{1}{2}$ lbs.).

Ninth Month.—The hair begins to disappear from the body, but it remains long and abundant on the head. The skin becomes paler, the plumpness increases, and the umbilicus reaches the centre of the body. At the end of the ninth month, when the fœtus is born, it measures about 50 cm. from vertex to heels (20 in.), and it weighs from $3-3\frac{1}{2}$ kilogrammes ($6\frac{6}{10}-7\frac{7}{10}$ lbs.).

The age of a fœtus may be estimated, approximately, by Hasse's rule, viz., Up to the fifth month the length in centimeters, the lower limbs being included, equals the square of the age in months, and after the fifth month the length in centimeters equals the age multiplied by five.

OSTEOLOGY.

THE SKELETON.

By ARTHUR THOMSON, F.R.C.S.

Professor of Anatomy, University of Oxford.

THE term **skeleton** (from the Greek, *σκελετός*, dried) is applied to the parts which remain after the softer tissues of the body have been disintegrated or removed, and includes not only the bones, but also the cartilages and ligaments which bind them together. In the restricted sense of the word the skeleton denotes the osseous framework of the body. It is in this sense that it is generally employed in human anatomy.

The skeleton serves to support the softer structures which are grouped around it, and also affords protection to many of the delicate organs which are lodged within its cavities. By the articulation of its several parts, its segments are converted into levers which constitute the passive portion of the locomotory system. Recent research has also proved that certain cells found in bone-marrow are intimately associated with the development and production of some of the corpuscles of the blood.

Bone may be regarded as white fibrous tissue which, having become calcified, has undergone subsequent changes, so as to be converted into true osseous tissue. Most probably all bone is of membranous origin, but it may pass through a stage in which cartilage plays an important part in its development. In many instances the cartilage persists, and is not converted into bone, as in the case of the articular cartilage which clothes the joint surfaces, the nasal septum, the cartilages of the nose, and the cartilages of the ribs. A persistence of the membranous condition is met with in man in the case of the tentorium cerebelli, which in some groups of animals (Carnivora) is converted into a bony partition.

Skeletal structures may be derived from each of the three layers of the trilaminar blastoderm. The **exo-skeleton** includes structures of ectodermal, and some of mesodermal origin, in the shape of hair, nails, feathers, teeth, scales, armour-plates, etc., whilst the **endo-skeleton**, with which we are more particularly concerned, is largely derived from the mesodermal tissue, but also includes the notochord, an entodermal structure which forms the primitive endo-skeleton, around which the axial skeleton is subsequently developed in the Vertebrata. The endo-skeleton is divisible into an axial portion, appertaining to the trunk and head, and an appendicular part associated with the limbs. It also includes the **splanchnic skeleton**, which comprises certain bones developed in the substance of some of the viscera, such as the os cordis and os penis of certain mammals. In man, perhaps, the cartilaginous framework of the trachea and bronchi may be referred to this system.

The number of the bones of the skeleton of man varies according to age. Owing to a process of fusion taking place during growth, the number in the adult is less than the number in the child. The following table does not include the sesamoid bones, which are frequently developed in tendons, the most constant ossicles of this description being those in relation to the metacarpo-phalangeal joint of the thumb, and the metatarso-phalangeal joint of the great toe.

The table represents the number of bones distinct and separable during adult life:—

		Single Bones.	Pairs.	Total.
Axial skeleton	{ The vertebral column	26	...	26
	{ The skull . . .	6	8	22
	{ The sternum . . .	1	...	1
	{ The ribs . . .	...	12	24
	{ The hyoid bone . . .	1	...	1
Appendicular skeleton	{ The upper limbs . . .	...	32	64
	{ The lower limbs . . .	...	31	62
The ossicles of the ear . . .		...	3	6
		34	86	206

Bones are often classified according to their shape. Thus **long bones**, that is to say, bones of elongated cylindrical form, are more or less characteristic of the limbs. **Broad or flat bones** are plate-like, and serve as protective coverings to the structures they overlie; the bones of the cranial vault display this particular form. Other bones, such as the carpus and tarsus, are termed **short bones**; whilst the bones of the cranial base, the face, and the vertebræ, are frequently referred to as **irregular bones**.

Various descriptive terms are applied to the prominences commonly met with on a bone, such as *tuberosity*, *eminence*, *protuberance*, *process*, *tubercle*, *spine*, *ridge*, *crest*, and *line*. These may be articular in their nature, or may serve as points or lines of muscular and ligamentous attachment. The surface of the bone may be excavated into *pits*, *depressions*, *fossæ*, *cavities*, *furrows*, *grooves*, and *notches*. These may be articular or non-articular, the latter serving for the reception of organs, tendons, ligaments, vessels, and nerves. In some instances the substance of the bone is hollowed out to form an *air space*, *sinus*, or *antrum*. Bones are traversed by *foramina* and *canals*; these may be for the entrance and exit of nutrient vessels, or for the transmission of vessels and nerves from one region to another. A *cleft*, *hiatus*, or *fissure* serves the same purpose. Channels of this kind are usually placed in the line of a suture, or correspond to the line of fusion of the primitive portions of the bone which they pierce.

Composition of Bone.—Bone is composed of a combination of organic and inorganic substances in about the proportion of one to two.

Organic matter (Fat, etc., Collagen)	31·04
Mineral matter—	
Calcic phosphate	58·23
Calcic carbonate	7·32
Calcic fluoride	1·41
Magnesian phosphate	1·32
Sodic chloride	·69
	68·97
	100·00

The animal matter may be removed by boiling or charring. According to the completeness with which the fibrous elements have been withdrawn, so the brittleness of the bone increases. When subjected to high temperatures the earthy matter alone remains. By soaking a bone in acid the salts may be dissolved out, leaving only the organic part. The shape of the bone is still retained, though it has now become soft, and can be bent about in any direction. The toughness and elasticity of bone depends therefore on its organic constituents, whilst its hardness is due to its mineral matter.

Bone may be examined either in the fresh or dry condition. In the former state it retains all its organic parts, which include the fibrous tissue in and around it, the blood-vessels and their contents, together with the cellular elements found within the substance of the bone itself, and the marrow which occupies the lacunar spaces and marrow cavity. In the dried or macerated bone most of these have disappeared, though a considerable portion of the organic matter still remains, even in bones of great antiquity and in a more or less fossil condition. Considering its nature and the amount of material employed, bone possesses a remarkable strength, equal to nearly twice that of oak, whilst it is capable of resisting a

greater crushing strain; it is stated that a cubic inch of bone will support a weight of over two tons. Its elasticity is remarkable, and is of the greatest service in enabling it to withstand the shocks to which it is so frequently subjected. In regions where wood is scarce the natives use the ribs of large mammals as a substitute in the construction of their bows. Its hardness and density vary in different parts of the skeleton, and its permanency and durability exceed that of any other tissue of the body, except the enamel and dentine of the teeth. The osseous remains of a race over eighty centuries old are now being excavated in Egypt.

Structure of Bone (Macroscopic).—To obtain an idea of the structure of a bone it is necessary to examine it both in the fresh or recent condition and in the macerated state. In the former the bone is covered by a membrane which is with difficulty torn off, owing to the abundance of fine fibrils which enter the substance of the bone from its deep surface. This membrane, called the **periosteum**, overlies the bone, except where the bone is coated with cartilage. This cartilage may form a bond of union between contiguous bones or, in the case of bones united to each other by movable joints, may be moulded into smooth articular surfaces called the **articular cartilages**. The attachment of the various ligaments and muscles can also be studied, and it will be noticed that where tendon or ligament is attached, the bone is often roughened to form a ridge or eminence; where fleshy muscular fibres are attached, the bone is, as a rule, smooth. In the macerated condition, when the cartilage and fibrous elements have been destroyed, it is possible, however, to determine with considerable accuracy the parts of the bone covered with articular cartilage, since the bone here is smooth and conforms generally to the curves of the articular areas of the joint; these areas are referred to as the **articular surfaces** of the bone. The bone stripped of its periosteal covering displays a dense surface finely pitted for the entrance of the processes derived from the periosteum, which thus establish a connexion between the bony substance and that vascular layer; here and there, more particularly in the neighbourhood of the articular extremities, these pits increase in size and number and allow of the transmission of small blood-vessels. If careful examination is made, one or two foramina of larger size will usually be noticed. These vascular foramina or canals allow the passage of arteries of considerable size into the interior of the bone, and are called the *canales nutritii* or **nutrient canals** or *foramina* of the bone. There are also corresponding channels for the escape of veins from the interior.

In order more fully to ascertain the structure of bone it will be necessary to study it in section. Taking first a long bone, such as one meets with in the extremities, one notices on longitudinal section, that the bone is not of the same density throughout, for, whilst the external layers are solid and compact, the interior is made up of loose spongy bone called *substantia spongiosa* (**cancellous tissue**). Further, it will be observed that in certain situations this spongy substance is absent, so that there is a hollow in the interior of the bone called the **medullary cavity**. In the recent condition this cavity is filled with the marrow and is hence often called the **marrow cavity**. This marrow, which fills not only the marrow cavity but also the interstices between the cancellous fibres, consists largely of fat cells together with some marrow cells proper supported by a kind of retiform tissue. The appearance and constituents of this marrow differ in different situations. In the medullary cavity of long bones the marrow, as above described, is known as *medulla ossium flava* (**yellow marrow**). In other situations, viz., in the diploë of the cranial bones (to be hereafter described), in the spongy tissue of such bones as the vertebræ, the sternum, and the ribs, the marrow is more fluid, less fatty, and is characterised by the presence of marrow-cells proper, which resemble in some respects colourless blood corpuscles. In addition to these, however, there are small reddish-coloured cells, akin to the nucleated red corpuscles of the blood of the embryo. These cells (erythroblasts) are concerned in the formation of the coloured corpuscles of the blood. Marrow which displays these characteristic appearances is distinguished from the yellow variety, already described, by being called the *medulla ossium rubra* (**red marrow**). The marrow met with in the cancellous tissue of the cranial bones of aged individuals often undergoes degenerative changes and is sometimes referred to as **gelatinous marrow**.

A better idea of the disposition of the bony framework of a long bone can be obtained by the examination of a section of a macerated specimen. Here the marrow has been destroyed and the osseous architecture of the bone is consequently better displayed.

Within the shaft is seen the marrow cavity extending towards, but not reaching, either extremity of the bone. This cavity is surrounded on all sides by a loose spicular network of bone, which gradually increases in compactness until it reaches the circumference of the shaft, where it forms a dense surrounding wall. In the shaft of a long bone the thickness of this outer layer is not the same throughout, but tends to diminish as we approach the extremities, nor is it of uniform thickness on all sides of the bone. All the long bones display curves in varying degree, and it is a uniform rule that the thicker dense bone is found along the concave surface of the curve, thus assisting in materially strengthening the bone. Towards the extremities of the long bone the structure and arrangement of the bone undergoes a change. There is no marrow cavity, the spongy tissue is not so open and irregular, and the external wall is much thinner than in the shaft; indeed in many instances it is little thicker than stout paper. A closer examination of the arrangement of this spongy tissue throughout the bone suggests a regularity in its arrangement which might escape notice; and if, in place of one bone only being examined, sections of other bones are also inspected, it will be observed that the spicules of this tissue are so arranged as best to withstand the strains and stresses to which the bone is habitually subjected.

From what has been said it will be obvious that the arrangements above described are those best adapted to secure the maximum of strength with the minimum of material, and a consequent reduction in the weight of the skeleton. The same description applies, with some modification, to bones of flattened form. Taking as an example the expanded plate-like bones of the cranial vault, their structure, as displayed on section, exhibits the following appearance: The outer and inner surfaces are formed by two compact and dense layers, having sandwiched between them a layer of spongy tissue called the *diploë*, containing red marrow. Note that there is no medullary cavity, though in certain situations and at certain periods of life the substance of the *diploë* may become absorbed and converted, by the evagination of the mucous membrane of the respiratory tract, into air-spaces or air-sinuses.

Structure of Bone (Microscopic).—True bone differs from calcified cartilage or membrane in that it not merely consists of the deposition of earthy salts within its matrix, but displays a definite arrangement of its organic and inorganic parts. Compact bone merely differs from loose or spongy bone in the denseness of its tissue, the characteristic feature of which is the arrangement of the osseous lamellæ to form what are called **Haversian systems**. These consist of a central or **Haversian canal**, which contains the vessels of the bone. Around this the **osseous lamellæ** are arranged concentrically, separated here and there by interspaces called *lacunæ*, in which the bone corpuscles are lodged. Passing from these *lacunæ* are many fine channels called **canaliculi**. These are disposed radially to the Haversian canal, and pass through the osseous lamellæ. They are occupied by the slender processes of the bone corpuscles. Each Haversian system consists of from three to ten concentric rings of osseous lamellæ.

In addition to the lamellæ of the Haversian systems there are others which are termed the **interstitial lamellæ**; these occupy the intervals between adjoining Haversian systems, and consist of Haversian systems which have undergone a process of partial absorption. Towards the surface of the bone, and subjacent to the periosteal membrane which surrounds the shaft, there are lamellæ arranged circumferentially; these are sometimes referred to as the outer **fundamental lamellæ**. The **periosteal membrane** which surrounds the bone, and which plays so important a part in its development, sends in processes through the various Haversian systems, which carry with them vessels and cells, thus forming an organic meshwork around which the earthy salts are deposited.

Ossification of Bone.—For an account of the earlier development of the skeleton the reader is referred to the section on Embryology. Concerning the

subsequent changes which take place, these are dependent on the conversion of the scleratogenous tissue into membrane and cartilage. A characteristic of this tissue is that it contains elements which become formed into bone-producing cells, called **osteoblasts**. These are met with in the connective tissue from which the membrane bones are formed, whilst they also appear in the deeper layers of the investing tissue of the cartilage (perichondrium), and so lead to its conversion into the bone-producing layer or periosteum. All true bone, therefore, may probably be regarded as of membranous origin, though its appearance is preceded in some instances by the deposition of cartilage; in this case calcification of the cartilage is an essential stage in the process of bone formation, but the ultimate conversion into true bone, with characteristic Haversian systems, leads to the absorption and disappearance of this primitive calcified cartilage. In considering the development of bone an inspection of the skeleton of a foetus will enable the student to realise that much of what is bone in the adult is preformed in cartilage, whilst a part of the fully developed skeleton is represented only by membrane: hence, in regard to this ossification, bones have been described as of **cartilaginous** and **membranous** origin. If the development of a long bone is traced through successive stages from the cartilaginous condition in which it is preformed, it will be noticed that ossification first begins in the shaft. This ossific centre is referred to as the **diaphysis**, and, since it is the first to appear, is also spoken of as the **primary centre of ossification**. As yet, the extremities of the shaft are cartilaginous knobs, but at a later stage one or more ossific centres appear in these cartilaginous extremities. These centres, which are independent of the diaphysis and appear much later, at variable periods, are termed **epiphyses** or secondary centres. If there are more than one such centre at the extremity of a bone, these associated centres unite, and at a later stage the osseous mass so formed joins with the shaft or diaphysis, and in this way the formation of the bone is completed. Complete fusion by osseous union of the epiphyses with the diaphyses occurs at variable periods in the life of the individual. Prior to this taking place, the two are bonded together by a cartilaginous layer which marks the position of the **epiphyseal line**. If the bone is macerated at this stage of growth, the epiphysis falls away from the diaphysis. In the case of the articular ends of bone it will be noticed that the surfaces exposed by the separation of the epiphysis from the diaphysis are not plane and smooth, but often irregular, notched, and deeply pitted, so that when the two are brought together they interlock, and, as it were, dovetail into each other. In this way the extremities of the bone as yet ununited by osseous growth are, during youth and adolescence, able to withstand the shocks and jars to which during life they are habitually subjected. A long bone has been taken as the simplest example, but it by no means follows that these secondary centres or epiphyses are confined to the articular extremities of long bones. They are met with not only in relation to the articular surfaces of bones of varied form, but also occur where bones may be subjected to unusual pressure or to the strain of particular muscles. For this reason epiphyses of this nature have been called **pressure** and **traction epiphyses** (Parsons). There occur, however, secondary independent centres of ossification, which cannot be so accounted for. Possibly these are of phylogenetic interest only, and may accordingly be classed as **Atavistic**.

Ossification in Membrane.—Membrane bones are such as have developed from fibrous tissue without having passed through a cartilaginous stage. Of this nature are the bones of the cranial vault and the majority of the bones of the face, viz., the maxillæ, zygomatic (malar), nasal, lacrimal, and palate bones, as well as the vomer. The medial lamina of the pterygoid process (internal pterygoid plate) is also of membranous origin. In the course of the development of a bone from membrane, as, for example, the parietal bone, the fibrous tissue corresponding to the position of the primary centre becomes osteogenetic, because here appear the bone-forming cells (osteoblasts), which rapidly surround themselves with a bony deposit more or less spicular in arrangement. As growth goes on these osteoblasts become embedded in the ossifying matrix, and remain as the corpuscles of the future bone, the spaces in which they are lodged corresponding to the lacunæ and canaliculi of the fully developed osseous tissue. From the primary centre ossifica-

tion spreads eccentrically towards the margins of the bone, where ultimately the sutures are formed. Here the growth rendered necessary by the expansion of the cranium takes place through the agency of an intervening layer of vascular connective tissue rich in osteoblasts; but in course of time the activity of this is reduced until only a thin layer of intermediate tissue persists along the line of the suture; this may eventually become absorbed, leading to the obliteration of the suture by the osseous union of the contiguous bones. Whilst the expansion of the bone in all directions is thus provided for, its increase in thickness is determined by the activity of the underlying and overlying strata. These form the periosteum, and furnish the lamellæ which constitute the inner and outer compact osseous layers.

Ossification in Cartilage.—Cartilage bones are those which are preformed in cartilage, and include most of the bones of the skeleton. Their growth is often described as endochondral and ectochondral, the former term implying the deposition of membrane bone in the centre of the cartilage, while the latter signifies a deposit of membrane bone on the surface of the cartilage, the osteogenetic layer on the surface of the cartilage being named the perichondrium till once bone has been formed, when it is called the periosteum.

In a cartilage bone changes of a similar nature occur. The cartilage, which may be regarded histologically as white fibrous tissue + chondro-sulphuric acid and a certain amount of lime salts, undergoes the following changes:—**First**, the cartilage cells being arranged in rows, become enlarged; **secondly**, the matrix between the cartilage cells becomes calcified by the deposition of an additional amount of lime salts; **thirdly**, the rows of cells become confluent; and, **fourthly**, into the spaces so formed extend the blood-vessels derived from the vascular layer of the periosteum. Accompanying these vessels are osteoblasts and osteoclasts, the former building up true bone at the expense of the calcified cartilage, the latter causing an absorption of the newly formed bone, and leading to its conversion into a marrow cavity, so that in due course all the cartilage or its products disappear. At the same time that this is taking place within the cartilage, the perichondrium is undergoing conversion into the periosteum, an investing membrane, the deeper stratum of which, highly vascular, furnishes a layer of osteoblast cells which serve to develop the circumferential lamellæ of the bone. It is by the accrescence of these layers externally, and their absorption internally through the action of the osteoclast cells, that growth takes place transversely. A transverse section of the shaft of a long bone shows this very clearly. Centrally there is the marrow cavity, formed primarily by the absorption of the calcified cartilage; around this the spongy tissue produced by the partial erosion of the primary periosteal bone is disposed, whilst externally there is the dense envelope made up of the more recent periosteal growth.

Growth of Bone.—The above description, whilst explaining the growth of bone circumferentially, fails to account for its growth in length; hence the necessity in long bones for some arrangement whereby ossification may take place at one or both extremities of the shaft. This zone of growth is situated where the ossified shaft becomes continuous with the cartilaginous epiphysis. In addition, within these epiphysial cartilages calcification of the cartilage takes place centrally, just as in the diaphysis. The two parts of the bone, viz., the diaphysis and epiphysis, are thus separated by a layer of cartilage, sometimes called the cartilage of conjugation, as yet uncalcified, but extremely active in growth owing to the invasion of vessels and cells from a vascular zone which surrounds the epiphysis. The nucleus of the epiphysis becomes converted into true bone, which grows eccentrically. This arrangement provides for the growth of the shaft towards the epiphysis, and the growth of the epiphysis towards the shaft; so that as long as the active intervening layer of cartilage persists, extension of growth in a longitudinal direction is possible. As might be expected, experience proves that growth takes place more actively, and is continued for a longer time, at the end of the bone where the epiphysis is the last to unite. In consequence, surgeons sometimes term this the “growing end of the bone.” Subsequently, however, at variable periods the intervening layer of cartilage becomes calcified, and true bony growth occurs within it, thus leading to complete osseous union between the shaft and epiphysis. When this has taken place all further growth in a longitudinal

direction ceases. In cases where the epiphysis enters into the formation of a joint, the cartilage over the articular area persists and undergoes neither calcification nor ossification.

Vascular, Lymph, and Nervous Supply of Bone.—From what has been said it will be gathered that the vascular supply of the bone is derived from the vessels of the periosteum. These consist of fine arteries which enter the surface of the diaphysis and epiphysis; but in addition there is a larger trunk which enters the diaphysis and reaches the medullary cavity. This is called the **nutrient artery** of the bone. The direction taken by this vessel varies in different bones. In the upper limb the artery runs distally in the case of the humerus and proximally in the radius and ulna; in the lower limb the nutrient vessel of the femur is directed towards the proximal extremity of the shaft, whilst in the tibia and fibula it follows a distal course. The direction of the nutrient artery in the bone is a mechanical result of the unequal growth of the two extremities of the bone. During the greater part of intra-uterine life the principal nutrient arteries of the long bones are directed towards the distal extremity of the limb. In the process of development the point of entrance of the artery is turned away from the epiphysis which furnishes the greatest amount of bone, and thus, together with the nutrient canal, acquires an obliquity directed towards the extremity of the bone which develops last (Piollet, *J. de l'Anat. et de la Phys.*, 1905, p. 57).

It may assist the memory to point out that when all the joints are flexed, as in the position occupied by the fetus *in utero*, the direction taken by the vessels is the same, and corresponds to a line passing from the head towards the tail-end of the embryo. Consequently, in the upper limb the vessels run towards the elbow, whilst in the lower limb they pass from the knee.

The **veins** which permeate the spongy texture of the bone are large and thin-walled. They do not accompany the arteries, and, as a rule, in long bones they escape through large openings near the articular surfaces. In flat bones they occupy channels within the diploë, and drain into an adjacent sinus, or form communications with the superficial veins of the scalp.

The **lymph vessels** are mainly periosteal, but enter the bone along with the blood-vessels and become perivascular.

The **nerves** which accompany the arteries are probably destined for the supply of the coats of these vessels. Whether they end in the bony tissue or not is unknown.

The attention of anatomists has long been directed to the elucidation of the laws which regulate bone-growth. Our present knowledge of the subject may be briefly summarised in the following generalisations:—

1. In bones with a shaft and two epiphyses, the epiphysis towards which the nutrient artery is directed is the first to unite with the shaft.

2. In bones with a shaft and two epiphyses, as a rule the epiphysis which commences to ossify latest unites soonest with the shaft. (The fibula is a notable exception to this rule.)

3. In bones with a shaft and one epiphysis the nutrient artery is directed towards the end of the bone which has no epiphysis. (This arrangement holds good in the case of the clavicle, the metacarpus, metatarsus, and phalanges.)

4. When an epiphysis is ossified from more than one centre, coalescence takes place between the separate ossific nuclei before the epiphysis unites with the shaft.

Highly suggestive, too, are the following propositions—That ossification first commences in the epiphysis which ultimately acquires the largest relative proportion to the rest of the bone, and that the ossification of the epiphysis is also correlated with its functional importance. In cases of long bones with only one epiphysis, the epiphysis is placed at the end of the bone where there is most movement.

COLUMNA VERTEBRALIS.

The **vertebral column** of man consists of thirty-three superposed segments or **vertebræ**. In the adult, certain of these vertebræ have become fused together in the process of growth to form bones, the segmental arrangement of which

is somewhat obscured, though even in their fully developed condition sufficient evidence remains to demonstrate their compound nature. The vertebræ so blended are termed the **fixed** or **false vertebræ**, whilst those between which osseous union has not taken place are described as the **movable** or **true vertebræ**. This fusion of the vertebral segments is met with at either extremity of the vertebral column, more particularly below, where the column is modified to adapt it for union with the girdle of the lower limb, and also in the region of man's degenerated caudal appendage. But a partial union of the vertebral segments also takes place above, between the two highest vertebræ, in association with the mechanism necessary to provide for the movements of the head on the column.

For descriptive purposes the vertebral column is subdivided according to the regions through which it passes. Thus the vertebræ are described as **cervical** (vertebræ cervicales), **thoracic** (vertebræ thoracales), **lumbar** (vertebræ lumbales), **sacral** (vertebræ sacrales), and **coccygeal** (vertebræ caudales), according as they lie in the regions of the neck, thorax, loins, pelvis, and tail. The number of vertebræ met with in these regions is fairly constant, though, as will be hereafter pointed out, variations may occur in the number of the members of the different series. The vertebræ in man are thus apportioned—7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 or 5 coccygeal; the three former groups comprise the **true** or **movable** vertebræ, the two latter the **false** or **fixed** vertebræ. The **vertebral formula** may be thus expressed:—

Movable or True Vertebræ.			Fixed or False Vertebræ.		
Cervical.	Thoracic.	Lumbar.	Sacral.	Coccygeal.	
7	12	5	5	4	= 33.

The **vertebræ**, though displaying great diversity of characters in the regions above enumerated, yet preserve certain features in common. All possess a solid part, **corpus vertebræ** or **body** (centrum); all have **articular processes** by which they articulate with their fellows; most have **muscular processes** developed in connexion with them; whilst the majority display a **vertebral foramen** formed by the union of a bony arcus vertebræ (**vertebral arch**) with the body. These common characters may best be studied by selecting for description an intermediate member of the series. For this purpose one of the middle or lower thoracic vertebræ may be chosen.

A **typical vertebra** may be described as consisting of a **body** composed of a mass of spongy bone, more or less cylindrical in form. The size and shape of the body is liable to considerable variation according to the vertebra examined. The superior and inferior surfaces of the body are very slightly concave dorso-ventrally and from side to side, due to the thickening of the bone around its margins. In the recent condition these surfaces afford attachment for the inter-vertebral fibro-cartilages, which are placed like pads between the bodies of the movable members of the series. The circumference of the body, formed as it is of more compact bone than the interior, is usually slightly concave from above downwards, though the dorsal surface becomes flat, where the body forms the anterior boundary of the vertebral foramen, at which point it is usually slightly concave from side to side. The vertical surfaces of the body are pierced here and there by foramina for the passage of nutrient vessels, more particularly on the dorsal surface, where a depression of considerable size receives the openings of the canals through which some of the veins which drain the body of the bone escape. Connected with the body posteriorly there is a bony **vertebral arch**, which, by its union with the body, encloses a foramen of variable size, the **vertebral foramen**. When the vertebræ are placed on the top of each other these foramina form, with the uniting ligaments, a continuous canal—**vertebral canal**—in which the spinal medulla with its coverings is lodged. The **vertebral arch**, which is formed by the union of the roots of the **vertebral arches** (pedicles) and **laminae**, besides enclosing the vertebral foramen, also supports the **spinous** and **transverse** processes, which may be regarded as a series of levers to which muscles are

attached, whilst others are **articular** and assist in uniting the different vertebræ together by means of a series of movable joints. The **roots of the vertebral arches** (O.T. **pedicles**) are the bars of bone which pass from the dorsum of the body of the vertebræ on either side to the points where the articular processes are united to the arch. These roots are compressed laterally, and have rounded superior and inferior borders. Since the vertical breadth of the roots is not as great as the thickness of the body to which they are attached, it follows that when the vertebræ are placed one above the other a series of intervals is left between the roots of the vertebral arches of the different vertebræ. These spaces, enclosed anteriorly by the bodies of the vertebræ and their intervertebral fibrocartilages and posteriorly by the coaptation of the articular processes, form a series of holes communicating with the vertebral canal; these are called the **intervertebral foramina**, and allow the transmission of spinal nerves and vessels. As each intervertebral foramen is bounded above and below by one of the roots of the vertebral arch, the grooved surfaces in correspondence with the upper and lower borders of the roots are called the **incisuræ vertebrales superior et inferior** (upper and lower **intervertebral notches**). Posteriorly, the two roots of the vertebral arch are united by two somewhat flattened plates of bone—the **laminae**, which converge towards the median plane, and become fused with the root of the projecting **spinous process**. The breadth of the laminae and their sloping arrangement are such, that, when the vertebræ are articulated together, they leave little space between them, thus enclosing fairly completely the vertebral canal, of which they form the posterior wall. The edges and inner surfaces of the laminae are rough for the attachment of the ligaments which bind them together.

The **muscular processes** are three in number, viz., two **processus transversi**—one on either side—and one central or median, the **processus spinosus**. The **transverse processes** project laterally on either side from the arch at the point where the root of the vertebral arch joins the lamina. The **spinous process** extends backwards in the median plane from the point of fusion of the laminae. The spinous processes display much variety of length and form.

The **articular processes** (**zygapophyses**), four in number, are arranged in pairs—one superior, the other inferior; the former are placed on the upper part of the arch where the roots of the arch (pedicles) and laminae join, the latter on the lower part of the arch in correspondence with the superior. Whilst differing much in the direction of their articular surfaces, the upper have generally a backward tendency, whilst the lower incline forwards.

FIG. 106.—FIFTH THORACIC VERTEBRA, (A) as viewed from the right side, (B) as viewed from above.

THE TRUE OR MOVABLE VERTEBRÆ.

Vertebræ Cervicales.

The **cervical vertebræ**, seven in number, can be readily distinguished from all the other vertebræ by the fact that their transverse processes are pierced by a foramen. The two highest, and the lowest, require special description; the remaining four conform to a common type.

Their **bodies**, the smallest of all the true vertebræ, are oblong in shape, the transverse diameter being much longer than the antero-posterior width. The superior surface, which slopes from behind forwards and downwards, is concave from side to side, owing to the marked projection of its lateral margins. Its anterior lip is rounded off, whilst its posterior edge is sharply defined.

The inferior surface, which is more or less saddle-shaped, is directed downwards and backwards. It is convex from side to side, and concave from before backwards, with a slight rounding off of the projecting anterior lip. The vertical diameter of the body is small in proportion to its width. The anterior surface is flat in the middle line, but furrowed laterally. The posterior surface, which is rough and pierced by many small foramina, is flat from side to side and above down-

FIG. 107.—FOURTH CERVICAL VERTEBRA, (A) from above, and (B) from the right side.

wards; it forms part of the anterior wall of the vertebral foramen. The lateral aspects of the body, particularly in their upper parts, are fused with the costal parts of the transverse processes, and form the medial wall of the foramen transversarium. The **roots of the vertebral arches**, which spring from the posterior half of the lateral aspects of the body, about equidistant from their superior and inferior margins, are directed horizontally backwards and laterally. The **superior** and **inferior notches** are nearly equal in depth. The **laminae** are long, and about as wide as the body of the bone is thick. The **vertebral canal** is larger than in the thoracic and lumbar regions; its shape is triangular, or more nearly semilunar. The **transverse processes**, so called, are pierced by the **foramen transversarium** (vertebrarterial or transverse foramen). They consist of two parts—the part behind the foramen, which springs from the vertebral arch and is the true transverse process, and the part in front, which is homologous with the ribs in the thoracic portion of the column. These two processes, united laterally by a bridge of bone, which thus converts the interval between them into a foramen, terminate in two tubercles, known as the *tubercula anterius et posterius* (anterior and posterior tubercles). The general direction of these processes is laterally, slightly forwards, and a little downwards, the anterior tubercles lying medial to the posterior. The two tubercles are separated above by a groove directed laterally, downwards, and forwards; along this the spinal nerve trunk passes. The **foramen transversarium** is often subdivided by a spicule of bone, and is traversed by the vertebral artery and vein in the upper six vertebræ. The **spinous processes**, which are directed backwards, are short, compressed vertically, and bifid. The **articular processes** are supported on cylindrical masses of bone fused with the arch where the roots

of the vertebral arches and the laminæ join. These cylinders are sliced away obliquely above and below, so that the superior articular facets, more or less circular in form, are directed upwards and backwards, whilst the corresponding inferior surfaces are turned downwards and forwards.

The Atlas or First Cervical Vertebra.—This bone may be readily recognised by the absence of the body and spinous process. It consists of two **lateral masses**, which support the articular and transverse processes. The lateral masses are themselves united by two curved bars of bone, the **anterior** and **posterior arches**, of which the former is the stouter and shorter. Each **lateral mass** is irregularly six-sided, and so placed that it lies closer to its fellow of the opposite side in front than behind. Its upper surface is excavated to form an elongated oval facet called the **fovea articularis superior**, which is concave from before backwards, and inclined obliquely medially; not infrequently this articular surface displays indications of division into two parts. These facets are for the reception of the condyles of the occipital bone.

The **foveæ articulares inferiores** (inferior articular facets) are placed on the inferior surfaces of the lateral masses. Of circular form, they display a slight side-to-side concavity, though flat in the antero-posterior direction. Their disposition is such that their surfaces incline downwards and slightly medially. They rest on the superior articular processes of the second cervical vertebra or epistropheus. Springing from the anterior and medial aspects of the lateral masses, and uniting them in front, is a curved bar of bone, the **arcus anterior** (anterior arch); compressed on either side, this is thickened centrally so as to form on its anterior aspect the rounded **tuberculum anterius** (anterior tubercle). In correspondence with this, on the posterior surface of this arch is a **circular facet** (**fovea dentis**) for articulation with the **dens** of the epistropheus.

The medial surface of the lateral mass is rough and irregular, displaying a little **tubercle** for the attachment of the transverse ligament of the atlas, which passes across the space included between the two lateral masses and the anterior arch, thus holding the dens of the epistropheus in position. Behind each tubercle there is usually a deep pit, opening into the bottom of which are the canals for the nutrient vessels.

Laterally to the lateral mass, and principally from its upper half, the transverse process arises by two roots which include between them the foramen transversarium. The **transverse process** is long, obliquely compressed, and down-turned; the anterior and posterior tubercles have fused to form one mass.

The **posterior arch** arises in part from the posterior surface of the lateral mass, and in part from the posterior root of the transverse process. Compressed from above downwards anteriorly, where it bounds a groove which curves around the posterior aspect of the superior articular process, which groove is also continuous laterally with the foramen transversarium, the posterior arch becomes thicker medially, at which point it displays posteriorly a rough irregular projection—the **tuberculum posterius** (posterior tubercle), the feeble representative of the spinous process. A prominent little tubercle, arising from the posterior extremity of the superior articular process, overhangs the groove above mentioned, and not in-

FIG. 108.—THE ATLAS FROM ABOVE.

frequently becomes developed so as to form a bridge of bone across it, converting the groove into a canal through which the vertebral artery and the posterior ramus of the suboccipital nerve pass—a condition normally met with in many animals. It is noteworthy that the grooves traversed by the two highest spinal nerves lie behind the articular processes, in place of in front, as in other parts of the column.

The ring formed by the lateral masses and the anterior and posterior arches is of irregular outline. The anterior part, cut off from the rest by the transverse ligament, serves for the lodgment of the dens of the epistropheus; the larger part behind corresponds to the upper part of the vertebral canal.

Epistropheus or Second Cervical Vertebra.—This is characterised by the presence of the tooth-like **dens** (O.T. **odontoid process**) which projects upwards from the superior surface of the body. Slightly constricted where it joins the body, the dens tapers to a blunt point superiorly, on the sides of which there are surfaces for the attachment of the alar ligaments. When the atlas and epistropheus are articulated this process lies behind the anterior arch of the atlas, and displays on its anterior surface an oval or circular facet which rests on that on the posterior surface of the anterior arch of the atlas. On the posterior aspect of the neck of the dens there is a shallow groove in which lies the transverse ligament of the atlas, which holds it in position.

FIG. 109.—EPISTROTHEUS (O.T. AXIS), (A) from behind and above, (B) from the left side.

The anterior surface of the **body** has a raised triangular surface, which ends superiorly in a ridge passing upwards to the neck of the dens. The **roots of the vertebral arches** are concealed above by the superior articular processes; inferiorly, they are deeply grooved. The **laminae**—prismatic on section—are thick and strong, ending in a stout, broad, and **bifid spinous process**, the under surface of which is deeply grooved, whilst its sides meet superiorly in a ridge. Placed over the roots of the vertebral arches and the anterior root of the transverse processes are the **superior articular surfaces**. These are more or less circular in shape, slightly convex from before backwards, flat from side to side, and are directed upwards and a little laterally. They are channelled inferiorly by the foramina transversaria, which turn laterally beneath them. The grooves by which the second cervical nerves leave the vertebral canal cross the laminae immediately behind the superior articular processes. The **inferior articular processes** agree in form and position with those of the remaining members of the series, and are placed behind the inferior intervertebral notches. The **transverse process** is markedly down-turned, with a single pointed extremity.

The **sixth cervical vertebra** often displays an enlargement of the anterior tubercle on the transverse process, called the carotid tubercle from the circumstance that the carotid artery may be conveniently compressed against it. It is necessary to add, however, that the tubercle is not always well developed.

The **seventh cervical vertebra** (*vertebra prominens*) receives the latter name from the outstanding nature of its **spinous process**, which ends in a single broad tubercle. This forms a well-marked surface projection at the back of the root of the neck. The **transverse processes** are broad, being flattened from above downwards; they project considerably beyond those of the sixth. The maximum width between their extremities agrees with that between the transverse processes of the atlas, these two constituting the widest members of the cervical series. The anterior tubercle is very small and is placed near the body. The **foramen transversarium** is small and does not as a rule transmit the vertebral artery. Usually a small vein passes through it. Not infrequently the costal element is separate from the true transverse process, thus constituting a **cervical rib**.

Vertebræ Thoracales.

The **thoracic vertebræ**, twelve in number, are distinguished by having facets on the sides of their bodies for the heads of the ribs, and in most instances also articular surfaces on their transverse processes for the tubercles of the ribs (Fig. 124, p. 111).

The **body** is described as characteristically heart-shaped, though in the upper and lower members of the series it undergoes transition to the typical forms of the cervical and lumbar vertebræ, respectively. Its antero-posterior and transverse widths are nearly equal; the latter is greatest in line with the facets for the heads of the ribs. The bodies are slightly thicker behind than in front, thus adapting themselves to the anterior concavity which the column displays in this region. The bodies of the second to the ninth thoracic vertebræ inclusive, each possess four **foveæ costales** or **costal facets**, a superior pair placed on the superior margin of the body, close to the junction of the root of the vertebral arch with the body, and an inferior pair situated on the inferior edge, close to and in front of the inferior intervertebral grooves.

When contiguous vertebræ are articulated, the upper pair of facets of the lower vertebra coincide with the lower facets of the higher vertebra, and, together with the intervening intervertebral fibro-cartilage, form an articular cup for the reception of the head of a rib. Of these facets on the body the upper pair are the primary articular surfaces for the head of the rib; the lower are only acquired secondarily. Moreover, these facets, though apparently placed on the body, are in reality developed on the sides of the roots of the vertebral arches behind the line of union of the roots with the body (neuro-central synchondrosis), as will be explained hereafter.

The **roots of the vertebral arches** (*O.T. pedicles*) are short and thick, and directed posteriorly and slightly upwards. The superior vertebral notch is faintly marked; the inferior is deep. The **laminæ** are broad, flat, and sloping, having sharp superior and inferior margins. When the vertebræ are superposed the latter overlap the former in an imbricated manner. The **vertebral foramen** is smaller than in the cervical and lumbar regions, and nearly circular in shape.

The **spinous processes** vary in length and direction, being shorter and more horizontal in the upper and lower members of the series, longest and most oblique in direction towards the middle of this part of the column. Nearly all have a downward inclination, and are so arranged that they overlap one another. Triangular in section where they spring from the vertebral arch, they become laterally compressed towards their extremities, which are capped by more or less distinct tubercles. The **transverse processes** are directed backwards and laterally, and a little upwards. They gradually decrease in size and length from above downwards. Each has a somewhat expanded extremity, the anterior surface of which, in the case of the upper ten vertebræ, is hollowed out in the form of a circular facet for articulation with the tubercle of the rib which rests in the upper facet of the vertebra to which the transverse process belongs. The **superior articular processes** are vertical, and have their surfaces directed backwards, slightly upwards, and a little laterally; the **inferior**, correspondingly forwards, downwards, and medially.

Certain of the thoracic vertebræ display characters by which they can readily

be recognised. These are the first, tenth, eleventh, and twelfth, and sometimes the ninth.

The **first thoracic vertebra** resembles the seventh cervical in the shape of its body, and the length and direction of its spine. There is a circular facet on either side of the body for the head of the first rib, and one facet on each side at the inferior border of its body, to complete the socket for the head of the second rib. Its **transverse processes** are long, and the superior intervertebral notch is better marked than in other members of the thoracic series. The superior articular surfaces are directed backwards and upwards, not laterally as in the lower members of the series.

The **ninth thoracic vertebra** occasionally has only the upper pair of facets on its body; at other times it conforms to the usual type.

The **tenth thoracic vertebra** may have only one complete costal facet on each side for the Xth rib, though sometimes the articular socket may be completed by the ninth dorsal vertebra. The facet on the transverse process is generally small, and sometimes absent.

The **eleventh thoracic vertebra** has a complete circular facet on the lateral side of each root of the vertebral arch for articulation with the XIth rib. Its transverse processes are short and stunted, and have no facets.

The **twelfth thoracic vertebra** has a single facet on each root of the vertebral arch for the XIIth rib. Its transverse processes, short and stunted, have no facets, and are broken up into smaller tubercles, called the

lateral, superior, and inferior tubercles. These are homologous with the transverse, mamillary, and accessory processes of the lumbar vertebræ. Indications of these processes may also be met with in the tenth and eleventh thoracic vertebræ. The twelfth thoracic vertebra may usually be distinguished

from the eleventh by the arrangement of its inferior articular processes, which resemble those of the lumbar series in being turned laterally; but the eleventh occasionally displays the same arrangement, in which case it is not always easy to distinguish between them.

Vertebræ Lumbales.

The **lumbar vertebræ**, five in number, are the largest of the movable vertebræ. They have no costal articular facets, nor are their transverse processes pierced by a foramen. In this way they can be readily distinguished from the members of the cervical and thoracic series.

The **body** is kidney-shaped in outline, and of large size, exhibiting a gradual transition from the thoracic form in the higher segments. The transverse diameter is usually about a half greater than the antero-posterior width. The anterior vertical thickness is slightly greater than the posterior, being thus adapted to the anterior convex curve of the column in this region. The **roots of vertebral arches** (O.T. pedicles), directed horizontally backwards, are short and stout; the superior notches are shallow, but deeper than in the thoracic region; the inferior grooves are deep. The **laminæ** are broad and nearly vertical, sloping but little. They support on their inferior margins the inferior articular processes. The **vertebral foramen** is large and triangular.

The **spinous processes**, spatula shaped, with a thickened posterior margin, project backwards and slightly downwards. The **transverse processes**, more slender than in the thoracic region, pass horizontally laterally, with a slight backward inclination and usually with an upward tilt. Arising from the junction of the roots of the vertebral arches with the laminæ in the higher members of the series, they tend to advance so as to become fused with the lateral side of the root and posterior aspect of the body in the lower two lumbar vertebræ. In these latter vertebræ the superior intervertebral grooves are carried obliquely across the superior surfaces of the bases of the transverse processes. The transverse processes lie in line with the lateral tubercles of the lower thoracic vertebræ, with

FIG. 111.—THIRD LUMBAR VERTEBRA, (A) from above, and (B) from the left side.

which they are serially homologous, and are to be regarded as representing the costal element. Placed on their bases posteriorly, and just lateral to and inferior to the superior articular processes, are the small **accessory processes**, which are in series with the inferior tubercles of the lower thoracic vertebræ. The **superior articular processes** are stout, oval, curved plates of bone, fused in front with the roots and laminae, and having their concave articular surfaces vertical and turned medially. Laterally, and on their posterior edge, the bone rises in the form of an elongated oval tubercle, the **processus mamillaris** (mamillary process); these are in correspondence with the superior tubercles of the lower thoracic transverse processes.

The **inferior articular processes** lie on either side of the root of the spinous process, supported on the inferior margin of the laminae. Their articular surfaces, oval in outline, convex from side to side, and plane from above downwards, are turned laterally. The inferior articular processes are much closer together than the superior; so that when the vertebræ are articulated the superior articular processes of the lower vertebra embrace the inferior articular processes of the higher vertebra.

The **fifth lumbar vertebra** is characterised by the size of its body, which is the largest of all the vertebræ. Further, the inferior surface of the body is cut away at the expense of its posterior part: hence the thickness of the body in front much exceeds the vertical diameter behind. By its articulation with the first sacral segment the inferior border of the body of this bone assists in the formation of the sacro-vertebral angle. The **transverse process** is pyramidal in form, and stouter than those of the other lumbar vertebræ. It arises by a broad base from the side of the back of the body, as well as from the pedicle, and is directed outwards and a little backwards and upwards. Its upper surface is slightly grooved by the superior intervertebral notch. A deep notch separates it posteriorly from the superior articular processes, which are less in-turned than in the other members of the series, their articular surfaces being directed more backwards than inwards, and displaying less concavity. The inferior articular processes are further apart than is the case with the other members of the series: they lie in line with the superior. The spinous process is shorter and narrower than the other lumbar spines, particularly so in the female. The vertebral canal is somewhat compressed at its lateral angles.

THE FALSE OR FIXED VERTEBRÆ.

Os Sacrum.

The **sacrum**, of roughly triangular shape, is formed normally by the fusion of five vertebræ. The **anterior surface** of the bone is slightly hollow from side to side and concave from above downwards, the curve being usually most pronounced opposite the third sacral segment. The central part corresponds to the bodies of the sacral vertebræ, the lines of fusion of which are indicated by a series of four parallel ridges which cross the medial part of the bone at gradually diminishing intervals from above downwards; laterally, these ridges disappear on either side on the medial walls of the four **foramina sacralia anteriora** (anterior sacral foramina). The size of these holes decreases from above downwards. The upper and under border of each foramen is formed by a stout bar of bone, of which there are five on each side, corresponding in number with the vertebræ present. These unite laterally so as to form the **pars lateralis** (O.T. **lateral mass**), thus enclosing the foramina to the lateral side, though here the edge is not abrupt, but sloped so as to pass gradually into the canal. The large anterior branches of the sacral nerves pass through these foramina and occupy the shallow grooves. The bone is broadest across the first sacral vertebra, tends to narrow opposite the second, and again usually increases in width opposite the third. When this condition is well marked, the edge has a notched appearance (sacral notch) which

assists in the interlocking of the sacro-iliac joint; this feature is common in the Simiidae and some of the lower races of mankind (Paterson). The surface of bone between and lateral to the first, second, third, and fourth foramina affords attachment to the fibres of origin of the piriformis, which may in some instances extend on to the bodies of the second and third segments (Adolphi), whilst on the edge lateral to and below the fourth foramen the coccygeus is inserted.

The **posterior surface** is rough and irregular. Convex from above downwards, it displays in the median plane the **crista sacralis media**, a crest whereon are seen four elongated tubercles—the spines of the upper four sacral vertebrae. Lateral to these the bone forms a groove—the **sacral groove**—the floor of which is made up of the confluent laminae of the corresponding vertebrae. In line with the intervals between the spines, and wider apart above than below, another series of tubercles is to be

FIG. 112.—THE SACRUM (anterior view).

seen. These are due to the fusion of the **articular processes** of the sacral vertebrae, which thus form faint interrupted ridges on either side of the bone (**cristae sacrales articulares**). Normally, the spine of the lowest sacral segment is absent, and the laminae do not coalesce medially, thus leaving a gap in which the sacral canal is exposed (**hiatus sacralis**); whilst inferiorly the tubercles corresponding to the inferior articular processes of the last sacral vertebra form little down-projecting processes—the **sacral cornua**—by means of which the sacrum is in part united to the coccyx. Just wide of the articular tubercles are the **posterior sacral foramina**, for the transmission of the posterior branches of the sacral nerves. These are in correspondence with the anterior foramina, so that a probe can be passed directly through both openings; but be it noted that the posterior are much smaller, and their margins much sharper, than is the case with the anterior. The surface of the **pars lateralis** (lateral mass) lateral to the posterior sacral foramina is rough and irregular, owing to the presence of four more or less elevated tubercles, which constitute the lateral ridges on either side of the bone (**cristae sacrales**

laterales), and which are serially homologous with the true transverse processes of the lumbar vertebrae. The posterior surface of the bone furnishes an extensive surface for the origin of the *sacro-spinalis*, whilst the edge of the bone lateral to the third and fourth foramen gives attachment to the *glutæus maximus*.

The base of the bone displays features more in accordance with a typical vertebra. Centrally, and in front, is placed the **body**, the superior surface of which articulates with the last lumbar vertebra through the medium of an intervertebral fibro-cartilage. The anterior margin is thin and projecting, overhanging the general concavity of the pelvic surface of the bone, and forming what is called the **promontory**. Posterior to the body, the sacral canal, of triangular form but slightly compressed dorso-ventrally, is seen, whilst still more posteriorly is the short spinous

FIG. 113.—THE SACRUM (posterior view).

process, forming the highest tubercle of the median crest. Spreading out from the sides, and partly from the back of the body on either side, is a fan-shaped mass of bone, the upper surface of which is slightly concave from side to side, and convex from above and behind downwards and forwards. This, the *ala sacralis*, corresponds to the thick upper border of the *lateral part*, and is formed, as will be explained hereafter, by elements which correspond to the roots of the vertebral arches (O.T. pedicles) and the transverse processes of the sacral vertebrae, together with superadded structures—the sacral ribs. The lateral margin of the lateral part, as seen from above, is sharp and laterally convex, terminating posteriorly in a prominent tubercle—the highest of the series of elevations seen on the posterior surface of the bone, which have been already described as serially homologous with the true transverse processes of the lumbar vertebrae. Fused with the dorsal surface of each lateral part, and separated from it laterally by a narrow but deep notch, is the **superior articular process**. This supports a vertical articular surface, which is of circular or oval form, and concave from side to side, having a general direction backwards and a little medially.

The **borders** of the sacrum are thick above, where they articulate with the ilia,

thin and tapering below, where they furnish attachments for the powerful **sacro-tuberosus** ligaments (O.T. great sacro-sciatic). The **iliac articular surfaces** are described as auricular in shape (*facies auricularis*), and overlie the lateral parts formed by the first three sacral vertebrae, though this arrangement is liable to considerable variation. Posterior to the auricular surface the bone is rough and pitted by three distinct depressions for the attachment of the strong sacro-iliac ligaments. Inferiorly, the edge formed by the lateral parts of the fourth and fifth sacral vertebrae becomes gradually thinner, and at the **inferior lateral angle** changes its direction and sweeps medially towards the body of the fifth sacral segment.

The **apex**, or lower end of the sacrum, is formed by the small oval body of the fifth sacral vertebra, which articulates with the coccyx.

The **sacral canal** follows the curve of the bone; more or less triangular in shape above, it becomes compressed and flattened dorso-ventrally below. Inferiorly, its posterior wall is deficient owing to the imperfect ossification of the laminae of the fifth, and, it may be, of the fourth sacral segments. Passing obliquely downwards and laterally from this canal into the lateral parts on either side are the four pairs of intervertebral foramina, each of which is connected laterally with a V-shaped canal which terminates in front and behind in the anterior and posterior sacral foramina. The posterior limb of the V is shorter and narrower than the anterior.

The female sacrum is proportionately broader than the male, its curves are liable to great individual variation; usually it is flattened above, and somewhat abruptly curved below, as contrasted with the male sacrum, in which the curve is more uniformly distributed throughout the bone. In the female the absolute depth of the curve is less than in the male. The iliac articular surface of the female sacrum is smaller than, and of a different shape from, that of the male; in the majority of cases it only extends over two sacral segments, whereas in the male it invariably includes a part, and at times the whole of the third segment (Derry).

The variation in the proportions of the breadth to the length of the sacrum is expressed by the formula $\frac{\text{breadth} \times 100}{\text{length}} = \text{Sacral Index}$. Sacra with an index above 100 are **platyhieric** and are generally characteristic of the higher races, those with an index below 100 are **dolichohieric** and are more commonly met with in the lower races of men. The average European index is 112.4 for males and 116.8 for females.

Os Coccygis.

The **coccyx** consists of four—sometimes five, less frequently three—rudimentary vertebrae, which tend to become fused. The **first piece** is larger than the others; it has an oval hollow facet on its superior surface, which articulates with the body of the last sacral segment. Posteriorly, two processes, **cornua coccygea**, which lie in series with the articular processes of the sacrum, extend upwards and unite with the sacral cornua, thus bridging over the notch for the exit of the fifth sacral nerve, and converting it into a foramen, the last of the intervertebral series. From the lateral sides of the body project rudimentary **transverse processes**, which may, or may not, unite with the sacrum close to the lower lateral angles; in the latter case the fifth anterior sacral foramina are enclosed. Inferiorly, the body of the bone articulates with the succeeding vertebra. The **second coccygeal vertebra** displays

FIG. 114. —THE COCCYX.

A. Posterior Surface. B. Anterior Surface.

1. Transverse process. 2. Transverse process. 3. For Sacrum. 4. Cornu.

slight traces of a transverse process and the rudiments of roots of the vertebral arch. The succeeding segments are mere rounded or oval-shaped nodules of bone.

Fusion between the lower elements occurs normally in middle life, whilst union between the first and second segments occurs somewhat later. It is not unusual, however, to find that the first coccygeal vertebra remains separate from the others. Though very variable, as a rule, fusion occurs more commonly in the male, and at an earlier age, than in the female. Szawłowski has recorded a case in which a curved process arose from the ventral surface of the first coccygeal segment. He regards this as possibly the homologue of a ventral arch (*Anat. Anz. Jena*, vol. xx. p. 320).

From the posterior surface of the coccyx the glutæus maximus arises, whilst to it is attached the *filum terminale* of the spinal medulla. To its lateral borders are attached the coccygei and levatores ani muscles, and from its tip spring the fibres of the sphincter ani externus.

THE VERTEBRAL COLUMN AS A WHOLE.

When all the vertebræ are articulated together, the resulting column displays certain characteristic features. The division of the column into a true or movable part, comprising the members of the cervical, thoracic, and lumbar series, and a false or fixed portion, including the sacrum and coccyx, can now be readily recognised. The vertebræ are so disposed that the bodies form an interrupted column of solid parts anteriorly, which constitutes the axis of support for the head and trunk; whilst the vertebral arches posteriorly provide a canal for the lodgment and protection of the spinal medulla and its membranes. In the movable part of the column both the anterior supporting axis and the vertebral canal are liable to changes in their disposition, owing to the movements of the head and trunk. Like the bodies and vertebral arches, the spinous and transverse processes are also superposed, and fall in line, forming three series of interrupted ridges—one (the spinous) placed centrally and behind, the others (the transverse) placed laterally. In this way two **vertebral grooves** are formed which lie between the central and lateral ridges. The floor of each groove is formed by the laminae and articular processes, and in these grooves are lodged the muscles which serve to support and control the movements of the column.

Further, the column so constituted is seen to display certain **curves** in an antero-posterior direction. These curves are, of course, subject to very great variation according to the position of the trunk and head, and can only be satisfactorily studied in a fresh specimen; but if care is exercised in the articulation of the vertebræ, the following characteristic features may be observed, assuming, of course, that the column is erect and the head so placed that the axis of vision is directed towards the horizon. There is a forward curve in the cervical region, which gradually merges with the backward thoracic curve; this becomes continuous below with an anterior convexity in the lumbar region, which ends more or less abruptly at the union of the fifth lumbar with the first sacral vertebra, where the sacrum slopes suddenly backwards, causing the column to form a marked projection—the **sacro-vertebral angle**. Below this, the anterior concavity of the front of the sacrum is directed downwards as well as forwards. Of these four curves, two—the thoracic and sacral—are **primary**, they alone exist during foetal life; whilst the cervical and lumbar forward curves only make their appearance after birth—the former being associated with the extension and elevation of the head, whilst the latter is developed in connexion with the use of the hind limb in the hyper-extended position, which in man is correlated with the assumption of the erect posture; this curve, therefore, only appears after the child has begun to walk. For these reasons the cervical and lumbar curves are described as **secondary** and **compensatory**.

Not infrequently there is a slight **lateral curvature** in the thoracic region, the convexity of the curve being usually directed towards the right side. This may be associated with a greater use of the muscles of the right upper limb, or may depend on the pressure exercised by the upper part of the thoracic aorta on the

vertebræ of the thoracic region, thus causing a slight lateral displacement, together with a flattening of the side of the fifth thoracic vertebra (*impressio aortica*) as was first pointed out by Wood (*Journ. Anat. and Physiol.* vol. iii.). Above and below this curve there are slight compensatory curves in the opposite direction.

The line which unites the tips of the spinous processes is not a repetition of the curves formed by the bodies. This is due to the fact that the length and direction of the spinous processes vary much in different regions; thus in the neck, with the exception of the second, sixth, and seventh, they are all short (absent in the case of the atlas). In the thoracic region the spinous processes, though long, are obliquely placed—a circumstance which much reduces their prominence; that of the seventh thoracic vertebra is usually the longest and most slanting. Below this point their length gradually decreases, and their position more nearly approaches the horizontal. In the loins the spinous processes have all a slight downward direction.

The spinous processes of the upper three or four sacral vertebrae form an osseous ridge with interrupted tubercles. The ridge formed by the vertebral spines is an important determinant of the surface form, as it corresponds to the medial furrow of the back, and here the individual spines may be felt and counted from the seventh cervical down to the sacral region. This is best done when the back is well bent forwards.

Taken as a whole, the spinous processes of the movable vertebrae in man have a downward inclination—a character which he shares with the anthropoid apes and a few other animals. This character serves to distinguish his column from those of lower mammals in which the spines of the lumbar vertebrae are directed headwards towards the “centre of motion,” which is usually situated near the caudal extremity of the thorax, where a vertebra is placed the direction of whose spine is vertical to the horizontally disposed column; this vertebra is often referred to as the *anticlinal vertebra*.

As viewed from the front, the vertebral bodies increase in width from the second cervical to the first thoracic; thence a reduction in breadth takes place to the level of the fourth thoracic, below which there is a gradual increase in their transverse diameters until the sacrum is reached. Here a rapid reduction in width takes place, terminating inferiorly in the nodules of the coccyx.

The transverse processes of the atlas are wide and outstanding. The succeeding four cervical vertebrae have transverse processes of nearly equal width; the seventh, however, displays a marked increase in its transverse diameter, and is about equal in width to the first thoracic vertebra. Below this a gradual and regular diminution in width characterises the transverse processes of the thoracic vertebrae, until in the case of the eleventh and twelfth they are merely represented by the small lateral tubercles. In the lumbar region the transverse processes again appear outstanding, and of nearly equal length.

The transverse diameter of the lateral part of the first sacral vertebra forms the widest part of the column. Below this, a decrease in width occurs until the

FIG. 115.—VERTEBRAL COLUMN FROM THE LEFT SIDE.

level of the third sacral segment is reached, at which point the transverse diameter is somewhat abruptly diminished, a reduction in width which is further suddenly accentuated opposite the fifth sacral segment.

As viewed from the side, the bodies display a gradual increase in their antero-posterior width until the second lumbar vertebra is reached, below which, this diameter is slightly reduced. In the sacral region the reduction in this diameter is great in the first and second sacral segments, more gradual and less marked in the last three segments. The facets for the heads of the ribs in the upper thoracic region lie on the sides of the bodies; those for the tenth, eleventh, and twelfth are placed farther back on the roots of the vertebral arches.

The **intervertebral foramina** increase in size from above downwards in the movable part of the column, being largest in the lumbar region. In the sacral region they decrease in size from above downwards. In the cervical region the two highest cervical nerves pass out behind the articular processes of the atlas and epistropheus, and lie, therefore, behind the corresponding transverse processes of these vertebrae. The succeeding cervical nerves pass out through the intervertebral foramina, which are placed between the transverse processes and anterior to the articular processes. In the thoracic and lumbar vertebrae the intervertebral foramina lie anterior to both the articular and transverse processes. The arrangement of these foramina in the sacrum has been already sufficiently explained.

The **vertebral canal** for the lodgment of the spinal medulla and its meninges is largest in the cervical and lumbar regions, in both of which it assumes a triangular form; whilst it is narrow and circular in the thoracic region. These facts are correlated with the movements of the column which are most free in those regions where the canal is largest, *i.e.* the neck and loins.

The **average length** of the vertebral column is from 70 to 73 centimetres, or from $27\frac{1}{2}$ to $28\frac{3}{4}$ inches. Of this the cervical part measures from 13 to 14 cm.; the thoracic, 27 to 29 cm.; lumbar, 17 to 18 cm.; and the sacro-coccygeal, 12 to 15 cm. The individual differences in the length of the column are less than one might expect, the variation in height of different individuals being often largely dependent on the length of the lower limbs. In the female the average length of the column is about 60 centimetres, or $23\frac{3}{4}$ inches, and the curve in the lumbar region is usually more pronounced.

DEVELOPMENT OF THE VERTEBRAL COLUMN.

The Cartilaginous Column.

As has been already stated (p. 37), the neural tube and the notochord are enveloped by a continuous sheath of mesodermal tissue which forms the **membranous vertebral column**. It is by the chondrification of this that the cartilaginous column is developed. This process commences about the end of the first or the beginning of the second month of foetal life. In correspondence with each vertebral segment, two symmetrical nodules of cartilage appear on either side of the notochord; these rapidly surround and constrict it. By their fusion they constitute the body of a

FIG. 116.—VERTEBRAL COLUMN AS SEEN FROM BEHIND.

cartilaginous vertebra, and are so disposed that they alternate in position with the muscle plates which are lying on either side. In this way a vertebral body corresponds in position to the posterior half of the anterior myotome, and the anterior half of the posterior myotome, the intermyotomic intervals, which contain the connective tissue plates separating the muscle segments, lie in line laterally with the mid-points of the sides of the cartilaginous vertebræ. It is by chondrification of these intersegmental layers that in certain regions the ribs are ultimately developed. Meanwhile, the scleratogenous tissue between the chondrifying vertebral bodies undergoes little change and persists as the intervertebral fibro-cartilage. Here the embedded notochord undergoes but slight compression and enlarges, so that if a length of the column be examined in longitudinal section the notochord displays a moniliform appearance, the constricted parts corresponding to the bodies, the enlarged portions to the fibro-cartilages. The former disappear at a later stage when ossification begins, but the latter persist in the adult as the pulpy core in the centre of the intervertebral fibro-cartilage.

The portions of the scleratogenous tissue which lie lateral to the notochord have next to be considered; these extend dorsally around the vertebral canal, and ventralwards beneath the notochord. The former is sometimes called the vertebral bow, the latter the hypochordal bow. The vertebral bow begins to chondrify on either side, and forms the lateral portions of the cartilaginous vertebral

FIG. 117.—THE DEVELOPMENT OF THE MEMBRANOUS BASIS OF A VERTEBRA (after Keith).

A, in transverse section. B, in horizontal section, showing the relation of the vertebræ to the primitive segments.

arch, the extremities of which usually unite dorsally about the fourth month of foetal life; if from defective development this union should fail to occur a deformity known as *spina bifida* is the result.

From the cartilaginous vertebral arch, so formed, arise the chondrified rudiments of the spinous, transverse, and articular processes.

The chondrification of the vertebral arch is variously described as being independent of the body or an extension from it; in any case, union between it and the body is rapidly effected.

The scleratogenous tissue between the cartilaginous vertebral arches which does not undergo chondrification persists as the ligaments uniting the vertebral laminae.

As regards the so-called hypochordal bow, for the most part it disappears. By some it is regarded as being represented by a fibrous strand in the intervertebral fibro-cartilage in front of the vertebra to which it belongs. It is, however, noteworthy that in the case of the atlas vertebra there is an exception to this arrangement; for here the hypochordal bow chondrifies and subsequently by ossification forms the anterior arch of that bone—an arch which lies ventral to, and embraces the dens of the epistropheus (*q.v.* p. 91).

It is only in the thoracic region that the ribs, developed as stated above by the chondrification of the intersegmental septa, attain their full dimensions. In the cervical, lumbar, and sacral regions they exist only in a rudimentary or modified form, as has been described elsewhere. In the construction of the chest wall the ribs are supported ventrally by the sternum, as to the development of which there is some difference of opinion. Ruge has described this bone as formed by the fusion of two cartilaginous bands produced by the coalescence of the expanded ends of the first five

or seven cartilaginous ribs. Paterson, on the other hand, regards the sternum as arising independently of the ribs by the union of a right and left sternal bar in the median ventral line. There are also reasons for supposing that the presternum is intimately associated with the development of the ventral part of the shoulder girdle.

Ossification of the Vertebrae.—The vertebrae are developed by ossification of the cartilage which surrounds the notochord and which passes dorsally over the sides of the vertebral canal. The centres for the bodies first appear in the lower thoracic vertebrae about the tenth week. An oval nucleus develops in each body. At first it is placed dorsal to the notochord, but subsequently surrounds and causes the disappearance of that structure. Occasionally, however, the primitive centre appears to be formed by the coalescence of two primary nuclei. Support is given to this view by the occasional occurrence of vertebrae in which the body is developed in two lateral halves, or in cases where only one-half of the body persists (Turner); normally, however, it is impossible to make out this division. From these single nuclei the bodies are developed, the process extending up and down the column until, by the fifth month, all the centra possess ossific nodules, except the coccygeal segments. About the seventh week a single centre appears in the vertebral arch on either side. These commence first to ossify in the upper cervical region and extend rapidly downwards throughout the column. They first appear near the bases of the superior articular processes, and extend backwards into the laminae, laterally into

FIG. 118.—OSSIFICATION OF VERTEBRÆ.

the transverse processes, and forwards into the roots of the vertebral arches. These latter project anteriorly and form a considerable portion of the postero-lateral aspects of the body, from which, however, they are separated by a cartilaginous strip—the **neuro-central synchondrosis**—which does not entirely disappear until about the fifth or sixth year. It is important to note that in the thoracic region the costal facets lie behind the neuro-central synchondrosis, and are therefore borne on the lateral aspects of the roots of the vertebral arches. Fusion of the laminae in the median plane posteriorly begins, after birth, in the lumbar region and extends upwards, so that by the fifteenth month or thereabouts the arches in the cervical region are completed posteriorly. In

the sacral region ossification is slower, the vertebral canal not being enclosed till the seventh to the tenth year. The spinous processes are cartilaginous at birth, but these become ossified by the extension into them of the bony laminae.

At puberty certain **secondary centres** or **epiphyses** make their appearance; these are five in number. One caps the summit of the spinous process, except in the cervical region. A single epiphysis on either side appears at the extremity of the transverse process, and in the thoracic region assists in forming the articular surface for the tubercle of the rib. Two epiphysal plates are formed—one for the superior, and the second for the inferior surface of the body, including also that part which lies posterior to the neuro-central synchondrosis and is formed by the root of the vertebral arch; from these the thickened circumference of both upper and lower aspects of the body are derived. Fusion of these centres with the rest of the bone is not complete till the twenty-fifth year.

In the cervical region independent centres are described as occurring in the anterior roots of the transverse processes of the sixth and seventh vertebrae. These correspond to the costal element, and may occasionally persist in the form of cervical ribs. Elsewhere they are formed by lateral extensions from the root of the vertebral arch.

In the lumbar region the transverse process of the first lumbar vertebra is occasionally associated with an independent costal centre, which may blend with it, or persist as a lumbar rib. The mamillary processes are derived from separate epiphyses. The vertebral arch of the fifth lumbar vertebra is occasionally developed from two centres on either side, as is demonstrated by the fact that the arch is sometimes divided by a synchondrodial joint running obliquely across between the superior and inferior articular processes on either side. (See *ante*, p. 91; also *Fortschritte auf dem Gebiete der Röntgenstrahlen*. Ergänzungsheft i.; “die Entwicklung des menschlichen Knochengerüstes während des fötalen Lebens,” von Lambert.) At the eighteenth year there are two epiphyses at the end of the costo-transverse process of the fifth lumbar vertebra; one caps the transverse element, the other caps the costal element (Fawcett).

Atlas.—The lateral masses, transverse processes, and posterior arch are developed from two centres—one on either side—which correspond with the centres from which the vertebral arches of the other members of the series are developed. These make their appearance about the seventh week, and do not unite posteriorly till after the third year. Their point of union is sometimes preceded by the formation of a distinct spinal

nucleus (Quain). The transverse processes are completed by epiphyses about the eighteenth year (Fawcett). The anterior arch is developed from centres variously described as single or double, which appear in one of the hypochondral arches of cartilage described by Froriep (*Arch. f. Anat. u. Physiol., Anat. Abth.* 1886) which here persists. In this cartilage ossification commences during the first year of life. Union with the lateral masses is delayed till six or eight years after birth. The lateral extremities of the anterior arch assist in forming the anterior part of the superior articular processes.

Epistropheus.—The epistropheus ossifies from five primitive centres. Of these, two—one on either side—appear about the seventh week, and form the articular and transverse processes, together with the laminae and spinous process. One, or it may be two, nuclei appear in the inferior part of the body about the fifth month. The superior part of the body, including a small part of the superior articular process, and the base of the dens,

19. Centre for transverse process and vertebral arch; appears about 8th week.
20. Synchondroses close about 3rd year.

21. Centre for summit of dens; appears 3rd to 5th year, fuses 8th to 12th year.
22. Appears about 5th or 6th month; unites with opposite side 7th to 8th month.
23. Synchondrosis closes from 4th to 6th year.
24. Inferior epiphysial plate; appears about puberty, unites about 25th year.
25. Single or double centre for body; appears about 5th month.

Atlas.

26. Posterior arch and lateral masses developed from a single centre on either side, which appears about 7th week. In this figure the posterior arch is represented complete by the union posteriorly of its posterior elements.
27. Anterior arch and portion of superior articular surface developed from single or double centre, appearing during 1st year.

Thoracic vertebra.

28. Epiphysis for transverse process; appears about puberty, unites about 25th year.
29. Epiphysis appears about puberty; unites about 25th or 27th year.
30. Centre for vertebral arch on either side; appears about 6th or 7th week, the laminae unite from birth to 15th month. The arch is here shown complete posteriorly.
31. Centre for body; appears about 6th week, unites with vertebral arch from 5th to 6th year.

are developed from two laterally-placed nuclei which appear shortly after, and fuse together at the seventh or eighth month, so that at birth the bone consists of four pieces. Fusion between these parts takes place in the following order:—The dens unites with the body and lateral parts about the third or fourth year; union between the two lateral portions posteriorly and the body and lateral parts anteriorly, is complete at from four to six years.

The summit of the dens is developed from a separate centre, occasionally double, which appears from the third to the fifth year, and fuses with the rest of the bone from the eighth to the twelfth year. About puberty an annular epiphysis is developed on the inferior surface of the body, with which it is completely united during the twentieth to the twenty-fifth year. Some authorities state that a few granules between the base of the dens and the superior surface of the body represent the superior epiphysial plate; but

as fusion between the dens and the body occurs before the time for the appearance of these secondary epiphysal plates, this can hardly be regarded as correct. The line of fusion of the dens with the body is defined by a small disc of cartilage which persists within the substance of the bone till an advanced period of life.

A pair of epiphyses placed over the tubercles of the spinous process, if not always present, are at least frequent.

Sacrum.—Each of the sacral segments is ossified from three centres: one for the body, and two for the vertebral arch—that for the body, which makes its appearance in the first three sacral vertebræ about the end of the third month, about the fifth to the eighth month for the last two segments. From the two centres for the vertebral arches, which make their appearance about the fifth or sixth month in the higher segments, the laminae, articular processes, and the posterior half of the alæ on either side are developed. The sacral canal is not enclosed till the seventh to the tenth year, the laminae usually failing to meet in the lowest segment, and occasionally, to a greater or less extent, in some of the higher segments. The anterior portion of the lateral parts is developed from separate centres which represent the costal elements (Gegenbauer). These appear about the sixth to the eighth month, and may develop in relation to the upper four sacral segments; more usually they are met with in connexion with the first three, and exceptionally they may be found only in the upper two. It is by fusion of these

FIG. 120.—DIAGRAM (after Fawcett) OF THE ARRANGEMENT OF THE COSTAL AND TRANSVERSE EPIPHYSES AT THE EIGHTEENTH YEAR.

C.D., Dorsal epiphysis.

The numbers indicate the segments to which the epiphyses belong.

with the posterior arches that the lateral parts, which support the hip bones, are formed. The costal elements fuse about the second to the fifth year with the vertebral arches, prior to their union with the bodies; and the segments of the lateral parts unite with each other sooner than the union of the bodies is effected. The latter only takes place after puberty by the fusion of the epiphysal plates, a pair of which make their appearance between the bodies of each segment. The lower segments begin to unite together about the eighteenth year, but fusion between the first and second sacral vertebræ is not completed till the twenty-fifth year or after. In addition to the foregoing there are costal and transverse epiphyses. According to Fawcett they are arranged as follows. **Costal epiphyses:** The costal processes of the I. and II. sacral segments bear at their lateral ends inferiorly two such epiphyses, one dorsal and one ventral; these, by their fusion

and expansion mainly in an upward direction, form a plate—the auricular facet. The III. and IV. costal processes have only one epiphysis each, viz., the ventral. All these appear about the eighteenth year. **Transverse epiphyses:** Epiphyses are developed on all the transverse processes of the sacral vertebræ except the II. Those of the IV. and V. play an important part in the moulding of the lower lateral region of the sacrum. Thus, the transverse epiphysis of the IV. segment becomes comma-shaped by downward and lateral growth, the head of the comma fuses with the costal epiphysis of the III. sacral segment, which in turn unites with the epiphysis of the transverse process of the V. segment, the ultimate result being a Z-like arrangement on the posterior and inferior aspect of the sacrum. The extremities of the superior spinous processes are occasionally developed from independent epiphyses. On making a median section of an adult bone the persistence of the intervertebral fibro-cartilages between the bodies is indicated by a series of oval cavities.

Coccygeal Vertebræ.—These are cartilaginous at birth. Each has a separate centre; the first appears from the first to the fourth year, the second from the sixth to the tenth year, the third and fourth segments at or about puberty. Secondary centres, for the coccygeal cornua and epiphysal plates for the bodies are also described. Fusion of the various segments begins below and proceeds upwards, but is liable to great individual variation. In advanced life the coccyx is often ossified to the sacrum.

THE STERNUM.

The **sternum** occupies the middle of the upper part of the thoracic wall anteriorly. It is connected laterally with the cartilages of the first seven ribs, and supports, superiorly, the clavicles. It consists of three parts, named respectively

the **manubrium** or handle; the **corpus sterni** or body; and the **processus xiphoideus** (or **xiphoid cartilage**). Of these the body is formed by the fusion in early life of four segments or *sternebrae*.

The **manubrium** or superior part, usually separate throughout life from the rest of the bone, though occasionally fused with it, is of a flattened triangular form. The anterior surface, slightly saddle-shaped, affords attachment to the fibres of the pectoralis major and sterno-mastoid muscles. It is bounded above by a thick border, the lateral parts of which are hollowed out obliquely to form the facets (*incisurae claviculares*) for the sternal ends of the clavicles; around the facets, which have an upward, lateral, and slightly backward direction, the bone is faintly lipped. In the interval between these two facets there is a slight notch (*incisura jugularis*) which forms the floor of the characteristic hollow seen at the root of the neck anteriorly—the supra-sternal notch. The lateral borders are excavated immediately below the clavicular facets for the reception of the cartilages of the first ribs. Below this, the margin of the bone slopes medially, and is sharp, except inferiorly, where it presents a facet which supports a part of the second costal cartilage. Around this the bone is usually lipped anteriorly. The upper angles correspond to the ridge separating the clavicular facets from the first costal facets: whilst the lower angle, which may be regarded as cut across transversely, forms the surface which is united by cartilage to the body of the sternum. The anterior edge of this surface is usually prominent. The posterior aspect of the manubrium is smoother than the anterior, is pierced by numerous foramina, and is slightly concave from side to side and above downwards. Here are attached some of the fibres of the sterno-hyoid and sterno-thyroid muscles.

The **body** or middle part of the sternum, usually twice the length and from half to two-thirds the width of the manubrium, displays evidence of its composite nature. If the **planum sternale**, (anterior surface) which is slightly convex from above downwards, and faintly concave from side to side, is carefully examined, three ill-marked ridges may be seen crossing it transversely; these correspond to the lines of fusion between the four primitive segments. To this surface of the bone the great pectoral muscles are extensively attached on either side of the median plane. The lateral borders are thick and interrupted at points corresponding to the transverse lines already mentioned by U-shaped hollows, the edges of which are more or less projecting. These are for the reception of the cartilages of the third, fourth, and fifth ribs. The superior border is united to the manubrium above, and forms with it an angle of variable degree—the **angulus sterni** (sternal angle). A small facet is formed at the expense of the lateral extremity of this

FIG. 121.—THE STERNUM (anterior view).

border, and in conjunction with the facet on the inferior edge of the manubrium forms a recess on either side, in line with the articulation between the manubrium and body, into which the cartilage of the second rib fits. The **inferior border** of the body is curved, and is united in the middle line with the xiphoid process, whilst on either side it is pitted to receive the cartilages of the sixth and seventh ribs, the latter being in part supported by the xiphoid process. The middle line of the body of the sternum anteriorly corresponds to the floor of the medial surface furrow, which runs down the front of the chest in the interval between the two great pectoral muscles. The **posterior surface** is slightly concave from above downwards, and displays faint indications of three transverse lines in correspondence with those placed anteriorly. It is in relation with the pleura and pericardium, and affords attachment at its inferior extremity to the transversus thoracis muscle.

The **xiphoid process** displays many varieties of form and structure. It is a pointed process of cartilage, supported by a core of bone connected above with the inferior end of the body of the sternum, and having its lower extremity, to which the linea alba is attached, free. It lies somewhat posterior to the plane of the anterior surface of the manubrium, and forms a floor to the V-shaped interval between the cartilages of the seventh ribs. In this way a depression is formed, the surface hollow in correspondence with which is called the pit of the stomach or **infrasternal depression**. To the sides of this process are attached the aponeuroses of the abdominal muscles, whilst posteriorly the fibres of the diaphragm and transversus thoracis muscles derive attachment from it. It remains partly cartilaginous until middle life, at which time it generally undergoes ossification, particularly at its upper part, becoming fused with the body. Of varied form, it may be met with of spatula-shape, bifid, circular, pierced in the centre, or twisted and deflected to one or other side, or turned forward.

The **sternum as a whole** is broadest above, where the first rib cartilages are attached. It becomes narrow opposite the second rib cartilages, but again expands until the level of the fifth rib cartilage is reached, below which it is rapidly

reduced in width and ends below in the pointed xiphoid process. Its position in the body is oblique from above downwards and forwards; its axis, if prolonged upwards, would touch the vertebral column opposite the third or fourth cervical vertebra. Though liable to changes in position by the rising and falling of the chest wall, its upper extremity corresponds to the level of the lower border of the second thoracic vertebra, whilst the lower end of the xiphoid process usually falls in line with the fibro-cartilage between the tenth and eleventh thoracic vertebrae.

FIG. 122.—OSSIFICATION OF THE STERNUM.

In this figure the second as well as the third segment of the body possesses two centres.

1. Appears about 5th or 6th month. 2. Appear about 7th month; unite from 20 to 25. 3. Appear about 8th or 9th month; third segment unites with second about puberty; fourth segment unites with third in early-childhood. 4. Appears about 3rd year or later.

than the female, whilst the male body is proportionately longer and narrower than the female.

Ossification.—The cartilaginous sternum, developed from the fusion medially of two cartilaginous bands uniting the anterior extremities of the cartilages of the first eight ribs, according to the researches of Ruge and more recently of Eggeling, begins

In women the sternum as a whole is usually narrower and shorter than in men, and its position less oblique. On the other hand, Paterson has shown that the male manubrium is proportionately wider and shorter

to ossify about the sixth month of foetal life. About this time a single centre appears in the manubrium; at birth this is well developed. Two centres placed vertically have also been recorded. Secondary epiphyses have been described in connexion with the clavicular facets; these do not unite with the rest of the manubrium till adult life is reached. The body, formed by the fusion of four segments, is ossified from independent centres, either single or double, for each segment. These appear—the highest as early as the sixth month of intrauterine life—in some cases even before the manubrium has begun to ossify (Lambertz), the lowest towards the end of full term. The common arrangement met with at birth is a single centre for the first, and double centres for each of the succeeding segments. Union between these segments occurs rather irregularly, and is liable to much variation. The fourth unites with the third segment in early childhood, the third with the second about puberty, whilst the fusion of the second with the first segment may not be complete till the twentieth or twenty-fifth year.

The xiphoid process usually ossifies from a single centre, which may appear as early as the third year, though often very much later. The xiphoid process usually unites with the body about forty or fifty, and in exceptional cases osseous union between the body and manubrium may occur in advanced life.

According to Paterson the manubrium or presternum is developed in association with the shoulder girdle and becomes only secondarily associated with the ventrally growing ribs.

COSTÆ—RIBS.

The **ribs**, of which there are twelve pairs, form a series of curved osseous bands which support the thoracic wall; posteriorly they articulate with the thoracic vertebræ, anteriorly each rib is provided with a costal cartilage. The first seven ribs articulate with the sternum by means of their cartilages, and are termed the *costæ veræ*, true or **vertebro-sternal ribs**. The lower five ribs are not so supported, and are described as the *costæ spuria* (false ribs). Of these the eighth, ninth, and tenth are united by their cartilages to the cartilage of the seventh rib, and are called the **vertebro-chondral ribs**, whilst the last two ribs are free at their anterior extremities, and are named the **floating or vertebral ribs**.

A typical rib consists of a *capitulum costæ* (head), a *collum costæ* (neck), a *tuberculum costæ* (tubercle), and a *corpus costæ* (shaft), on which, near its posterior end, is the *angulus costæ* (angle).

The **head**, placed on the posterior or vertebral end of the bone, is somewhat expanded. Medially, its articular surface is wedge-shaped and divided into two parts, a superior and inferior, by a ridge or crest (*crista capituli*), to which the inter-articular ligament of the head of the rib is attached. Of these two facets the inferior is usually the larger, and articulates with the superior facet on the body of the vertebra in numerical correspondence with it, whilst the superior facet is for the corresponding area on the inferior part of the body of the vertebra above. The head is supported by a more or less constricted bar of bone, the **neck**, which lies anterior to the transverse process of the lower of the two vertebræ with which the rib articulates, and thus assists in the formation of the costo-transverse cleft. The neck is continuous with the shaft laterally, at which point there is a well-marked tubercle on its posterior surface. The anterior surface of the neck is smooth; its posterior aspect is rough, and pierced by numerous small holes for vessels. Here is attached the ligament of the neck of the rib. Not uncommonly the superior border of the neck is lipped and ridged (*crista colli costæ*), especially in the case of the sixth, seventh, and eighth ribs, and affords attachment to the anterior costo-transverse ligament. The inferior border is continuous with the costal groove laterally.

The **tubercle** consists of an articular and a non-articular part; the former is medial and inferior to the latter. Its articular surface, of rounded or oval shape, is directed downwards, posteriorly, and a little medially, and rests upon a facet on the transverse process of the vertebra in numerical correspondence with the rib. The non-articular part, most prominent in the upper ribs, has the fibres of the ligament of the tubercle of the rib attached to it. It is usually separated from the superior border of the neck and shaft by a groove, in which lies the lateral division of the posterior branch of a thoracic nerve.

The **shaft** is thin, flattened, and band-like. Its length varies much;

the seventh and eighth, which are usually the longest, are from two and a half to three times the length of the first and twelfth ribs respectively. The shafts are curved so as to adapt them to the form of the thoracic wall. More acute in the upper members of the series, where the shafts are shorter, the curve opens out in the middle and lower parts of the thorax, where the diameters of that cavity are greater. The curve, however, is not uniform. Including the whole length of the bone, it will be seen to be most accentuated towards the posterior part, where, in correspondence with the point at which the bend is most pronounced, there is a rough ridge placed obliquely across the outer surface of the shaft for the attachment of the slips of the ilio-costalis muscle; this is the *angulus costæ*. The distance between the angle and the tubercle is greatest on the eighth rib; above that, the width between these two points gradually decreases until, in the case of the first rib, the two coincide. Below the level of the eighth rib the distance slightly diminishes in conformity with the general narrowing of the thorax below that level. Towards the anterior extremity of the rib where the digitations of the serratus anterior and external oblique muscles are attached to its outer surface the curve of the shaft is somewhat more pronounced, and is referred to as the *anterior angle*.

Combined with this curve, there is in many of the ribs a twist. This may best be understood if the student will take a strip of stiff paper and bend it in the form of the curve of the rib. If, after he has done this, he pulls down the anterior end and turns up the posterior end of the strip, he will have imparted to the strip of paper a twist similar to that met with in the rib. This appearance is best seen in the middle members of the series, notably in the seventh and eighth ribs, above and below which it gradually becomes less marked. It is the occurrence of this twist which prevents the extremities of the ribs, together with the shaft, from resting on the same plane surface. To this rule there are certain notable exceptions, viz., the first and second, the twelfth, and not infrequently the eleventh.

The shaft has two surfaces, inner and outer, and two borders, a superior and an inferior. The *outer surface*, which is smooth, conforms to the general vertical convexity of the thorax, being directed upwards in the first rib, upwards and outwards in the higher ribs, outwards in the middle series, and outwards and slightly downwards in the tenth, eleventh, and twelfth. The *inner surfaces* are arranged conversely and are covered by the parietal pleura. Towards the sternal end of the middle ribs, where the downward twist is most marked, there is often an oblique line across the outer surface. This is sometimes referred to as the *anterior angle*. The upper border of the shaft is thick and rounded behind, thinner and sharper in front; to it are attached the fibres of the internal and external intercostal muscles. The lower border is grooved behind at the expense of the inner surface, and is overhung laterally by a sharp margin. Anteriorly this *sulcus costalis* (*costal groove*) fades away, and its lips coalesce to form a rounded edge. The intercostal vessels and nerve are lodged in this groove, whilst its lips afford

FIG. 123.—FIFTH RIGHT RIB
AS SEEN FROM BELOW.

attachment to the external and internal intercostal muscles respectively. On the floor of the groove may also be seen the openings of the canals for the transmission of the nutrient vessels, which are directed towards the vertebral end of the rib.

The anterior or sternal extremity of the shaft, often slightly enlarged, displays an elongated oval pit into which the costal cartilage is sunk.

Peculiar Ribs.—The first, second, tenth, eleventh, and twelfth ribs all display characters by which they can be readily recognised.

The first rib can be easily distinguished from the others by its size, curvature, and flattened form, as well as by the great proportionate width of its shaft. The head, which is of small size, has a single oval or circular facet, which is directed medially and slightly backwards for articulation with the side of the body of the first thoracic vertebra. The neck is flattened from above downwards, and is slightly down-turned towards the end which supports the head. Its anterior border is rounded and smooth; its posterior edge rough for the attachment of ligaments. At the point where the neck joins the shaft posteriorly, a prominent tubercle curves upwards and backwards.

FIG. 124.—FIFTH RIGHT RIB AS SEEN FROM BEHIND.

FIG. 125.—FIRST AND SECOND RIGHT RIBS AS SEEN FROM ABOVE.

The inner and under surface of this process has a small circular facet which rests on a corresponding articular surface on the transverse process of the first thoracic vertebra. The angle coincides with the tubercle, and thus assists in emphasising its prominence. The surfaces of the body of the rib are directed upwards and downwards, its borders inwards and outwards. If the finger is run along the thin inner border, a distinct spine or tubercle can be readily felt about an inch or an inch and a quarter from its anterior extremity. This is the *tuberculum scaleni* (*scalene tubercle of Lisfranc*), which also forms an elevation on the upper surface of the shaft and affords an attachment for the scalenus anterior muscle. There is a shallow, oblique groove crossing the superior surface of the shaft in front of this, for the lodgment of the subclavian vein; whilst behind the tubercle there is another groove, usually better marked, and passing obliquely forwards for the subclavian artery (*sulcus subclaviæ*). In this groove, behind and below the artery, is lodged that part of the first thoracic nerve which contributes to the formation of the brachial plexus. According

to Wood Jones the development of the groove depends upon the size of the nerve passing over it. The space on the upper surface of the rib between this latter groove and the tubercle posteriorly is somewhat rough, and affords attachment to the fibres of the scalenus medius muscle. In many specimens these features are

but faintly marked. The anterior extremity of the rib is thickened and often expanded for the reception of its costal cartilage, which is not infrequently ossified. Here on the upper surface are attached the costo-clavicular ligament and the subclavius muscle. The inferior surface of the rib is smooth and is covered by pleura. The outer convex border, thin in front, is usually thick and rough behind the subclavian groove, where it has attached to it the fibres of the first digitation of the serratus anterior. Along this edge, also, are attached the external and internal intercostal muscles of the first intercostal space. The inner concave border is thin, and has connected with it the aponeurotic expansion known as Sibson's fascia.

The **second rib** may be distinguished by the size of its curve; the absence of any twist on its shaft, so that it can be laid flat on the table; the oblique direction of the surfaces of its shaft, the lateral being directed upwards and outwards, whilst the inner is turned downwards and inwards; and the presence of a well-marked, rough, oval area about the middle of its lateral surface and lower border for part of the first, and the whole of the second digitation of the serratus anterior muscle. The head has two facets, and the angle is close to the tubercle posteriorly.

The **tenth rib** has usually only a single articular facet on the head, and may or may not have a facet on the tubercle.

The **eleventh and twelfth ribs** are recognised by their length. Their heads, usually large in proportion to their shafts, support a single facet for articulation with the eleventh and twelfth thoracic vertebræ respectively. The tubercles are ill-developed and have no articular facets. The angle is faintly marked on the

eleventh, scarcely perceptible on the twelfth. Their anterior extremities are narrow and pointed and tipped with cartilage. The costal groove is absent in the twelfth, and but slightly seen in the eleventh. The twelfth is considerably shorter than the eleventh rib.

FIG. 126.—THE THORAX AS SEEN FROM THE FRONT.

Ossification. — Ossification begins in the cartilaginous ribs about the sixth week, and rapidly extends along the shaft, so that by the end of the third month it has reached the permanent costal cartilage. The sixth and seventh ribs are the earliest to ossify; the first rib being the last (Lambert). At puberty, or before, secondary centres appear. One for the head. In the first rib there is one epiphysis for the tubercle. In the second to the sixth ribs inclusive there are two epiphyses for the tubercle, one for the articular part and one for

the non-articular part. In the remaining ribs which have articular tubercles there is only one epiphysis (Fawcett). By the twenty-fifth year fusion between these and the shaft is complete.

THE COSTAL CARTILAGES.

The **costal cartilages**, of which there are twelve pairs, are bars of hyaline cartilage united to the anterior extremities of the ribs, into which they are recessed and held in position by the periosteum. Through these cartilages the first seven ribs are connected directly with the sternum by means of synovial joints corresponding to the notches along the margins of the breast bone. To this there is an exception in the case of the first rib, the cartilage of which is directly blended with the manubrium sterni. The eighth, ninth, and tenth are connected indirectly with the sternum by their union with each other, and their articulation, through the medium of the eighth, with the seventh rib cartilage, whilst the eleventh and twelfth cartilages tip the ribs to which they belong, and lie free in the muscles of the flank. The costal cartilages increase in length from the first to the seventh, below which they become shorter. The first inclines obliquely downwards and medially to unite with the superior angle of the manubrium. The second lies more or less horizontally. The third to the seventh gradually become more and more curved, inclining downward from the extremities of their respective ribs, and then turning upwards to reach the sternum. The tenth cartilage articulates by means of a synovial joint with the ninth, the ninth with the eighth, and the eighth with the seventh. There are also surfaces for the articulation of the seventh with the sixth, and sometimes for the sixth with the fifth.

THE THORAX AS A WHOLE.

The bony and cartilaginous thorax is barrel-shaped, being narrower above than below, and compressed from before backwards. Its posterior wall is longer than its anterior, and its transverse width, which reaches its maximum opposite the eighth or ninth rib, is much in excess of its sagittal diameter. This is largely owing to the forward projection of the thoracic part of the vertebral column into the thoracic cavity.

The **anterior wall** is formed by the ribs and rib cartilages, together with the sternum. The **posterior wall** comprises the thoracic part of the vertebral column and the ribs as far as their angles. Owing to the posterior curve of the ribs, and the projection forwards of the vertebral bodies, the antero-posterior diameter of the thoracic cavity is considerably greater on either side of the medial plane than in the median plane, thus allowing for the lodgment of the rounded

FIG. 127.—THE THORAX AS SEEN FROM THE RIGHT SIDE.

posterior borders of the lungs. For the same reason the furrow on either side of the spinous processes of the thoracic vertebræ is converted into a broad groove (**vertebral groove**), the floor of which is in part formed by the ribs as far as their angles. The grooves so formed are each occupied by the fleshy mass of the sacro-spinalis muscle.

The **lateral walls** are formed by the costal arches. The ribs, which run obliquely from above downwards and forwards, do not lie parallel to each other, but spread somewhat, so that the intervals between them (**intercostal spaces**) are wider in front than behind.

The **superior aperture** or inlet formed by the body of the first thoracic vertebra behind, the arches of the first rib on either side, and the upper border of the manubrium sterni in front, is contracted and of reniform shape, measuring on an average from 10 to 12 cm. transversely and 5 cm. in an antero-posterior direction. The plane of the inlet is oblique from behind downwards and forwards, so that in expiration the superior border of the sternum lies on a level with the fibro-cartilage between the second and third thoracic vertebræ.

The **inferior aperture**, of large size, is bounded in the median plane behind by the twelfth thoracic vertebra; passing thence the twelfth ribs slope laterally, inferiorly, and forwards. From these a line carried horizontally forwards from their tips touches the end of the eleventh rib, and then curving slightly superiorly reaches the cartilage of the tenth rib. Here it follows the confluent margins of the cartilages of the tenth, ninth, eighth, and seventh ribs, finally reaching the xiphoid process, where it forms with the costal margin of the opposite side the infrasternal angle, the summit of which coincides with the xiphi-sternal articulation; in expiration this joint usually lies on a level with the intervertebral fibro-cartilage between the ninth and tenth thoracic vertebræ, and corresponds with the surface depression familiarly known as the pit of the stomach. The inferior aperture of the thorax is occupied by the vault of the diaphragm.

In the fœtal condition the form of the thorax differs from that of the adult. It is laterally compressed—in this respect resembling the simian type. Its antero-posterior diameter is relatively greater than in the adult. At birth changes in form take place dependent on the expansion of the lungs; during subsequent growth, the further expansion of the thoracic cavity in a transverse direction is correlated with the assumption of the erect posture, and the use of the fore-limbs as prehensile organs.

Sexual Differences.—The thorax of the female is usually described as being proportionately shorter and rounder than the male. It also tends to narrowness in the lower segment. It is hardly necessary to point out that the natural form is often modified by the use of tight or ill-fitting corsets.

The **Thoracic Index** = $\frac{\text{Transverse diameter} \times 100}{\text{Antero-posterior diameter}}$ taken at the level of the junction of the xiphoid process with the body expresses the proportions of these diameters. That of the female is on an average lower than the male, indicating a more rounded form.

THE SKULL.

(In view of the vast amount of accurate knowledge the medical student is now called upon to acquire, it is, in the opinion of the writer of this article, desirable that less stress should be laid upon the details of the disarticulated bones of the skull and more emphasis placed on the study of the skull *as a whole*.)

It has hitherto been the custom to disarticulate the bones of the skull, imposing on the student the task of again reconstructing it, much after the manner of a Chinese puzzle. In this way a minute acquaintance with the forms and articulations of the individual bones became necessary, and the student's memory was burdened with a mass of detail of little or no practical or scientific value, for in regard to the latter aspect of the subject the points of phylogenetic and ontogenetic interest are best illustrated by a consideration of the details of the evolution of the skull and the development and ossification of its parts. With possibly the exception of the temporal bones and the mandible, the author holds that most of the useful information relating to the skull can best be studied in the complete cranium, or in sections of it made in different planes. By this method the student acquires a more intimate knowledge of its structure and topography, and is consequently better equipped to deal with the regions he may have to explore in the living.

With this object in view, the writer of this article has given more space to the description of the skull as a whole and in section than is usually the case. Such a plan has doubtless given rise to some repetition; at the same time it renders more complete, and, it is hoped, also more useful from a practical standpoint, the account supplied.

It must, however, be borne in mind that a text-book of Anatomy serves the double purpose of a "Manual" of instruction and a work of reference. In view of this, the author has furnished a detailed account of the disarticulated cranial bones, such as has been hitherto supplied in works of a like kind.

The student, however, must not assume on this account that this section of the article should be neglected. He will find most of the more important details described in the article on the skull as a whole; but he would do well to supplement his knowledge by a reference to the more detailed account for information regarding the development, ossification, and variations of the individual bones.

In this edition additional figures have been introduced, with the object of displaying additional points in the development and ossification of the skull.)

THE BONES OF THE SKULL (*Ossa Cranii*).¹

The term skull (*cranium*) is commonly employed to signify the entire skeleton of the head. This comprises the bony envelope which surrounds the brain (*cranium cerebrale*), and the osseous structures which support the face (*ossa faciei*).

The *cranium cerebrale* is composed of the *occipital*, the *sphenoid*, the *ethmoid*, the *frontal*, the two *parietals*, and the two *temporals*, the *inferior nasal conchæ* (O.T. *inferior turbinated bones*), the *lacrimals*, the *nasal*, and the *vomer*—fifteen bones in all.

The bones of the face (*cranium viscerale, ossa faciei*) include the following:—One single, viz., the *mandible*, and six bones, arranged in pairs, viz., the *maxillæ*, *zygomatic* (O.T. *malar*), *palate*—seven bones in all.

The *hyoid bone* is usually described along with the skull. If, in addition, the bones of the middle ear, three on each side (*malleus*, *incus*, and *stapes*), be included, the skeleton of the head consists of twenty-nine bones.

THE SEPARATE BONES OF THE SKULL.

Os Frontale.

The **frontal bone**, situated in the anterior part of the *cranium*, is a single bone formed by the fusion in early life of two symmetrical halves. It consists of a **frontal part**, which corresponds to the region of the forehead; an **orbital part**, which enters into the structure of the roof of the orbits; and a **nasal part**, which assists in forming the roof of the nasal fossæ.

Pars Frontalis.—The **frontal part** is the shell-like portion of the bone which rises upwards above the orbital arches. Its external surface is rounded from side to side and from above downwards. This convexity is most pronounced about $1\frac{1}{4}$ inches above the orbital arches on either side of the median plane, constituting what are known as the **frontal tuberosities**. These mark the original sites of the centres from which the bone ossifies. The inferior margin of this part is formed on either side of the median plane by the curved **supraorbital margin**, the lateral and medial extremities of which constitute the **zygomatic process** (O.T. **external angular**) and the **medial angular process**, respectively. The latter, which descends to a lower level than the former, articulates with the lacrimal bone, and is separated from its fellow by a rough articular surface—the **nasal notch** for the nasal and maxillary bones. The curve of the supra-orbital margin varies in different individuals and races; towards its medial third

¹ In catalogues of craniological collections the terms used are as follows:—

Skull = entire skeleton of head, including the mandible.

Cranium = the skull, minus the mandible.

Calvaria = that part of the skull which remains after the bones of the face have been removed or destroyed.

it is crossed by a groove, often (25 per cent, Krause) converted into a foramen—the **supraorbital notch or foramen**. Through this there pass the supraorbital nerve and artery. Sometimes (16 per cent, Loja) a series of grooves, radiating upwards and laterally, indicate the course of the nerve (Dixon). Above the supraorbital margin the character of the bone displays marked differences in the two sexes: in the male, above the interval between the two medial angular processes, there is usually a well-marked prominence, called the **glabella**; from this the fulness extends laterally above the supraorbital margin, varying in degree and extent, and forming the elevations known as the **arcus superciliares** (superciliary arches). The prominence of these naturally reacts on the character of the supraorbital margins, which are thicker and more rounded in the male than in the female. Passing upwards over the glabella, the remains of the suture which originally separated the two halves of the frontal bone can usually be seen; above this point all trace of the suture is generally obliterated.

Extending from the **zygomatic process** is a well-marked ridge, which

FIG. 128.—THE FRONTAL BONE (Anterior View).

curves upwards and slightly medially, then, turning backwards, it arches across the lateral aspect of the bone. This is the **linea temporalis**, which serves to separate the anterior surface of the frontal portion of the bone from its temporal aspect. The latter (**facies temporalis**) forms the floor of the upper and anterior part of the temporal fossa, and serves for the attachment of the temporal muscle.

Pars Orbitalis.—The orbital part of the bone consists of two transversely curved plates, each having the form of a sextant; their medial edges, which are irregular and formed of cellular bone, lie parallel to each other, and are separated in their posterior half by the **incisura ethmoidalis** (**ethmoidal notch**), in which the ethmoid bone is lodged. The edges of the notch on either side are grooved in front and behind by the **anterior** and **posterior ethmoidal foramina**, which are completed when the ethmoid is *in situ*. The anterior transmits the anterior ethmoidal branch of the naso-ciliary nerve (O.T. nasal) and the anterior ethmoidal vessels; the posterior, the posterior ethmoidal vessels. Anterior to the ethmoidal notch is the nasal notch, from the centre of which the **nasal process** projects downwards and forwards to terminate in the **frontal spine**, which lies between, and articulates with the nasal bones and perpendicular part of the

ethmoid. On either side of the root of this process the **pars nasalis** (nasal part) of the bone is grooved obliquely from above downwards and forwards, and enters into the formation of the narrow roof of the nasal cavity. Anteriorly the nasal notch is limited by a rough U-shaped serrated surface, the medial part of which articulates with the nasal bones, whilst on either side the frontal processes of the maxillæ are united with it. Behind this, amid the broken cells, the passages leading into the frontal sinuses are readily distinguished, and here the medial edges of the orbital plates articulate with the lacrimal bones. The **orbital part** is thin and brittle. Anteriorly it is bounded by the supraorbital margin, just within which, midway between the medial angular process and the supraorbital notch, there is a small shallow depression (*fovea trochlearis*), often displaying a spicule of bone arising from its edge (*spina trochlearis*), which affords attachment to the pulley of the superior oblique muscle of the eyeball. Laterally the orbital part is overhung by the supraorbital margin and the zygomatic process, and in the hollow so produced (*fossa glandulæ lacrimalis*) the lacrimal gland is lodged. The extremity of the **zygomatic process** articulates with the frontal process of the zygomatic bone.

FIG. 129.—THE FRONTAL BONE AS SEEN FROM BELOW.

Behind this the irregular edge of the orbital surface is united with the great wing of the sphenoid by a triangular area, which also extends on to the inferior aspect of the temporal surface of the frontal bone. The apex of the orbital surface, for the space of about half an inch, articulates with the small wing of the sphenoid.

The **cerebral surface** of the bone forms a fossa in which lie the anterior and inferior parts of the frontal lobes of the cerebrum, the gyri of which impress their form on the inner table of the bone. Here, too, on either side of the median plane, may be seen depressions called *foveolæ granulares*, for the lodgment of arachnoidal granulations (O.T. Pacchionian bodies). Descending from the centre of the upper margin of the bone is a vertical groove, the **sagittal sulcus**; narrowing below, this ends in a ridge—the **frontal crest**—which nearly reaches the anterior part of the ethmoidal notch, where it terminates in a small orifice, the **foramen cæcum**, placed usually in the suture between the anterior part of the ethmoid and the frontal. This foramen may, or may not, transmit a small vein from the nose to the commencement of the superior sagittal sinus. This sinus, which is interposed between the layers of the falx cerebri, is at first attached to the frontal crest, but subsequently occupies the sagittal sulcus. Deeply concave from side to side and from above downwards, the lateral aspects of the fossa are seen to be traversed by small grooves for the anterior branches of the middle meningeal arteries. Below, the

orbital parts bulge into the floor of the fossa, so that the ethmoidal notch appears recessed between them. On either side of the notch faint grooves for the meningeal branches of the ethmoidal vessels may be seen. The circumference of the fossa is formed by the serrated edges of the bone which articulate with the parietals above, and on either side below with the great and small wings of the sphenoid.

Connexions.—The frontal articulates with twelve bones, viz., *posteriorly* with the parietals and sphenoid; *laterally* with the zygomatic bones; *inferiorly* and *medially* with the nasals, maxillæ, lacrimals, and ethmoid.

Ossification.—Ossification begins in membrane from one centre for each half. This makes its appearance about the sixth or seventh week in the region above the processus

FIG. 130.—OSSIFICATION OF THE FRONTAL BONE.

a, Metopic suture still open. *b*, Position of primary centre. *c*, Centre for zygomatic process. *d*, Centre for region of trochlea. *e*, Centres for nasal spine.

zygomaticus. From these the two halves of the frontal part of the bone are developed, and by extension medially and posteriorly from their lower part the orbital parts are also formed. Serres, Rambaud and Renault, and v. Ihering describe the occurrence of three pairs of secondary centres somewhat later: one pair for the frontal spine on either side of the foramen cæcum; a centre on either side in correspondence with the position of each trochlear pit; and a centre for each zygomatic process. Fusion between these secondary and the primary centres is usually complete about the sixth or seventh month of foetal life. At birth the two symmetrical halves of the bone are separated by the *metopic suture*, obliteration of which, commencing as a rule on a level with the frontal tubera, gradually takes place, so that about the fifth or sixth year it is more or less completely closed, traces only of the suture being left above and below. In about 8 per cent of Europeans, however, the suture persists in the adult (see *ante*). At birth the supraorbital notches lie near the middle of the supraorbital margins.

Traces of the frontal sinuses may be met with about the second year, but it is only about the age of seven that they can be definitely recognised. From that time they increase in size till the age of puberty, subsequent to which time they attain their maximum development.

Ossa Parietalia.

The **parietal bones**, two in number, are placed on either side of the vault of the cranium, articulating with the frontal *anteriorly*, the occipital *posteriorly*, and the temporals and sphenoid *inferiorly*. Each bone possesses a parietal and cerebral surface, four borders, and four angles.

The **parietal surface**, convex from above downwards and from before backwards, displays towards its centre a more or less pronounced elevation, the **tuber parietale** (parietal tuberosity). This marks the position of the primitive ossific centre, and not infrequently corresponds to the point of maximum width of the head. At a variable distance from the inferior border of the bone, and more or less parallel to it, two curved lines can usually be distinguished. The **linea temporalis superior** (superior temporal line) serves for the attachment of the temporal fascia; the **linea temporalis inferior** (inferior temporal line) defines the attachment of the temporal muscle, the extent and development of which necessarily determine the position of the line. The surface below the lines enters into the formation of the floor of the temporal fossa, and is called the **planum temporale**; it also affords origin to the temporal muscle, and is often faintly marked by grooves which indicate the course of the middle temporal artery.

Above the superior temporal line the bone is covered only by the tissues of the scalp. Near its superior border, and about an inch from its occipital angle, is the small **parietal foramen**, through which pass a small arteriole and an emissary vein.

The **cerebral surface** is concave from side to side and from above downwards. It is moulded over the surface of portions of the frontal, parietal, occipital, and temporal lobes of the cerebrum, and displays impressions corresponding to the arrangement of the gyri of these portions of the brain. It also presents a series of well-marked grooves for the lodgment of the venous sinuses which accompany the branches of the middle meningeal artery (F. Wood Jones); these radiate from the sphenoidal angle of the bone, the best marked running upwards at some little distance behind and parallel to its anterior border. Within the superior margin is a series of depressions for arachnoideal granulations, and here also the bone is channelled so as to form a groove (*sulcus sagittalis*), which is completed by articulation with its fellow of the opposite side. Within this groove lies the superior sagittal venous sinus, and to its edges the *falx cerebri* is attached. Close to the mastoid angle there is also a curved groove, the *transverse sulcus*, in which the highest portion or bend of the transverse venous sinus is lodged.

FIG. 131.—THE RIGHT PARIETAL BONE (Parietal Surface).

The *anterior*, *superior*, and *posterior* borders are deeply serrated. The **anterior border** articulates with the frontal bone, forming with it the coronal suture. In the superior part of this suture the frontal bone overlaps the parietal, while the parietal overlies the frontal below. The **posterior border** is united with the occipital bone to form the lambdoid suture. The **superior border** articulates with its fellow of the opposite side by means of the sagittal suture; in the interval between the two parietal foramina this suture is usually simple in its outline. The **frontal angle** is almost rectangular, and corresponds to the site of the anterior fontanelle. The **occipital angle**, usually more or less rounded, corresponds in position to the posterior fontanelle. The **inferior border** (*margo squamosus*) is curved, and shorter than the others; it lies between the sphenoidal and mastoid angles. Sharp and bevelled at the expense of its outer table, it displays a fluted arrangement, and articulates with the *squama temporalis* of the temporal bone. The **sphenoidal angle**, pointed and prominent, articulates with the great wing of the sphenoid. It is wedged into the angle formed by the union of that bone with the frontal, and is bevelled at the expense of its inner table anteriorly,

whilst inferiorly it is thinned at the expense of its outer table. The **mastoid angle** is a truncated angle lying between the inferior and posterior borders. It is deeply serrated, and articulates with the mastoid process of the temporal bone. Not infrequently there is a channel in this suture which transmits an emissary vein.

Connexions.—The parietal bone articulates with its fellow, with the frontal, occipital, mastoid and squama temporalis of the temporal, and with the sphenoid. Occasionally the

FIG. 132.—THE RIGHT PARIETAL BONE (Cerebral Surface).

sphenoidal angle may not reach the great wing of the sphenoid, being separated from it by the articulation of the squama temporalis of the temporal with the frontal (Appendix B).

Ossification.—Ossification takes place in membrane by two centres which appear, one superior to the other, about the end of the second month (Toldt); these gradually unite during the fourth month and correspond in position to the future tuber parietale; from this ossification spreads in a radial manner towards the edges of the bone, where, however, the membranous condition still for some time persists, constituting the fontanelles. These correspond in position to the angles of the bone. Ossification is also somewhat delayed in the region of the parietal foramina, constituting what is known as the sagittal fontanelle, a membranous interval which is not infrequently apparent even at birth.

Os Occipitale.

The **occipital bone**, placed at the posterior and lower part of the cranium, consists of four parts, arranged around a large oval hole, called the foramen occipitale magnum or foramen magnum. At birth these parts are all separate. The expanded curved plate posterior to the foramen is the **squama occipitalis** or **tabular part**. The thick rod-like portion anterior to the foramen is the **basilar part**. On either side the foramen is bounded by the **lateral** or **exoccipital parts**.

The **squamous** or **tabular part** in shape somewhat resembles a Gothic arch, and is curved from side to side and from above downwards. It forms inferiorly a small portion of the middle of the posterior boundary of the foramen magnum, and unites, on either side of that, with the lateral parts of the bone. About the centre of the parietal surface of the squama there is a prominence—the **protuberantia occipitalis externa** (**external occipital protuberance**), which varies considerably in its distinctness and projection, and serves for the attachment of the ligamentum nuchæ. From the protuberance on either side two lines curve out towards the lateral angles of the bone. These are known respectively as the **linea nuchæ suprema** and **linea nuchæ superior** (**highest and superior curved lines**). To the upper of these the **galea aponeurotica** (O.T. **epicranial aponeurosis**) is attached, whilst the lower serves for the origin of the trapezius and occipitalis muscles and the insertion of the sternomastoid and splenius capitis muscles. The two lines together serve to divide the **external surface** of the squama occipitalis into an upper or **occipital plane** (**planum occipitale**), covered by the hairy scalp, and a lower or **nuchal plane** (**planum nuchale**), serving for the attachment of the fleshy muscles of the back of the neck. As a rule the occipital part bulges backwards beyond the external occipital protuberance; exceptionally, however, the latter process is the most outstanding part of the bone.

The **nuchal plane**, irregular and rough, is divided into two lateral halves by a medial ridge—the **crista occipitalis externa** (**external occipital crest**), which stretches from the external occipital protuberance above to the posterior border of the foramen magnum below. Crossing the nuchal plane transversely, about its middle, is the **inferior nuchal line**, which passes laterally and forwards on either side towards the lateral margins of the bone. The areas thus marked out serve for the attachment of the semispinalis capitis (O.T. **complexus**), obliquus capitis superior, and rectus capitis posterior major and minor muscles.

The **cerebral surface** of the squamous part, concave from side to side and from above downwards, is subdivided into four fossæ by a crucial arrangement of grooved ridges called the **eminentia cruciata**. In the upper pair of fossæ are lodged the occipital lobes of the cerebrum, whilst the lobes of the cerebellum occupy the lower pair. Near the centre of the eminence is the **protuberantia occipitalis interna** (**internal occipital protuberance**), an irregular elevation, the sides of which are variously channelled according to the disposition of the grooves. Leading from this to the posterior margin of the foramen magnum is a sharp and well-defined ridge, the **internal occipital crest**, which serves for the attachment of the falx cerebelli, a process of dura mater which separates the two cerebellar hemispheres. Passing upwards from the internal occipital protuberance there is usually a well-marked ridge, to one or other side of which, more frequently the right (with the bone in the normal position and viewed from behind), there is a well-defined groove, the **sulcus sagittalis**, the lateral lip of which is generally less prominent. Placed in this groove is the superior sagittal venous sinus, and attached to the lips is the falx cerebri. At right angles to the foregoing, and at the level of the internal occipital protuberance, with which they become confluent, are two transverse grooves, the **sulci transversi**. These grooves, which have more or less prominent edges, lie between the upper and lower pairs of fossæ, and serve for the attachment of the tentorium cerebelli as well as the lodgment of the transverse sinuses. Commonly the right transverse groove is confluent with the groove to the right side of the median ridge, but exceptions to this rule are not infrequent. The angle formed by the union of the venous sinuses lodged in these grooves constitutes the **confluens sinuum** (O.T. **torcular Herophili**), which may accordingly be placed to one or other side of the internal occipital protuberance, more frequently the right; in some cases, however, it may occupy a central position.

The **superior angle**, more or less sharp and pointed, is wedged in between the two parietal bones, its position corresponding to the site of the posterior fontanelle. The **lateral angles** articulate on either side with the posterior extremity of the mastoid portion of the temporal bone. The **superior borders**, much serrated, articulate with the parietal bones forming the **lambdoid suture**; and the **lateral borders**, extending from the lateral angles to the jugular process inferiorly, are connected with the medial sides of the mastoid portions of the temporals.

The **lateral** (or **exoccipital**) parts of the occipital bone are placed on

either side of the foramen magnum; on their under surface they bear the **condyli occipitales** by means of which the skull articulates with the atlas. Of elongated oval form, the **condyles** are so disposed that their anterior extremities, in line with the anterior margin of the foramen magnum, lie closer together than their posterior ends, which extend as far back as the middle of the lateral borders of the foramen. Convex from before backwards, they are skewed so that their surfaces, which are nearly plane from side to side, are directed slightly laterally. Each is supported on a boss of bone, pierced by the **canalis hypoglossi** (**hypoglossal canal**), which opens obliquely from within laterally and forwards on the floor of a fossa called the **fossa condyloidea**, situated just lateral to the anterior part of the condyle. The canal transmits the hypoglossal nerve, together with a meningeal branch of the ascending pharyngeal

FIG. 133.—THE OCCIPITAL BONE AS SEEN FROM BELOW.

artery and its companion veins. Behind the condyle is placed the **fossa condyloidea**, in the floor of which the **canalis condyloideus** (**condyloid canal**) frequently opens. Through this a vein passes which joins the transverse sinus. The fossæ lodge the posterior margins of the superior articular processes of the atlas in extension of the head. The edge of the foramen magnum immediately posterior to the condyle is often grooved for the passage of the vertebral artery around it. Jutting laterally from the posterior half of the condyle is a stout bar of bone, serially homologous with the vertebral transverse process—this is the **processus jugularis**; deeply notched in front (**jugular notch**) its anterior border is free and rounded, and forms the posterior boundary of the jugular foramen. Curving laterally from this margin, in line with the hypoglossal canal, there is often a small pointed projection, the **processus intrajugulare**, which serves to divide the jugular foramen into two compartments. Laterally the jugular process articulates by means of a synchondrosis with the jugular surface of the petrous part of the temporal bone. Its posterior border is confluent with the inferior and lateral portion of the occipital squama, and its under surface is rough and tubercular for the attachment of the

rectus capitis lateralis muscle. The *superior aspect* of the lateral part displays on either side of the foramen magnum an elevated surface of oval form, the **tuberculum jugulare**; this corresponds to the part of the bone which bridges over the canal for the hypoglossal nerve. Its upper surface in many instances displays an oblique groove running across it; in this are lodged the glosso-pharyngeal, vagus, and accessory nerves. The jugular process is deeply grooved superiorly for the lower part of the transverse blood sinus, or sigmoid sinus, which here turns round the anterior free edge of the process into the jugular foramen. Joining this, close to its medial edge, is the opening of the canalis condyloideus when it exists.

The **basilar part** of the occipital bone extends forwards and upwards from the foramen magnum. Its anterior extremity is usually sawn across, as,

FIG. 134.—OCCIPITAL BONE (Cerebral Surface).

after adult life, it is necessary to sever it in this way from the sphenoid, the cartilage uniting the two bones having by that time become completely ossified. Broad and thin posteriorly, it narrows laterally and thickens vertically anteriorly, where on section it displays a quadrilateral form. Projecting from its inferior surface some little distance anterior to the foramen magnum is the **pharyngeal tubercle** to which the fibrous raphe of the pharynx is attached; on either side of this the longus capitis and rectus capitis anterior muscles are inserted. The **superior surface** forms a broad and shallow groove which slopes upwards and forwards from the thin anterior margin of the foramen magnum; in this rests the medulla oblongata. On either side its lateral edges are faintly grooved for the inferior petrosal venous sinuses, below which the lateral aspect of the bone is rough for the cartilage which unites it to the sides and apex of the petrous part of the temporal bone.

The **foramen magnum**, of oval shape, so disposed that its long axis lies in the

sagittal plane, is of variable size and form. The plane of its outlet differs somewhat in individual skulls; in most instances it is directed inferiorly and slightly forwards. Anteriorly the condyles encroach upon it, and narrow to some extent its transverse diameter. To its margins are attached the ligaments which unite it with the atlas and epistropheus. Through it pass the lower part of the medulla oblongata where it becomes continuous with the spinal medulla, the two vertebral arteries, the accessory nerves, and the blood-vessels of the meninges of the superior part of the spinal medulla.

Connexions.—The occipital bone articulates with the two parietals in front and above, with the sphenoid in front and below, with the two temporals on either side, and with the atlas by means of its condyles.

Ossification.—The major part of the bone ossifies in cartilage, the upper part of the squamous part (interparietal) alone developing in membrane. The **basilar part** begins to ossify about the sixth week of fetal life by the appearance of two centres, one in front of the other; the anterior, according to Albrecht, constitutes the *basiotic*, the posterior the *basi-occipital*. These two centres—which there is some reason to believe may themselves be formed by the fusion of pairs placed laterally—rapidly unite, so that the occurrence of one centre alone is frequently described. From this the fore part of the margin of the foramen magnum is formed, together with a portion of the anterior end of the occipital condyle on either side. It helps also to close up the front of the hypoglossal canal. Union with the condylic parts is complete about the fourth or fifth year. Ankylosis between the basi-occipital and the sphenoid takes place about the twenty-fifth year.

The **lateral, condylic, or exoccipital parts** begin to ossify from a single centre about the end of the second month of fetal life. The notch for the hypoglossal canal appears about the third month. From this centre is formed the posterior three-fourths of the occipital condyle. The exoccipital is usually completely fused with the squamous part by the third year or earlier.

As already noted, the squamous part consists of two parts—the one above the occipital

FIG. 135.—OSSIFICATION OF THE OCCIPITAL BONE.

a, Basilar centre; *b*, Exoccipital; *c*, Ossicle of Kerkring; *d*, Supra-occipital (from cartilage); *e*, Fissure between supra-occipital and interparietal; *f*, Interparietal (from membrane); *g*, Fissure between interparietals.

crest, the other below it; the former develops in membrane, the latter in cartilage. In a three-months foetus this difference is very characteristic. The cartilaginous part (*supra-occipital*) begins to ossify from two centres (four according to Mall) about the sixth or seventh week, which rapidly join to form an elongated strip placed transversely in the region of the occipital protuberance. The centres for the superior part (*interparietal*) appear later. According to Maggi (*Arch. Ital. Biol.* tome 26, fas. 2, p. 301), they are four in number, of which two placed on either side of the median plane appear about the second month. The other pair, placed laterally, are seen about the third month; fusion between these takes place early, but their disposition and arrangement explain the anomalies to which this part of the bone is subject. The medial pair may persist as separate ossicles, or fuse to form the *pre-interparietals*, whilst the lateral pair may remain independent of the supra-occipital as a single or double *interparietal* bone, the former, owing to the frequency of its occurrence in Peruvian skulls, being sometimes called the "*os Incæ*." Union between the supra-occipital and the interparietal elements occurs about the third or fourth month; but evidence of their separation is frequently met with even in the adult by the persistence of a transverse suture running inwards from each lateral angle of the squamous part, or, as above mentioned, there may be an *os Incæ*.

The supra-occipital forms a small part of the median part of the posterior border of the foramen magnum, though here a small independent centre, known as the ossicle of Kerkring, is occasionally met with. Other independent centres are sometimes seen between the supra-occipital and the exoccipitals.

At birth the occipital consists of four parts—the interparietal and supra-occipital combined, the basi-occipital, and the exoccipitals—one on either side.

Ossa Temporalia.

The **temporal bone** lies about the centre of the inferior half of either side of the skull, and enters largely into the formation of the cranial base. It is placed between the occipital behind, the parietal above, the sphenoid in front, and the occipital and sphenoid medially and below. At birth it consists of three parts—a superior and lateral part, the **squama temporalis** or **squamous portion**; a medial and posterior portion, the **petro-mastoid**, which contains the parts specially associated with the sense of hearing, together with the organ associated with equilibration; and an inferior or **tympanic part**, from which the floor and anterior wall of the external acoustic meatus is formed.

The **squamous part** consists of a thin shell-like plate of bone placed vertically, having a medial (cerebral) and a lateral (temporal) surface and a semicircular upper border. Inferiorly, behind, and medially it is fused in early life with the petro-mastoid portion by means of the squamoso-mastoid and the petro-squamosal sutures, traces of which are often met with in the adult bone; whilst below and in front it is separated from the tympanic and petrous parts by the **petro-tympanic fissure**. Its **temporal surface**, smooth and slightly convex, enters into the formation of the floor of the temporal fossa, and affords attachment to the temporal muscle. Near its posterior part it is crossed by one or more ascending grooves for the branches of the middle temporal artery. In front and below there springs from it the **processus zygomaticus**. This arises by a broad attachment, the surfaces of which are inferior and superior; curving laterally and forwards, it then becomes twisted and narrow, so that its sides are turned medially and laterally and its edges directed upwards and downwards. Anteriorly it ends in an oblique serrated extremity which articulates with the temporal process of the zygomatic bone. Posteriorly the edges of the zygomatic process separate and are termed its roots. The superior edge, which becomes the **posterior root**, sweeps back over the external acoustic meatus, and is continuous with the **supra-mastoid crest**, which curves backwards and slightly upwards, and serves to define the limit of the temporal fossa posteriorly. Internally this ridge corresponds to the level of the floor of the middle cerebral fossa. The inferior edge turns medially and constitutes the **anterior root**; the inferior surface of this forms a transversely disposed rounded ridge, the **tuberculum articulare** (O.T. **articular eminence**), behind which there is a deep hollow, the **fossa mandibularis**, limited posteriorly by the tympanic plate, and crossed at its deepest part by an oblique fissure, the **petro-tympanic fissure**. This cleft, which is closed externally, transmits about its middle the tympanic branches of the internal maxillary artery, and lodges the anterior process of the malleus. At its medial end the lips of this fissure are frequently separated by a thin scale of bone, a downgrowth from the tegmen tympani of the petrous part, which here separates the tympanic from the squamous elements, forming in its descent the major part of the lateral wall of the osseous auditory tube, which lies just medial to it. Between this scale of bone and the posterior edge of the fissure there is a canaliculus, which transmits the chorda tympani nerve. The part of the mandibular fossa in front of the petro-tympanic fissure as well as the articular tubercle articulate with the condyle of the mandible, through the medium of the interposed articular disc. Posteriorly the part of the fossa behind the fissure is non-articular and lodges a portion of the parotid gland. At the angle formed by the divergence of the two roots of the zygoma, in correspondence with the lateral part of the articular tubercle, there is a rounded **tubercle**; to this are attached the fibres of the temporo-mandibular ligament of the mandibular joint. In front of the medial end of the articular tubercle there is a small triangular surface, limited anteriorly by the edge of the anterior root, and medially by a thick serrated margin which articulates with the temporal aspect of the great wing of the sphenoid; this area forms part of the roof of the infra-temporal (O.T. zygomatic) fossa. Just anterior to the external acoustic meatus and projecting

downwards from the inferior surface of the posterior root there is a conical process, called the **post-glenoid tubercle**, which forms a prominent anterior lip to the lateral extremity of the petro-tympanic fissure; it is the representative in man of a process which is developed in some mammals and prevents the backward displacement of the mandible. By some anatomists it is referred to as the **middle root** of the zygomatic process.

The **zygomatic process** by its inferior margin and medial surface gives origin to the masseter muscle, whilst attached to its superior edge are the layers of the temporal fascia. Behind the external acoustic meatus, and below the supramastoid crest, the squamous element extends downwards as a pointed process, which assists in forming the roof and posterior wall of the external acoustic meatus, where it unites inferiorly with the tympanic part and forms the lateral wall of a hollow within called the tympanic antrum. In the adult this process is occasionally

FIG. 136.—THE RIGHT TEMPORAL BONE SEEN FROM THE PARIETAL SIDE.

The squamo-zygomatic part is coloured blue; the petro-mastoid, red.

The tympanic part and styloid process are left uncoloured.

sharply defined posteriorly by an oblique irregular fissure, the remains of the masto-squamosal suture. Immediately above and behind the external acoustic meatus there is often a little projecting spur of bone, the **spina suprameatum** (**supra-meatal spine**).

The angular recess between this process and the supramastoid crest is of interest surgically, and is known as **Macewen's triangle**. The same authority has pointed out that the masto-squamosal suture frequently remains open till puberty and occasionally after, and may be of importance as a channel along which infective processes may extend.

The **cerebral surface** of the squamous part, less extensive than the parietal aspect owing to the bevelling of the parietal border, is marked by the impression of the gyri of the temporal lobe of the cerebrum, and is limited below by the petro-squamosal suture, the remains of which can frequently be seen. It is crossed in front by an ascending groove for the middle meningeal artery and its accompanying venous sinuses, branches from which course backwards over the bone in grooves more or less parallel to its parietal border.

The **parietal border** of the squamous part is curved, sharp, and scale-like, being

bevelled at the expense of its inner table, except in front, where the margin is thick and stout. Here it articulates with the great wing of the sphenoid, its union with that bone extending to near the anterior part of the summit of the curve, behind which it is united to the parietal, overlapping the squamous border of that bone; posteriorly the free margin of the squamous part ends at an angle formed between it and the mastoid process called the *incisura parietalis*.

Pars Tympanica.—The tympanic part of the temporal bone forms the anterior, lower, and part of the posterior wall of the external acoustic meatus. Bounded in front and above by the petro-tympanic fissure, it forms the posterior wall of the non-articular part of the mandibular fossa. Fused medially with the petrous part, its lower edge, sharp and well defined medially, splits to enclose the root of the projecting **styloid process**, and is hence called the *vagina processus styloidei* (sheath of the styloid process). Laterally it unites with the anterior part of the

FIG. 137.—THE RIGHT TEMPORAL BONE (Cerebral aspect).

The squamo-zygomatic part is coloured blue; the petro-mastoid part, red.

The styloid process is left uncoloured.

mastoid process, and higher up with the descending process of the squamous part, from both of which it is separated by the **tympano-mastoid fissure**, through which the auricular branch of the vagus escapes. Its free border, which forms the anterior, lower, and part of the posterior border of the external acoustic meatus, is usually somewhat thickened and rough, and serves for the attachment of the cartilaginous part of the external acoustic meatus.

The **meatus acusticus externus** (external acoustic meatus) is directed obliquely inwards and a little forwards, and describes a slight curve, the convexity of which is directed upwards; of oval form, its long axis, close to its orifice, is nearly vertical, but, as it passes inwards, inclines somewhat forwards so as to give a twist to the canal. The depth of the canal to the attachment of the *membrana tympani* averages from 14 to 16 mm. The superior margin of the outer orifice overhangs considerably the lower edge, but owing to the obliquity of the inner aperture, to which the *membrana tympani* is attached, the superior wall of the osseous canal only exceeds the length of the lower wall by one or two millimetres.

Pars Petrosa et Pars Mastoidea.—The petro-mastoid part of the temporal

bone, of pyramidal form, is fused to the medial aspect of the tympanic and squamosal portions, extending behind them, however, to form the well-marked and prominent **mastoid process**, which lies posterior to the external acoustic meatus. This process forms a nipple-like projection, the size of which differs considerably in different individuals. Usually larger in the male than in the female, its rough lateral surface and inferior border serve for the insertions of the sterno-mastoid, splenius capitis, and longissimus capitis muscles. Within and below its pointed extremity there is a deep groove (*incisura mastoidea*), usually well marked, which gives origin to the posterior belly of the digastric muscle; whilst lying to the medial side of this, and separated from it by a more or less well-defined rough ridge, there can oftentimes be seen a narrow, shallow furrow, which indicates the course of the occipital artery. The **medial surface** of the mastoid portion forms, in part, the lateral wall of the posterior cranial fossa, in which the cerebellar lobes are lodged. Coursing across this aspect of the bone there is a broad curved groove, the convexity of which is directed forwards and lies in the angle formed by the base of the petrous part and its fusion with the mastoid portion. The depth to which the bone is here channelled varies considerably, and is important from a surgical standpoint, as herein lies the sigmoid portion of the transverse venous sinus. Anteriorly the mastoid is fused with the descending process of the squamosal above, and below, where it is united with the tympanic, it enters into the formation of the posterior wall of the external acoustic meatus and the cavity of the tympanum. Above, its free margin is rough and serrated, and articulates with the mastoid angle of the parietal; behind and below it articulates by a jagged suture with the occipital. Traversing this suture, or near it, is the **mastoid foramen**, which transmits a vein from the transverse sinus to the cutaneous occipital vein, together with a small branch of the occipital artery.

The **petrous part (pyramis)** of the petro-mastoid is of the form of an elongated three-sided pyramid. By its base it is united obliquely to the inner sides of the squamosal and tympanic parts. Its apex is directed medially, forwards, and a little upwards. Its three surfaces are arranged as follows:—The **anterior** looks upwards, slightly forwards, and a little laterally, and forms part of the floor of the middle cranial fossa. The **posterior** is directed backwards and medially, and forms part of the anterior wall of the posterior cranial fossa. The **inferior** is seen on the under surface of the base of the skull, and is directed downwards. The borders or angles are named respectively anterior, superior, and posterior.

The **anterior angle** is short, and forms an acute angle with the anterior part of the squamous part; within this angle is wedged the spinous part of the great wing of the sphenoid. Here, too, the **osseous part of the auditory tube (canalis musculo-tubarius)** may be seen leading backwards and laterally from the summit of the angle to reach the anterior part of the cavity of the tympanum in the interior of the bone. On looking into it, the canal is seen to be divided into two unequal parts by an osseous partition, the *septum tubæ*. The upper compartment, the smaller of the two (*semicanalis m. tensoris tympani*), lodges the tensor tympani muscle, whilst the lower (*semicanalis tubæ auditivæ*) forms the osseous part of a channel (the **auditory tube**), which serves to conduct air from the pharynx to the tympanum.

The **posterior angle** is in part articular and in part non-articular. Posteriorly and laterally it corresponds to the upper margin of an area on the inferior surface with which the extremity of the jugular process of the occipital articulates. In front of that it is irregularly notched, and forms the free anterior edge of the jugular foramen, medial to which it has a sharp curved border, often grooved, reaching to the apex. This groove, which is completed by articulation with the lateral side of the basi-occipital, lodges the inferior petrosal venous sinus.

The **superior angle** is a twisted edge which is continuous with the upper margin of the sulcus for the transverse sinus posteriorly, and anteriorly and medially reaches the apex of the bone. Running along it there is usually a well-marked groove for the superior petrosal venous sinus, and near its medial extremity it is slightly notched for the passage of the trigeminal nerve. Along the entire length of this border the tentorium cerebelli is attached.

On the inferior surface of the petrous part, which is bounded in front by the anterior border medially, the tympanic plate laterally, and behind by the posterior border, the following structures are to be noted:—Springing from and surrounded by its sheath is the slender and pointed **processus styloideus**, the length of which varies much. Projecting downwards and slightly forwards and medially, it affords attachments for the stylo-glossus, stylo-hyoid, and stylo-pharyngeus muscles, as well as the stylo-hyoid and stylo-mandibular ligaments. Just behind it, and between it and the mastoid process, is the **foramen stylomastoideum**, which lies at the anterior end of the mastoid groove, and transmits the facial nerve and the stylo-mastoid artery. Just medial to the styloid process there is a deep, smooth, excavated hollow, the **fossa jugularis**, which is converted into a foramen (jugular) by articulation with the occipital bone. Behind and lateral to the fossa there is a small **quadrilateral surface** of variable size, which is united to the extremity of the jugular process of the exoccipital by a synchondrosis. Inside the fossa, on its lateral aspect, or placed on its lateral border, is the opening of a small canal (**canaliculus mastoideus**), which passes outwards to open into the **canalis facialis**, and transmits the auricular branch of the vagus, which ultimately escapes through the petro-mastoid fissure (*vide ante*). In front of the jugular fossa and separated from it by a sharp crest, and just medial to the tympanic plate, is the circular opening of the inferior orifice of the **canalis caroticus** (carotid canal). Directed at first upwards, this canal bends at a right angle and turns forwards and inwards, lying parallel to the anterior angle; reaching the anterior part of the apex of the bone, it opens in front by an oblique ragged orifice. Through the canal the internal carotid artery, accompanied by a plexus of sympathetic nerves, passes into the cranium. On the ridge of bone separating the jugular fossa from the carotid canal is the opening of a small canal (**canaliculus tympanicus**), through which the tympanic nerve of the glosso-pharyngeal passes to reach the tympanum. Within the orifice of the carotid canal other small openings (**canaliculi carotici tympanici**) may be noticed which afford passage to the tympanic branches of the internal carotid artery and carotid sympathetic plexus. Occupying the interval posteriorly and medially between the jugular fossa and the carotid canal is a V-shaped depression (**fossula fenestræ cochleæ**), on the floor of which and close to the posterior border is the orifice of the **apertura externa aquæductus cochleæ** (aqueduct of the cochlea). In the fossa is lodged the petrous ganglion of the glosso-pharyngeal nerve, and the aqueduct transmits a tubular prolongation of the dura mater, which forms a channel of communication between the perilymph of the cochlea and the subarachnoid space. A small vein also passes through it. In front of and medial to the orifice of the carotid canal the under surface of the

FIG. 138.—THE RIGHT TEMPORAL BONE SEEN FROM BELOW.

The squamo-zygomatic part is coloured blue; the petro-mastoid, red. The tympanic portion and styloid process are left uncoloured.

Through the canal the internal carotid artery, accompanied by a plexus of sympathetic nerves, passes into the cranium. On the ridge of bone separating the jugular fossa from the carotid canal is the opening of a small canal (**canaliculus tympanicus**), through which the tympanic nerve of the glosso-pharyngeal passes to reach the tympanum. Within the orifice of the carotid canal other small openings (**canaliculi carotici tympanici**) may be noticed which afford passage to the tympanic branches of the internal carotid artery and carotid sympathetic plexus. Occupying the interval posteriorly and medially between the jugular fossa and the carotid canal is a V-shaped depression (**fossula fenestræ cochleæ**), on the floor of which and close to the posterior border is the orifice of the **apertura externa aquæductus cochleæ** (aqueduct of the cochlea). In the fossa is lodged the petrous ganglion of the glosso-pharyngeal nerve, and the aqueduct transmits a tubular prolongation of the dura mater, which forms a channel of communication between the perilymph of the cochlea and the subarachnoid space. A small vein also passes through it. In front of and medial to the orifice of the carotid canal the under surface of the

apex of the bone corresponds to a rough quadrilateral surface which forms the floor of the carotid canal, and also serves for the attachment of the cartilaginous part of the auditory tube as well as the origin of the levator veli palatini muscle; elsewhere it has attached to it the dense fibrous tissue which fills up the cleft (petro-basilar fissure) between it and the basilar part of the occipital bone.

The **anterior surface** bears the impress of the gyri of the under surface of the temporal lobe of the cerebrum, which rests upon it; in addition, there is a distinct but shallow depression (*impressio trigemini*) near the apex, corresponding to the roof of the carotid canal; in this is lodged the semilunar ganglion on the sensory root of the trigeminal nerve. Lateral to the middle of the upper surface, and close to its posterior border, is the elevation (*eminentia arcuata*), more or less pronounced, which marks the position of the superior semicircular canal, here developed within the substance of the bone. A little

FIG. 139.

Preparation to display the position and relations of the tympanic antrum. The greater part of the posterior wall of the external acoustic meatus has been removed, leaving only a bridge of bone at its inner extremity; under this a bristle is displayed, passing from the tympanic antrum through the iter to the cavity of the tympanum.

in front of this, and in line with the angle formed by the anterior border and the squamous part, is the slit-like opening of the **hiatus canalis facialis**, within the projecting lip of which two small orifices can usually be seen. These are the openings of the **canalis facialis**; if a bristle be passed through the more medial of the two openings it will be observed to pass into the bottom of the internal acoustic meatus, if into the more lateral, it will pass through the facial canal, and, provided the channel be clear, will appear on the under surface of the bone at the stylo-mastoid foramen. Leading forwards and medially from the hiatus towards the anterior border is a groove; in this lies the great superficial petrosal nerve, which passes out of the hiatus. A small branch of the middle meningeal artery also enters the bone here. A little lateral to the hiatus is another small opening (**apertura superior canalis tympanici**), often difficult to see; from this a groove runs forwards which channels the upper surface of the roof of the canal for the tensor tympani muscle. Through this foramen and along this groove passes the lesser superficial petrosal nerve. Behind this, and in front of the **arcuate eminence**, the bone is usually thin (as may be seen by holding it up to the light falling through the external acoustic meatus), roofing in the cavity

within the bone called the tympanum and forming the *tegmen tympani*. Laterally the line of fusion of the petrous with the squamous part is often indicated by a faint and irregular petro-squamous fissure.

Posterior Surface.—The most conspicuous object on the posterior surface of the petrous part of the bone is the *meatus acusticus internus* (internal acoustic meatus), about 8 mm. deep in the adult. This has an oblique oval aperture, and leads outwards and slightly downwards into the substance of the bone, giving passage to the acoustic and facial nerves, together with the *nervus intermedius* and the auditory branch of the basilar artery. The canal appears to end blindly; but if it be large, or still better, if part of it be cut away, its fundus will be seen to be crossed by a horizontal ridge, the *falciform crest*, which divides it into two fossæ, the floors of which (*laminæ cribrosæ*) are pierced by numerous small foramina for the branches of the acoustic nerve and the vessels passing to the membranous labyrinth, whilst in the anterior and upper part of the higher fossa the orifice of the *canalis facialis*, through which the facial nerve passes, is seen leading in the direction of the *hiatus canalis facialis* (*vide supra*). Lateral to the internal acoustic meatus and above it, close to the superior border, an irregular depression, often faintly marked, with one or two small foramina opening into it, is to be noticed. This is the *fossa subarcuata*, best seen

in young bones (see Fig. 143 C), where it forms a distinct recess, which is bounded above by the bulging caused by the superior semicircular canal, within the concavity of which it is placed; it lodges a process of the *dura mater*. Below and lateral to this, separated from it by a smooth, elevated curved ridge, is the opening of the *apertura externa aquæductus vestibuli* (aqueduct of the vestibule), often concealed in a narrow curved fissure overhung by a sharp scale of bone. In this is lodged the *sacculus endolymphaticus*, the remains of the stalk of the *otocyst*, together with a small vein. The ridge above it corresponds to the upper half of the posterior semicircular canal.

FIG. 140.—VERTICAL TRANSVERSE SECTION THROUGH THE LEFT TEMPORAL BONE (Anterior Half of Section).

the mandible. Occasionally the temporal articulates with the frontal, as happens normally in the anthropoid apes; although the region of the pterion is characterised by an X-like form, in the lower races of man there is no evidence that the occurrence of a fronto-squamosal suture is more frequent in the lower than the higher races, its occurrence being due to the manner of fusion of the so-called epipteric ossicles with the surrounding bones.

Ossification.—The temporal bone of man represents the fused periotic, squamosal, and tympanic elements; the two latter are membrane or investing bones, whilst the former is developed in cartilage around the auditory capsule. The cartilages of the I. and II. visceral arches are also intimately associated with its development, as will be elsewhere explained (Appendix E). The human temporal bone is characterised by the large proportionate size of the squamosal, the comparatively small size of the tympanic, the absence of an auditory bulla, and the exceptional development of the mastoid process.

Ossification commences in the ear capsule in the fifth month, and proceeds so rapidly that by the end of the sixth month the individual centres are more or less fused. Of these, one, the *Pro-otic* (Huxley), which appears in the vicinity of the *eminencia arcuata*, is the most definite in position and form; from this a lamina of bone of spiral form is developed, which covers in the medial limb of the superior semicircular canal, and forms the roof of the internal acoustic meatus, together with the commencement of the

facial canal. Reaching forwards, it extends to the apex of the petrous part; whilst laterally it forms part of the medial wall of the tympanum, surrounds the fenestra vestibuli, and encloses within its substance portions of the cochlea, vestibule, and superior semicircular canal. Another centre, the **Opisthotic**, appears in the vicinity of the promontory on the medial wall of the tympanum, surrounds the fenestra cochleæ, forms the floor of the vestibule, and extends medially to complete the floor of the internal acoustic meatus. Surrounding the cochlea inferiorly and laterally, it completes the floor of the tympanum, and ultimately blends with the anterior and under part of the tympanic ring. The carotid canal at first grooves it, and is then subsequently surrounded by it. According to Lambertz the lamina spiralis of the cochlea ossifies in membrane. The roof of the tympanum is formed from a separate centre, the **Pterotic**, which extends backwards towards the superior semicircular canal, and encloses the tympanic part of the facial canal; laterally this centre unites by suture with the squamosal, and sends down a thin process, which appears between the lips of the petro-tympanic fissure, and forms the lateral wall of the auditory tube. Nuclei, either single or multiple, **Epitotic**, appear in the base of the petrous part, and envelop the

FIG. 141.—VERTICAL TRANSVERSE SECTION THROUGH THE LEFT TEMPORAL BONE (Posterior Half of Section).

posterior and lateral semicircular canals. It is by extension from this part that the mastoid process is ultimately developed. The **styloid process**, an independent development from the upper end of the cartilage of the second visceral arch, is ossified from two centres. The upper or basal appears before birth, and rapidly unites with the petromastoid, the tympanic plate encircling it in front. This represents the **tympanohyal** of comparative anatomy. At birth, or subsequent to it, another centre appears in the cartilage below the above: this is the **stylohyal**. Ankylosis usually occurs in adult life between the tympanohyal and stylohyal, the union of the two constituting the so-called styloid process of human anatomy.

FIG. 142.—HORIZONTAL SECTION THROUGH THE LEFT TEMPORAL BONE (Lower Half of Section).

The centre from which the **squamo-zygomatic** develops appears in membrane about the end of the second month. Situated near the root of the zygoma, it extends forwards and laterally into that process, medially to form the floor of the infra-temporal fossa, and upwards into the squamosal. From this latter there is a downward and backward exten-

sion, which forms the post-auditory process; this ultimately blends with the posterior limb of the tympanic ring, being separated from it in the adult by the petro-mastoid fissure. It forms the lateral wall of the tympanic antrum, and constitutes the anterior and upper part of the mastoid process in the adult. About the third month a centre appears in the outer membranous wall of the tympanum: from this the **tympanic ring** is developed. Incomplete above, it displays two free extremities. Of these, the anterior is somewhat enlarged, and unites in front with the mandibular portion of the squamo-zygomatic, being separated from it by the petro-tympanic fissure and the downgrowth from the tegmen tympani; the posterior joins the post-auditory process of the squamo-zygomatic above mentioned. Below, it blends medially with the portion of the petro-mastoid which forms the floor of the tympanum and ensheathes the tympanohyal behind. From the medial surface of the ring below there is an extension medially and forwards which forms the floor of the osseous part of the auditory tube, as well as the lateral wall and half the floor of the carotid canal. From the lateral side of the lower part of this ring two tubercles arise;

The squamo-zygomatic part is coloured blue; the petro-mastoid red. The tympanic ring is left uncoloured.

FIG. 143.—A. THE PARIETAL SURFACE OF THE RIGHT TEMPORAL BONE AT BIRTH. B. THE SAME WITH THE SQUAMO-ZYGOMATIC PORTION REMOVED. (The lettering is the same in both A and B.) *a*, Tympanic ring. *b*, Medial wall of tympanum. *c*, Fenestra cochleæ. *d*, Fenestra vestibuli. *e*, Tympanic antrum. *f*, Mastoid process. *g*, Masto-squamosal suture, with foramen for transmission of vessels. *h*, Squamo-zygomatic, removed in figure B to show how its descending process forms the lateral wall of the tympanic antrum.

C. CEREBRAL SURFACE OF THE RIGHT TEMPORAL BONE AT BIRTH.

a, Squamo-zygomatic. *b*, Petro-squamosal suture and foramen (just above the end of the lead line). *c*, Subarcuate fossa. *d*, Aquæductus vestibuli. *e*, Aquæductus cochleæ. *f*, Internal acoustic meatus. *g*, Upper end of carotid canal.

these grow laterally, and so form the floor of the external acoustic meatus. The interval between them remains unossified till about the age of five or six, after which closure takes place. This deficiency may, however, persist even in adult life (see Appendix B, Temporal).

At birth the temporal bone can usually be separated into its component parts. The lateral surface of the petrous part not only forms the medial wall of the tympanum, but is hollowed out behind and above to form the inner side of the tympanic antrum, the outer wall of which is completed by the post-auditory process of the squamo-zygomatic. As yet the mastoid process is undeveloped. It only assumes its nipple-like form about the second year. Towards puberty its spongy substance becomes permeated with air spaces, which are in communication with and extensions from the tympanic antrum. Occasionally this pneumatic condition is met with in early childhood. The external acoustic meatus is unossified in front and below, the outgrowth from the tympanic ring occurring subsequent to birth. The mandibular fossa is shallow and everted; the jugular fossa is ill-marked; whilst the subarcuate fossa is represented by a deep pit, the so-called floccular fossa of comparative anatomy. The hiatus of the facial canal is an open groove, displaying at either end the openings of the medial and lateral portions of the facial canal.

Os Sphenoidale.

The **sphenoid bone** lies in front of the basilar part of the occipital medially, and the temporals on either side. It enters into the formation of the cranial, orbital, and nasal cavities, as well as the temporal, infra-temporal, and pterygo-

palatine fossæ. It consists of a body with three pairs of expanded processes, the great wings, the small wings, and the pterygoid processes.

The **corpus** (body), more or less cubical in form, is hollow, and contains within it the two large **sphenoidal air sinuses**. These are separated by a partition, which

FIG. 144.—THE SPHENOID SEEN FROM BEHIND.

is usually deflected to one or other side of the median plane. Each sinus extends laterally for a short distance into the root of the great wing, and downwards and laterally towards the base of the pterygoid process of the same side. They

FIG. 145.—THE SPHENOID SEEN FROM THE FRONT.

communicate by apertures with the upper and back part of the nasal cavities. In the adult the **posterior aspect** of the body displays a sawn surface due to its separation from the basi-occipital, with which in the adult it is firmly ankylosed. The **superior surface**, from the anterior angles of which the small wings arise, displays an appearance comparable to that of an oriental saddle. Over its middle there is a deep depression, the **sella turcica** or **fossa hypophyseos**, in which is lodged the hypophysis (O.T. pituitary body). Behind, this is overhung by a sloping ridge, the **dorsum sellæ**, the posterior surface of which is inclined upwards, and is in continuation with

the basilar groove of the occipital bone, supporting the pons and the basilar artery. Anteriorly and laterally the angles of this ridge project over the fossa hypophyseos in the form of prominent tubercles, called the **processus clinoides posteriores** (posterior clinoid processes). To these are attached the tentorium cerebelli and interclinoid ligaments. In front of the sella turcica there is a transverse elevation, the **tuberculum sellæ**, towards the lateral extremities of which, and somewhat behind, there are oftentimes little spurs of bone, the **processus clinoides medii** (middle clinoid processes). In front of the tuberculum sellæ is the **sulcus chiasmatis**, which passes laterally on either side to become continuous, between the roots of the small wings, with the optic foramina.

This groove is liable to considerable variations, and apparently does not always serve for the lodgment of the optic chiasma. (Lawrence, "Proc. Soc. Anat.," *Journ. Anat. and Physiol.* vol. xxviii. p. 18.)

In front of the **sulcus chiasmatis**, from which it is often separated by a thin sharp edge, the superior surface continues forwards on the same plane as the upper surfaces of the small wings, and terminates anteriorly in a ragged edge, which articulates with the cribriform plate of the ethmoid, and has often projecting from it, medially, a pointed process, the **sphenoidal spine**. The lateral aspects of the body are fused with the great wings, and in part also with the roots of the pterygoid processes. Curving along the side of the body, superior to its attachment to the great wing, is an -shaped groove, the **sulcus caroticus** (carotid groove), which marks the position and course of the internal carotid artery. Posteriorly, the hinder margin of this groove, formed by the salient lateral edge of the posterior surface of the body, articulates with the apex of the petrous portion of the temporal bone, and is hence called the **petrosal process**; just above this, on the lateral border of the **dorsum sellæ**, there is often a groove for the abducent nerve.

The anterior surface of the body displays a vertical medial **crista sphenoidalis** (sphenoidal crest), continuous above with the sphenoidal spine, and below with the pointed projection called the sphenoidal rostrum. This crest articulates in front with the perpendicular plate of the ethmoid. On either side of the median plane are seen the irregular openings leading into the sphenoidal air sinuses, the thin anterior walls of which are in part formed by the absorption of the sphenoidal **conchæ** (O.T. turbinated bones) with which in early life they are in contact. With exception of a broad groove leading downwards from the apertures above mentioned, which enters into the formation of the roof of the nasal fossa of the corresponding side, the lateral aspects of this surface of the bone are elsewhere in articulation with the labyrinths of the ethmoid and the orbital processes of the palate bones. The **sphenoidal rostrum** is continued posteriorly for some distance along the inferior surface of the body, where it forms a prominent keel which fits into the recess formed by the **alæ** of the vomer. The edges of the latter serve to separate the rostrum from the incurved vaginal processes at the roots of the medial plates of the pterygoid processes. Posteriorly the under surface of the body of the sphenoid is rougher, and covered by the mucous membrane of the roof of the pharynx; here, occasionally, a median depression may be seen which marks the position of the inferior extremity of a foetal channel, called the **canalis craniopharyngeus**.

Alæ Parvæ.—The small wings are two flattened triangular plates of bone which project forwards and laterally from the anterior and upper part of the body of the bone, with which they are united by two roots which enclose between them the **optic foramina** for the transmission of the optic nerves and ophthalmic arteries. Of these roots, the posterior springs from the body just wide of the tuberculum sellæ, separating the carotid groove behind from the optic foramen in front; laterally this root is confluent with the recurved posterior angle of the small wing, forming the projection known as the **processus clinoides anterior** (anterior clinoid process), which overhangs the anterior part of the body of the bone and affords an attachment to the tentorium cerebelli and interclinoid ligaments. The anterior root, broad and compressed, unites the upper surface of the small wing with the anterior and upper part of the body. Laterally the lateral

angle terminates in a pointed process which reaches the region of the pterion and there articulates with the frontal, and may come in contact with the great wing. The superior aspect is smooth, and forms in part the floor of the anterior cranial fossa. The inferior surface constitutes part of the posterior portion of the upper wall of the orbit, and also serves to roof in the **superior orbital fissure** (O.T. **sphenoidal fissure**), which separates the small wing from the great wing below. The anterior edge is ragged and irregular, and articulates with the orbital parts of the frontal. The posterior margin, sharp and sickle-shaped, separates the anterior from the middle cranial fossa, and corresponds to the position of the stem of the lateral cerebral fissure on the surface of the cerebrum.

Alæ Magnæ.—The **great wings**, as seen from above, are of a somewhat crescentic shape and form a considerable portion of the floor of the middle cranial fossa. If the medial convex edge of the crescent be divided into fifths, the posterior fifth extends backwards and laterally beyond the body of the bone, presenting a free posterior edge, which forms the anterior boundary of the foramen lacerum. This border ends behind in the horn of the crescent, from which a pointed process projects downwards, called the **spina angularis**; this is wedged into the angle between the petrous and squamous parts of the temporal bone. The medial surface of the posterior border and spine is furrowed for the cartilaginous part of the auditory tube (**sulcus tubæ**), whilst on the medial side of the spine the course of the chorda tympani nerve is indicated by a groove (Lucas). The second fifth of the convex border of the crescent is fused to the side of the body and united below with the root of the pterygoid process. The angle formed by the union of the great wing with the side of the body posteriorly corresponds to the hinder end of the carotid groove, the lateral lip of which is formed by a projecting lamina called the **lingula**. The remaining three-fifths of the convex border is divisible into two nearly equal parts; the medial is a free, curved, sharp margin, which forms the inferior margin of the **superior orbital fissure**, the cleft which separates the great wing from the small wing, and which establishes a wide channel of communication between the middle cranial fossa and the cavity of the orbit, transmitting the oculomotor, trochlear, ophthalmic division of the trigeminal, and the abducent nerves, together with the ophthalmic veins. Wide of the superior orbital fissure this edge becomes broad and serrated, articulating with the frontal bone medially, and at the part corresponding to the anterior horn of the crescent, by a surface of variable width, it unites with the sphenoidal angle of the parietal bone. The lateral border corresponds to the concave side of the crescent, and is serrated for articulation with the squamous part of the temporal, being thin and bevelled at the expense of its parietal surface above and laterally, and broad and thick behind as it passes towards the angular spine. The **superior or cerebral surface** is concave from behind forwards, and in its anterior part from side to side also; it forms a considerable part of the floor of the middle cranial fossa, and bears the impress of the convolutions of the extremity of the temporal lobe of the cerebrum which rests upon it; towards its lateral side it is grooved obliquely by an anterior branch of the middle meningeal artery. The following foramina pierce the great wing: close to and in front of the alar spine is the **foramen spinosum** for the transmission of the middle meningeal artery and its companion vein, together with the nervus spinosus from the mandibular division of the trigeminal nerve. In front of and medial to this, and close to the posterior free border, is the **foramen ovale**, of large size and elongated form. This gives passage to the motor root and mandibular sensory division of the trigeminal nerve, and admits the accessory meningeal branch of the middle meningeal artery; a small emissary vein from the cavernous sinus usually passes through this foramen, and occasionally also the small superficial petrosal nerve. Near the anterior part of the root of the great wing, and just below the sphenoidal fissure, is the **foramen rotundum**, of smaller size and circular form. Through this the maxillary division of the trigeminal nerve escapes from the cranium. Occasionally there is a small canal—the **foramen of Vesalius**—which pierces the root of the great wing to the medial side of the foramen ovale. This opens below into the scaphoid fossa at the base of the medial pterygoid lamina, and transmits a

small vein. Occasionally there is a small foramen (canaliculus innominatus) to the medial side of the foramen spinosum for the transmission of the small superficial petrosal nerve.

The **lateral surface** of the great wing enters into the formation of the walls of the orbital, temporal, infra-temporal, and pterygo-palatine fossæ by three well-defined areas; of these the upper two, the orbital and the temporal, are separated by an oblique jagged ridge, the **margo zygomaticus (zygomatic border)**, for articulation with the fronto-sphenoidal process of the zygomatic bone. Occasionally the lower part of this ridge articulates with the zygomatic process of the maxilla. The **facies orbitalis (orbital surface)** lies to the medial side of this crest and is directed forwards and a little medially; of quadrilateral shape, it forms the posterior and lateral wall of the orbit; plane and smooth, it is bounded posteriorly by the sharp inferior free margin of the superior orbital fissure, towards the medial extremity of which a pointed spine (*spina recti lateralis*), for the attachment of the inferior common ligament of origin of the ocular muscles, can usually be seen. It is limited superiorly by the edge of a rough triangular area which articulates with the frontal bone; anteriorly by the zygomatic border; whilst inferiorly a free, well-defined oblique margin constitutes the posterior and lateral boundary of the **fissura orbitalis inferior (inferior orbital fissure)**, which separates this part of the bone from the orbital surface of the maxilla. Below this border there is a grooved surface which leads medially toward the orifice of the foramen rotundum. In the articulated skull this forms part of the posterior wall of the pterygo-palatine fossa.

To the lateral side of the zygomatic border, which bounds it in front, is the **facies temporalis (temporal area)**, concavo-convex from before backwards. It slopes medially below, where it is separated from the spheno-maxillary area by a well-marked muscular ridge, the **crista infratemporalis (infra-temporal crest)**. Behind, the temporal surface is bounded by the margin of the great wing which articulates with the squamous part of the temporal (**margo squamosus**), and above by the edge which unites it with the sphenoidal angle of the parietal and the frontal bone. The temporal surface enters into the formation of the floor of the fossa of the same name, and affords an extensive attachment to the fibres of origin of the temporal muscle. The **facies sphenomaxillaris (spheno-maxillary surface)**, the third of the areas above referred to, is situated below the infra-temporal crest, and corresponds to the under surface of the posterior half of the great wing; it extends as far back as the angular spine and posterior border. Opening on it are seen the orifices of the foramen spinosum and ovale. It is slightly concave from side to side, and is confluent medially with the lateral surface of the lateral pterygoid plate. In front it is bounded by a ridge which curves upwards and laterally from the anterior part of the lateral pterygoid plate to join the infra-temporal crest. In the articulated skull this ridge forms the posterior boundary of the pterygo-maxillary fissure. The spheno-maxillary surface overhangs the infra-temporal fossa, and affords an origin for the superior head of the external pterygoid muscle.

The **processus pterygoidei (pterygoid processes)** spring from the inferior surface of the lateral aspect of the body as well as the under side of the root of the great wings, and pass vertically downwards. Each consists of two laminae, the **laminae processus pterygoidei lateralis et medialis**, fused together anteriorly, and enclosing between them posteriorly the **fossa pterygoidea (pterygoid fossa)**.

The **lateral pterygoid plate**, thin and expanded, is directed obliquely backwards and laterally, its lower part being often somewhat everted. Its hinder edge is sharp, and often has projecting from it one or two spines, to one of which (**processus pterygospinosus**) the pterygo-spinous ligament, which stretches towards the angular spine, is attached. Laterally it furnishes an origin for the inferior head of the external pterygoid muscle, and on its medial side, where it forms the lateral wall of the pterygoid fossa, it supplies an attachment for the internal pterygoid muscle.

The **medial pterygoid plate** is narrower and somewhat stouter. By its medial aspect it forms the posterior part of the lateral wall of the nasal cavities; laterally it is directed towards the pterygoid fossa. Its posterior edge ends

below in the **hamulus pterygoideus** (**pterygoid hooklet**), which, reaching a lower level than the lateral plate, curves backwards and laterally, furnishing a groove in which the tendon of the tensor veli palatini muscle glides; superiorly, the sharp posterior margin of the medial plate bifurcates, so as to enclose the shallow **scaphoid fossa** from which the tensor veli palatini muscle arises, and wherein may occasionally be seen the inferior aperture of the foramen Vesalii. To the medial edge of this fossa, as well as to the posterior border of the medial pterygoid plate, the **pharyngo-basilar fascia** (**pharyngeal aponeurosis**) is attached. Here, too, the cartilage of the auditory tube is supported on a slight projection, and the pharyngo-palatinus muscle receives an origin, whilst the superior constrictor of the pharynx arises from the inferior third of the same border and from the pterygoid hooklet. Superiorly and medially the medial plate forms an incurved lamina of bone, the **processus vaginalis** (**vaginal process**), which is applied to the under surface of the lateral aspect of the body reaching medially, towards the root of the rostrum, from which, however, it is separated by a groove, in which, in the articulated skull, the ala of the vomer is lodged. The angle formed by the vaginal process and the medial edge of the scaphoid fossa forms a projection called the **pterygoid tubercle**, immediately above which is the posterior aperture of the **canalis pterygoideus**, through which the nerve and artery of the canal (O.T. Vidian) are transmitted. On its under surface the vaginal process displays a groove (**sulcus pterygopalatinus**) which in the articulated skull is converted into the **pharyngeal canal** by its union with the palate bone. In front, at its root, the pterygoid process displays a broad smooth surface (**facies sphenomaxillaris**), which is confluent above with the root of the great wing around the foramen rotundum, and forms the posterior wall of the **pterygo-palatine fossa**. Here, to the medial side of the foramen rotundum, is seen the anterior opening of the **pterygoid canal**. Below, the pterygoid laminae are separated by an angular cleft, the **fissura pterygoidea** (**pterygoid notch**); in this is lodged the pyramidal process of the palate bone, the margins of which articulate with the serrated edges of the recess.

Connexions.—The sphenoid articulates with the occipital, temporals, parietals, frontal, ethmoid, sphenoidal conchæ, vomer, palate and zygomatic bones, and occasionally with the maxillæ.

Ossification.—The sphenoid of man is formed by the fusion of two parts, the **pre-sphenoid** and the **post-sphenoid**, each associated with certain processes. In most mammals the **orbito-sphenoids** or small wings fuse with the pre-sphenoid, whilst the **alisphenoids** or great wings, together with the **medial pterygoid lamina**, ankylose with the post-sphenoid. The ossification of these several parts takes place in cartilage, with the exception of the medial pterygoid lamina, which is developed from an independent centre in the connective tissue of the lateral wall of the oral cavity (Hertwig).

At the end of the second month a centre appears in the root of the great wing between the foramen ovale and foramen rotundum; from this the ossification spreads laterally and backwards and also downwards into the lateral pterygoid lamina. According to Fawcett the pterygoid laminae or the common root of the two laminae in the adult is practically the only part of the ala temporalis preformed in cartilage; the whole of the lateral pterygoid lamina and that part of the alisphenoid projected into the orbital and temporal fossæ are ossified in membrane; so too are the foramen ovale and foramen spinosum. Meanwhile two centres appear about the same time in the basi-sphenoid in relation to the floor of the sella turcica and on either side of the cranio-

FIG. 146.—OSSIFICATION OF THE SPHENOID.

a, Pre-sphenoid; b, Orbito-sphenoids; c, Alisphenoids;
d, Medial pterygoid laminae; e, Basi-sphenoid.

pharyngeal canal, around which they ossify, ultimately leading to the obliteration of this channel. Somewhat later a **sphenotic** centre appears on either side, from which the lateral aspect of the body and the **lingula** are developed. Fusion between these four centres is usually complete by the sixth month.

In the **pre-sphenoid** a pair of lateral nuclei make their appearance about the middle of the third month, just lateral to the optic foramina; from each of these the **orbito-**

sphenoids (small wings) and their roots are developed. About the same time another pair of centres, placed medial to the optic foramina, constitute the body of the pre-sphenoid. At first the superior surface of the body of the pre-sphenoid is exposed in the interval between the orbito-sphenoids, but by the ultimate coalescence of the medial borders of the orbito-sphenoids to form the **jugum sphenoidale** the body of the pre-sphenoid is almost completely covered over superiorly. By the coalescence of these in front, and their ultimate union with the basi-sphenoid behind, a cartilaginous interval is enclosed, of triangular shape, which, however, becomes gradually reduced in size by the ingrowth of its margins so as to form two medially placed foramina, as may be frequently observed in young bones—one opening on the surface of the olivary eminence, the other being placed anteriorly. (Lawrence, "Proc. Soc. Anat.," *Journ. Anat. and Physiol.* vol. xxviii. p. 19.)

As has been seen, the **medial pterygoid laminæ** are developed in membrane and are the first parts of the sphenoid to ossify. (Fawcett, *Anat. Anz.*, vol. xxvi. 1905, p. 280.) Each is derived from a single nucleus which appears about the ninth or tenth week, and fuses with the inferior surface of the great wing, there forming a groove which is converted into the pharyngeal canal when the alisphenoid and medial pterygoid laminæ fuse later with the body of the post-sphenoid. The hamulus, however, chondrifies before it ossifies during the third month. Fawcett also regards the external pterygoid plate as of membranous origin.

At birth the sphenoid consists of **three parts**: one comprising the orbito-sphenoids together with the body of the pre-sphenoid and the basi-sphenoid, the others consisting of the alisphenoids, one on either side. Fusion of the latter with the former occurs near the end of the first year. The dorsum sellæ at birth consists of a cartilaginous plate which separates the body of the post-sphenoid from the basi-occipital. This slowly ossifies, but the cartilage does not entirely disappear till the age of twenty-five, by which time bony ankylosis of the basi-cranial axis is complete. For a considerable time the under surface of the body of the pre-sphenoid displays a bullate appearance, with the sides of which the sphenoidal conchæ articulate. It is only after the seventh or eighth year is reached that the cancellous tissue within this part of the bone becomes absorbed to form the sphenoidal sinuses.

The **conchæ sphenoidales** (**sphenoidal conchæ**), or bones of Bertin, best studied in childhood, are formed by the fusion of four distinct ossicles (Cleland), the centres for which appear in the later months of utero-gestation. Each bone consists of a hollow, three-sided pyramid, the apex of which is in contact with the fore-part of the vaginal process of the medial pterygoid lamina, whilst the base fits on to the posterior surface of the lateral mass of the ethmoid. The *inferior surface* of each forms the roof of the corresponding nasal fossa, and completes the formation of the spheno-palatine foramen, whilst the lateral aspect is united with the palate bone and forms the medial wall of the pterygo-palatine fossa, and occasionally constitutes a part of the orbital wall posterior to the lamina papyracea of the ethmoid. The *superior surface* of the sphenoidal concha is applied to the fore and under surface of the body of the pre-sphenoid on either side of the rostrum. It is by the absorption of this wall that the sphenoidal sinuses are ultimately opened up. The base of the pyramid forms the aperture through which each of these sinuses opens into the nasal fossæ in the adult. Up to the age of five these ossicles remain independent, but subsequently, owing to their firm ankylosis with the surrounding bones, they are merely represented in the adult disarticulated skull by the irregular fragments adherent to the separated borders of the ethmoid, palate, and sphenoid bones.

Os Ethmoidale.

The **ethmoid bone** lies in front of the sphenoid, and occupies the interval between the orbital parts of the frontal, thus entering into the formation of the anterior cranial fossa as well as the medial walls of the orbits and the roof medial and lateral walls of the nasal cavities. The bone, which is extremely light, consists of two cellular parts—the **labyrinthis ethmoidales** (**ethmoidal labyrinths**), which are united superiorly to a median **lamina perpendicularis** (**perpendicular plate**) by a thin horizontal lamina which, from its perforated condition, is called the **lamina cribrosa** (**cribriform plate**). The general arrangement of the parts of the bone resembles the capital letter T; the median plate corresponds to the vertical limb, the cribriform plate to the horizontal limb of the T, whilst the ethmoidal labyrinths may be

regarded as comparable to the enlarged down-turned extremities of the horizontal limb of the letter.

The study of this bone will be much facilitated by cutting through the cribriform plate on one side of the perpendicular plate, thus removing the ethmoidal labyrinth of one side and exposing more fully the central perpendicular lamina.

FIG. 147.—THE ETHMOID SEEN FROM BEHIND.

project from the crista galli on either side. By articulation with the frontal bone this groove is converted into a canal, the *foramen cæcum*; this, however, is not always blind, but frequently transmits a vein to the roof of the nose. The posterior border of the perpendicular plate is thin, and articulates with the crest of the sphenoid. The posterior inferior border in the adult is ankylosed with the vomer; and the anterior inferior border, which is usually thicker than the others, unites with the cartilaginous nasal septum. The anterior superior border articulates with the spine of the frontal bone and with the median crest formed by the union of the two nasal bones. The perpendicular plate, which is usually deflected to one or other side, has generally smooth surfaces, except above, where they are channelled by short and shallow grooves leading to the foramina which pierce the cribriform plate; these are for the lodgment of the olfactory nerves.

FIG. 148.—THE ETHMOID SEEN FROM THE RIGHT SIDE.

The **ethmoidal labyrinth** is composed of exceedingly thin bone, enclosing a large number of air-cells; these are arranged in three groups—an anterior, a middle, and a posterior, the walls of which have been broken in front, above, behind, and below, in the process of disarticulation. Laterally they are closed in by a thin oblong lamina, the *lamina papyracea* or *orbital plate*, which forms a part of the medial wall of the orbit, and articulates above with the orbital part of the frontal, which here roofs in the ethmoidal cells. (The line of this suture is pierced by two canals, the *anterior* and *posterior ethmoidal foramina*, both of which transmit small ethmoidal vessels, whilst the anterior also gives passage to the naso-ciliary nerve.) In front the lamina papyracea articulates

The **perpendicular plate**, of irregular pentagonal shape, forms the superior part of the nasal septum. Its superior border projects above the level of the cribriform plate so as to form a crest, which is much elevated anteriorly, where it terminates in a thick, vertical, triangular process, called the *crista galli*, the interior of which is filled with fine spongy bone, but is occasionally pneumatic. The superior edge of this process is sharp and pointed, and affords attachment to the *falx cerebri*. In front of this process there is a groove which separates the *processus alares* (alar processes) which

with the lacrimal bone; whilst below, by its union with the orbital surface of the maxilla, the air-sinuses in both situations are completed. Posteriorly the lamina papyracea articulates with the sphenoid, and at its posterior inferior angle for a variable distance with the orbital process of the palate bone, both of which serve to close in the air-cells. The medial aspect of the ethmoidal labyrinth displays the convoluted *conchæ* of the nose, usually two in number, though occasionally there may be three—rarely more. In cases where there are two *ethmo-turbinals*¹ they are separated posteriorly by a deep groove. A channel is thus formed in the back part of the lateral and upper aspect of the nasal fossæ, called the *superior meatus*, which is roofed in by the *concha nasalis superior* (*superior concha*), whilst its floor is formed by the superior surface of the *concha nasalis media* (*middle concha*). The posterior ethmoidal cells open into this meatus. In front of the superior meatus, which only grooves the posterior half of this aspect of the bone, the surface is rounded from above downwards and before backwards, and forms the medial wall of the anterior and middle ethmoidal cells. Running obliquely from above downwards and backwards over the medial surface of the superior concha, are a number of fine grooves continuous above with the foramina in the cribriform plate; these are fewer and more scattered in front, do not pass on to the middle concha, and are for the olfactory nerves.

The *middle concha* is nearly twice the length of the superior. Its anterior extremity is united for a short distance to the ethmoidal crest on the medial side of the frontal process of the maxilla. By its thickened, free convoluted border it overhangs a deep groove which runs along the inferior surface of the ethmoidal labyrinth. This is the *middle meatus of the nose*. It receives the openings of the middle ethmoidal cells, which project into the meatus, forming a rounded elevation called the *ethmoidal bulla*. In front and below this is a groove, the *hiatus semilunaris*, which by articulation above with adjacent bones is converted into a canal, the *infundibulum*, which runs upwards and forwards and forms a channel of communication with the frontal sinus and the anterior ethmoidal cells. Curving downwards, backwards, and a little laterally from the roof of the anterior part of this meatus in front of the *infundibulum* is the *processus uncinatus*. This bridges across the irregular opening on the medial wall of the maxillary sinus, and articulates inferiorly with the ethmoidal process of the inferior concha. The posterior extremity of the middle concha articulates with the ethmoidal crest on the perpendicular part of the palate bone.

FIG. 149.—SECTION SHOWING THE NASAL ASPECT OF THE LEFT LABYRINTH OF THE ETHMOID.

FIG. 150.—SHOWING THE ARTICULATION OF THE INFERIOR CONCHA WITH THE ETHMOID.

The *middle concha* is nearly twice the length of the superior. Its anterior extremity is united for a short distance to the ethmoidal crest on the medial side of the frontal process of the maxilla. By its thickened, free convoluted border it overhangs a deep groove which runs along the inferior surface of the ethmoidal labyrinth. This is the *middle meatus of the nose*. It receives the openings of the middle ethmoidal cells, which project into the meatus, forming a rounded elevation called the *ethmoidal bulla*. In front and below this is a groove, the *hiatus semilunaris*, which by articulation above with adjacent bones is converted into a canal, the *infundibulum*, which runs upwards and forwards and forms a channel of communication with the frontal sinus and the anterior ethmoidal cells. Curving downwards, backwards, and a

little laterally from the roof of the anterior part of this meatus in front of the *infundibulum* is the *processus uncinatus*. This bridges across the irregular opening on the medial wall of the maxillary sinus, and articulates inferiorly with the ethmoidal process of the inferior concha. The posterior extremity of the middle concha articulates with the ethmoidal crest on the perpendicular part of the palate bone.

The *lamina cribrosa* (*cribriform plate*) is the horizontal lamina which con-

¹ So called to distinguish them from the maxillo-turbinals and naso-turbinals of comparative anatomy.

nects the ethmoidal labyrinths with the perpendicular plate. It occupies the interval between the orbital parts of the frontal bone, roofing in the nasal cavities inferiorly, and superiorly forming on either side of the crista galli two shallow

FIG. 151.—THE ETHMOID SEEN FROM ABOVE.

olfactory grooves in which, in the recent condition, the olfactory lobes of the cerebrum are lodged. Numerous foramina for the transmission of the olfactory nerves pierce this part of the bone; those to the medial and lateral sides of the groove are the largest and most regular in their arrangement. Along the lateral edges of the cribriform plate two notches can usually be distinguished; when articulated with the frontal bone these form the medial openings of the **ethmoidal foramina**. Leading forwards from the anterior of these there is often a groove which crosses to the side of the crista galli, where it ends in a slit which allows of the transmission of the naso-ciliary nerve to the nose. Posteriorly the cribriform plate articulates with the spine of the sphenoid.

Connexions.—The ethmoid articulates with the sphenoid and sphenoidal conchæ, the frontal, the two nasals, two maxillæ, two lacrimals, two inferior conchæ, two palates, and the vomer.

Ossification takes place in the cartilage of the nasal capsule. Each lateral mass has one centre, which appears about the fourth or fifth month in the neighbourhood of the lamina papyracea. According to Fawcett ossification first commences in a process which passes outside the naso-lacrimal duct to reach the frontal process of the maxilla. From this the laminae around the ethmoidal air-cells are formed, which are complete at birth, the air-sinuses in this instance not being formed by the absorption of cancellous bone. From these centres the conchæ are also developed, and these too are ossified at the ninth month.

At birth the ossified lateral masses are united to the cartilaginous septum by a fibrous layer. Two centres make their appearance in the septal cartilage on either side of the root of the crista galli about the end of the first year; from these, the crista galli and the vertical plate are ossified, as well as the medial part of the cribriform plate, the lateral portions of which are derived from a medial extension of the lateral mass.

Ossification is usually complete about the fifth or sixth year. About the twenty-fifth year bony union has taken place between the cribriform plate and the sphenoid, but ankylosis between the vertical plate and the vomer is not usual till the fortieth or forty-fifth year.

Conchæ Nasales Inferiores.

The **inferior conchæ** (O.T. **inferior turbinated bones**) are two shell-like laminae of bone lying along the lower part of the lateral wall of the nasal cavity on either

FIG. 152.—THE RIGHT INFERIOR CONCHA. A, Medial Surface; B, Lateral Surface.

side. Of elongated form, the bone displays two curved borders enclosing a medial and lateral surface.

The superior or attached border is thin and sharp in front and behind, where

it articulates with the inferior conchal crests on the medial surface of the body of the maxilla and the perpendicular part of the palate bone respectively. Between these two articulations the central part of the superior border rises in the form of a sharp crest, the anterior part of which forms the upstanding **processus lacrimalis** (**lacrimal process**) which articulates above with the descending process of the lacrimal bone, as well as with the edges of the naso-lacrimal groove of the maxilla, thus completing the osseous canal of the naso-lacrimal duct. The posterior end of this crest is elevated in the form of an irregular projection called the **processus ethmoidalis** (**ethmoidal process**). This unites with the uncinat process of the ethmoid bone (see Fig. 150). Spreading downwards from the middle of the superior border, on its lateral side, is a thin irregular plate of bone, the **processus maxillaris** (**maxillary process**), which partially conceals the lateral concave surface of the bone, and, by its union with the medial wall of the maxillary sinus, assists in the completion of the partition which separates that cavity from the inferior nasal meatus.

The **inferior** or **free border**, gently curved from before backwards and slightly out-turned, is rounded and full, and formed of bone which is deeply pitted and of a somewhat cellular character. The anterior and posterior extremities of the bone, formed by the convergence of the superior and inferior borders, are thin and sharp; as a rule the posterior end is the more pointed of the two. The **medial surface** projects into the nasal cavity; convex from above downwards, and slightly curved from before backwards, it forms the floor of the middle meatus. It is rough and pitted, and displays some scattered and longitudinally directed vascular grooves. The **lateral surface** overhangs the inferior meatus of the nose. Concave from above downwards, and to some extent from before backwards, it is directed towards the lateral wall of the nasal cavity. It is smooth in front, where it corresponds to the opening of the canal for the naso-lacrimal duct; behind and towards its inferior border it is irregular and pitted. In the disarticulated bone this surface is in part concealed by the downward projecting maxillary process.

Connexions.—The inferior concha articulates with the maxilla, lacrimal, ethmoid, and palate bones.

Ossification.—The inferior concha (the maxillo-turbinal of comparative anatomy) is derived from the cartilage forming the lateral wall of the nasal capsule, the upper portion of which forms the ethmo-turbinals. It ossifies, however, from a separate centre, which appears about the fifth month of foetal life, and later contracts a union by a horizontal lamella on its lateral side with the maxilla.

Ossa Lacrimalia.

The **lacrimal bone**, a thin scale of bone about the size of a finger-nail, forms part of the medial orbital wall behind the frontal process of the maxilla. Irregularly quadrangular, it has two surfaces—a medial and lateral—and four borders.

Its lateral or orbital surface has a vertical ridge, the **crista lacrimalis posterior** (**posterior lacrimal crest**), running downwards upon it. In front of this is the **sulcus lacrimalis** (**lacrimal groove**) for the lodgment of the lacrimal sac. The medial wall of this groove descends below the level of the bulk of the bone, and forms the **descending process**, which helps to complete the osseous canal for the naso-lacrimal duct, and articulates inferiorly with the inferior concha. The inferior end of the lacrimal crest terminates in a hook-like projection, the **hamulus lacrimalis** (**lacrimal hooklet**), which curves round the posterior and lateral edge of the naso-lacrimal notch of the maxilla, and thus defines the upper aperture of the canal for the naso-lacrimal duct. To the free edge of the crest behind the lacrimal groove are attached the reflected portion of the tendo oculi and the lacrimal part of the orbicularis oculi, the crest being sometimes thickened at the site of this attachment. The part of the bone behind the lacrimal crest is smooth and continuous with the surface of the lamina papyracea of the ethmoid. The **medial surface** is irregular and

FIG. 153.—RIGHT LACRIMAL BONE (Orbital Surface).

cellular above; it closes in some of the anterior ethmoidal cells and helps to complete the infundibulum. Where it is smoother it forms a part of the lateral wall of the middle meatus of the nose immediately behind the frontal process of the maxilla, and above the inferior concha. The **superior border** articulates with the orbital part of the frontal; the **anterior edge** with the posterior border of the frontal process of the maxilla, with which it completes the lacrimal groove for the lodgment of the lacrimal sac. The **inferior margin** articulates with the orbital surface of the maxilla, and in front by its **descending process** with the inferior concha. *Posteriorly* the bone articulates with the anterior border of the lamina papyracea of the ethmoid.

Connexions.—The lacrimal bone articulates with four bones—the frontal, ethmoid, inferior concha, and the maxilla.

Ossification.—The lacrimal is developed from a single centre, which makes its appearance about the end of the second or the beginning of the third month of intra-uterine life in the membrane around the cartilaginous nasal capsule.

Vomer.

The **vomer** or **ploughshare bone**, a bone of irregular quadrilateral shape, is placed in the posterior part of the nasal septum. It has four borders and two surfaces. The **superior border**, which can readily be distinguished by the presence on either side of an everted lip or *ala*, slopes from behind upwards and forwards, and articulates with the inferior surface of the body of the sphenoid, the pointed rostrum of which is received into the groove formed by the projecting *alæ*. Laterally these *alæ* are wedged in between the sphenoidal processes of the palate bones in front, and the vaginal processes at the root of the medial laminae of the

FIG. 154.—THE VOMER AS SEEN FROM THE RIGHT SIDE.

pterygoid processes behind. The **posterior border**, which slopes from behind downwards and forwards, is free, and forms a sharp, slightly curved edge; this constitutes the posterior margin of the nasal septum, and serves to separate the openings of the choanæ (O.T. posterior nares). The **inferior border**, more or less horizontal in direction, articulates with the nasal crest formed by the maxillæ and palate bones. The **anterior edge** is the longest; it slopes obliquely from above downwards and forwards. In its upper half it is ankyloused to the perpendicular plate of the ethmoid; in its lower half this margin is grooved for the reception of the septal cartilage of the nose. The **anterior extremity** of the bone forms a truncated angle, which articulates with the posterior border of the incisor crest of the maxillæ, and sends downwards a pointed process which passes between the incisor foramina. The *right* and *left surfaces* of the bone are smooth and covered by mucous membrane. It is not uncommon to find them deflected to one or other side. A few vascular grooves may be noticed scattered over these surfaces, and one, usually more distinct than the others, running obliquely downwards and forwards, indicates the course of the naso-palatine nerve.

Connexions.—The vomer articulates with the sphenoid, the ethmoid, the palates, and the maxillæ. In front it supports the septal cartilage.

Ossification.—The vomer commences to ossify in membrane at the end of the second month. A nucleus appears on each side of the middle line below the nasal septum medial to the plane of the anterior paraseptal cartilages and posterior to them. During the third month the nuclei, which have increased in height and length,

FIG. 155.

Vomer at Birth displaying its formation by two Osseous Laminae united inferiorly. The figure to the right exhibits the appearance of the bone, in vertical section, at the point marked * in the left figure.

fuse at their lower edges, and by forward growth invade the posterior end of each anterior paraseptal cartilage, thus forming a deep groove in which the septal cartilage is lodged (Fawcett). As growth goes on the groove becomes reduced by the further fusion of the lateral plates and the absorption of the cartilage, until the age of puberty, by which time the lateral laminae have united to form a median plate, the primitively divided condition of which is now only represented by the eversion of the alae and the grooving along the anterior border. According to Fawcett, the ossification of the Jacobsonian cartilage produces a hitherto undescribed element in the formation of the osseous nasal septum.

Ossa Nasalia.

The **nasal bones**, two in number, lie in the interval between the frontal processes of the maxillæ, there forming the root or bridge of the nose. Each bone is of elongated quadrangular form, having two surfaces—an inner and outer—and four borders. The **outer surface**, somewhat constricted about its middle, is convex from side to side, and slightly concavo-convex from above downwards. Near its centre there is usually the opening of a nutrient canal.

The **inner surface** is not so extensive as the outer, as the superior and anterior articular borders encroach somewhat upon it above. Concave from side to side, and also from above downwards, it is covered, in the recent condition, by the mucous membrane of the nose. Running downwards along this surface is a narrow groove (*sulcus ethmoidalis*) which transmits the anterior terminal branch of the naso-ciliary nerve. The **anterior or medial border**, narrow below, is thick above, and, in conjunction with its fellow at the opposite side, with which it articulates, forms a median crest posteriorly, which is united to the spine of the frontal, the perpendicular plate of the ethmoid, and the septal cartilage of the nose, in that order from above downwards. The **posterior or lateral border**, usually the longest, is serrated and bevelled to fit on to the anterior edge of the frontal process of the maxilla. The **superior border** forms a wide toothed surface, which articulates with the medial part of the nasal notch of the frontal bone anteriorly; whilst, posteriorly, it rests in contact with the root of the nasal process of the same bone. The **inferior border** is thin and sharp, and is connected below with the lateral cartilage of the nose, and is usually deeply notched near its medial extremity.

Connexions.—The nasal bone articulates with its fellow of the opposite side, with the frontal above, posteriorly with the perpendicular plate of the ethmoid and with the frontal process of the maxilla. It is also united to the septal and lateral cartilages of the nose.

Ossification.—The nasal bones are each developed from a single centre, which makes its appearance about the end of the second month in the membrane covering the anterior part of the cartilaginous nasal capsule. Subsequent to birth the underlying cartilaginous stratum disappears, persisting, however, below in the form of the lateral nasal cartilage, and behind as the septal cartilage of the nose.

Ossa Suturarum (O.T. Wormian).

Along the line of the cranial sutures and in the region of the fontanelles, isolated bones of irregular form and variable size are occasionally met with. These are the once so-called Wormian bones, named after the Danish anatomist Wormius. They are now called **ossa suturarum** (sutural bones). Their presence depends on the fact that they are either developed from distinct ossific nuclei, or it may be from a division of the primary ossific deposit. Their occurrence may also be associated with certain pathological conditions

FIG. 156.—THE RIGHT NASAL BONE.
A, Lateral side; B, Medial side.

which modify the development of the bone. They usually include the whole thickness of the cranial wall, or they may only involve the outer or inner tables of the cranial bones. They are most frequent in the region of the lambda and the lambdoid suture. They occur commonly about the pterion, and in this situation are called *epipteric bones* (Flower). By their fusion with one or other of the adjacent bones they here lead to the occurrence of a fronto-squamosal suture. Their presence has also been noted along the line of the sagittal suture, and sometimes in metopic skulls in the inter-frontal suture. They are occasionally met with at the asterion and more rarely at the obelion. They appear less frequently in the face, but their presence has been noted around the lacrimal bone, and also at the extremity of the inferior orbital fissure, where they may form an independent nodule wedged in between the great wing of the sphenoid, the zygomatic, and the maxillary bones.

OSSA FACIEI.

The bones of the face, seven in number, comprise two maxillæ, two palates, two zygomatics, with the mandible or lower jaw.

The Maxillæ.

The **maxillæ**, of which there are two, unite to form the upper jaw. Each consists of a **body**, with which are connected four projections, named respectively the **zygomatic**, **frontal**, **alveolar**, and **palatine** processes.

The **body** (corpus) is of pyramidal form, and contains within it a hollow called the **maxillary sinus**. It has four surfaces—an anterior or facial, an infra-temporal or postero-lateral, an orbital or supero-lateral, and a nasal or medial—and four processes—the malar, frontal, alveolar, and palatine.

Surfaces.—The **facies anterior** (anterior surface) is confluent below with the alveolar process. Above, it is separated from the orbital aspect by the **margo infraorbitalis** (infra-orbital margin), whilst medially it is limited by the free margin of the **nasal notch**, which ends below in the pointed **spina nasalis anterior** (anterior nasal spine). Posteriorly it is separated from the infra-temporal surface by

FIG. 157.—THE RIGHT MAXILLA (Lateral View).

the inferior border of the **zygomatic process**. The facial aspect of the bone is ridged by the sockets of the teeth (**juga alveolaria**). The ridge corresponding to the root of the canine tooth is usually the most pronounced; medial to this, and overlying the roots of the incisor teeth, is the shallow **incisive** or **myrtiform fossa**, whilst placed laterally, on a higher level, is the deeper **canine fossa**, the floor of which is formed in part by the projecting zygomatic process. Above this, and near the infra-orbital margin, is the **infra-orbital foramen**,

the external opening of the infra-orbital canal, which transmits the infra-orbital nerve and artery.

The **infra-temporal** or **postero-lateral surface** is separated above from the orbital aspect by a rounded free edge, which forms the anterior margin of the **inferior orbital fissure** in the articulated skull. Inferiorly and anteriorly it is separated from the anterior surface by the zygomatic process and its free lower border. Medially it is limited by a sharp, irregular margin with which the palate bone articulates. This surface is more or less convex, and is directed towards the infra-temporal and pterygo-palatine fossæ. It is pierced in a downward direction by the apertures of the **alveolar canals** (**foramina alveolaria**), two or more in number, which transmit the corresponding nerves and vessels to the molar teeth. Its lower part, slightly more prominent where it overhangs the root of the wisdom molar, is often called the **tuber maxillare** (**maxillary tuberosity**).

The **planum orbitale** (**orbital surface**), smooth and plane, is triangular in shape and forms part of the floor of the orbit. Its anterior edge corresponds to the infra-orbital margin; its posterior border coincides with the anterior boundary of the inferior orbital fissure. Its thin medial edge, which may be regarded as the base of the triangle, is notched in front to form the **sulcus lacrimalis** (**lacrimal groove**), behind which it articulates with the lacrimal bone for a short distance, then for a greater length with the lamina papyracea of the ethmoid, and terminates posteriorly in a surface for articulation with the orbital process of the palate bone. Its lateral angle corresponds to the base of the zygomatic process. Traversing its substance is the **infra-orbital canal**, the anterior opening of which has been already noticed on the anterior aspect of the body. Behind, however, owing to deficiency of its roof, the canal forms a groove which lips the edge of the bone which constitutes the anterior boundary of the inferior orbital fissure. If this canal be laid open, the orifices of the middle and anterior alveolar canals will be seen, which transmit the corresponding vessels and nerves to the premolar and incisor teeth.

The **facies nasalis** (**nasal surface**) of the body is directed medially towards the nasal cavity. Below, it is confluent with the superior surface of the palatine process; anteriorly it is limited by the sharp edge of the nasal notch; above and anteriorly it is continuous with the medial surface of the frontal process; behind this it is deeply channelled by the **lacrimal groove**, which is converted into a canal by articulation with the lacrimal and inferior conchal bones. The channel so formed conveys the naso-lacrimal duct from the orbital cavity above to the inferior nasal meatus below. Behind this groove the upper edge of this area corresponds to the medial margin of the orbital surface, and articulates from before backwards with the lacrimal, lamina papyracea of the ethmoid, and the orbital process of the palate bone. The posterior border, rough for articulation with the palate bone, is traversed obliquely from above downwards and slightly medially by a groove, which, by articulation with the palate bone, is converted into the **pterygo-palatine canal**, which transmits

FIG. 158.—THE RIGHT MAXILLA (Medial Aspect).

the greater palatine artery and posterior palatine nerve. Towards its upper and posterior part the nasal surface of the body displays the irregular, more or less triangular, opening of the *sinus maxillaris* (*maxillary sinus*). This aperture which, in the articulated skull opens into the middle meatus of the nose, is much reduced in size by articulation with the lacrimal, ethmoid, palate, and inferior conchal bones. In front of the lacrimal groove the nasal surface is ridged horizontally by the *crista conchalis* (*inferior conchal crest*), to which the inferior conchal bone is attached. Below this the bone forms the lateral wall of the inferior nasal meatus, receiving the termination of the lacrimal groove. Above, and for some little distance also on the medial side of the frontal process, it constitutes the smooth lateral wall of the atrium of the middle meatus.

Processes.—The *processus zygomaticus* (*zygomatic process*), which is placed on the antero-lateral surface of the body, is confluent anteriorly with the facial surface of the body; posteriorly, where it is concave from side to side, with the infra-temporal surface; whilst superiorly, where it is rough and articular, it forms the apex of the triangular orbital surface, and supports the zygomatic bone. Inferiorly, its anterior and posterior surfaces meet to form an arched border, which fuses with the alveolar process opposite the root of the first molar tooth, and serves to separate the anterior from the infra-temporal surfaces of the body.

The *processus frontalis* (*frontal process*) rises from the upper and anterior part of the body. It has two surfaces—one lateral, the other medial. The *lateral* is divided into two by a vertical ridge (*crista lacrimalis anterior*), which is the upward extension of the infra-orbital margin. The narrow strip of bone behind this ridge is hollowed out, and leads into the lacrimal groove below. Posteriorly the edge of the frontal process here articulates with the lacrimal, and so forms the fossa for the lodgment of the lacrimal sac (*fossa sacci lacrimalis*). In front of the vertical crest, to which the tendo oculi is attached, the lateral surface is confluent below with the facial surface of the body, and forms the side of the root of the nose. Here may often be seen a vascular groove entering the bone. Its anterior edge is rough, or grooved, for articulation with the nasal bone. Superiorly the summit of the process is serrated for articulation with the nasal notch of the frontal bone. The *medial surface* of the frontal process is directed towards the nasal cavity. It is crossed obliquely from below upwards and backwards by a ridge—the *agger nasi* or *ethmoidal crest* which is considered to be a vestige of the naso-turbinal which is met with in some mammals. Below this the bone is smooth and forms the upper part of the atrium of the middle meatus, whilst the ridge itself articulates posteriorly with the forepart of the middle conchal bone, formed by the inferior concha of the ethmoid bone.

The *processus alveolaris* (*alveolar process*) projects from the inferior surface of the body of the bone below the level of the palatal process. Of curved form, it completes, with its fellow of the opposite side, the alveolar arch, in which are embedded, in sockets or alveoli, the roots of the teeth of the maxilla; ordinarily in the adult, when dentition is complete, each alveolar process supports eight teeth. Piercing the medial surface of the alveolar border behind the incisor teeth two small vascular foramina are usually visible. When any or all the teeth are shed the alveoli become absorbed, and the process may under these circumstances be reduced to the level of the plane of the palatine process. Posteriorly the alveolar process ends below the *maxillary tuberosity* of the body; anteriorly it shares in the formation of the *intermaxillary suture*.

The *processus palatinus* (*palatine process*), of the form of a quadrant, lies in the horizontal plane; it has two surfaces—superior and inferior—and three borders, a straight medial, a more or less straight posterior, and a curved lateral, by which latter it is attached to the medial side of the body and alveolar process as far back as the interval between the second and third molar teeth. Its *under surface*, together with that of its fellow, forms the anterior three-fourths of the vaulted hard palate; it is rough and pitted for the glands of the mucous membrane of the roof of the mouth, and is grooved on either side, near the alveolar margin, by a channel which passes forward from the *pterygo-palatine canal* and transmits the

posterior palatine nerve and greater palatine artery. Its superior surface, smooth and concave from side to side, forms the floor of the corresponding nasal cavity. Its medial border, broad and serrated, rises in a ridge superiorly, so as to form with its fellow of the opposite side the *crista nasalis* (nasal crest), which is grooved superiorly to receive the inferior border of the vomer. In front of its articulation with the vomer this ridge rises somewhat higher, being named the *incisor crest*, anterior to which it projects beyond the free border of the nasal notch, and together with its fellow forms the pointed projection called the *anterior nasal spine*. These parts support the septal cartilage of the nose. Immediately to the lateral side of the incisor crest the superior surface of the palatine process is pierced by a foramen which leads downwards, forwards, and a little medially, to open into a broad groove on the medial border of the bone immediately behind the central incisor tooth. When the two maxillæ are articulated, the two grooves form the oval *foramen incisivum*, into which the two afore-mentioned foramina open like the limbs of a Y; these are called the *foramina of Stensen*, and represent the channels by which in lower forms the organs of Jacobson open into the mouth. In man they afford a means of establishing an anastomosis between the vessels of the mouth and nose. In front and behind these, and lying within the fossa and in the line of the suture, are the smaller *foramina of Scarpa*, which transmit the naso-palatine nerves, the right nerve usually passing through the posterior foramen, the left through the anterior. The posterior border of the palatine process, which is sharp and thin, falls in line with the interval between the second and third molar, and articulates with the horizontal part of the palate bone.

The *sinus maxillaris* (maxillary sinus) lies within the body of the bone, and is of corresponding pyramidal form, its base being directed towards the nasal cavity, with the middle meatus of which it communicates, its summit extending laterally into the root of the zygomatic process. It is closed in laterally and above by the thin walls which form the anterior, infra-temporal, and orbital surfaces of the body. Inferiorly it overlies the alveolar process in which the molar teeth are implanted, more particularly the first and second, the sockets of which are separated from it by a thin layer of bone.

The angles and corners of this cavity are frequently groined by narrow ridges of bone, one superiorly corresponds to the relief formed by the infra-orbital canal. A vascular and nervous groove is often exposed, curving along the floor of the maxillary sinus just above the alveoli of the teeth. The interior of the cavity is lined by an extension from the mucous membrane of the nose.

Connexions.—The maxilla articulates with the nasal, frontal, lacrimal, and ethmoid bones above, laterally with the zygomatic, and occasionally with the sphenoid, posteriorly and medially with the palate, whilst on its medial side it unites with its fellow of the opposite side, and also supports the inferior concha and the vomer.

Ossification.—The maxillæ (proper) are developed in the connective tissue around the oral aperture of the embryo. Ossification commences in membrane from one centre in the neighbourhood of the canine tooth germ. From this centre growth takes place rapidly in several directions, viz., upwards on the lateral side of the nasal capsule to form the hinder part of the *processus frontalis*, backwards to form the *processus zygomaticus*, downwards to form the lateral wall of the *processus alveolaris*, and inwards to form the *processus palatinus*. From the latter a process descends downward on the medial side of the teeth to form the medial wall of the *processus alveolaris*. At first a large gap intervenes between the greater part of the *processus palatinus* and the *processus zygomaticus*, but bridges of bone ultimately connect the two, separating the various tooth germs, and so forming the tooth sockets. About the fourth month the maxilla invades a small lateral cartilaginous process of the nasal capsule (Mihalkovics), and incorporates it within itself. The infra-orbital nerve is at first placed considerably above the *facies orbitalis* of the maxilla, and only comes in contact with it in the second month when a groove is formed on the bone, which by the uprising of its lateral wall and its folding over medialwards finally encloses the nerve and forms the infra-orbital canal and foramen. This account of the ossification of the maxilla, which differs considerably from that given in previous editions, is based on the work of Mall and Fawcett. In the early stages of the development of the bone the alveolar groove, in which the teeth are

developed, lies close below the infra-orbital groove, and it is not till later that they become separated by the growth of the maxillary sinus, which first makes its appearance as a shallow fossa to the medial side of the orbito-nasal element about the fourth month. In the adult bone the course of the infra-orbital canal and foramen indicates the line of fusion of the orbito-nasal and zygomatic elements, whilst the position of the anterior palatine canal serves to determine the line of union of the incisive with the palatine elements. In addition to the foregoing centres, Rambaud and Renault describe another, *infra-vomerine*, which, together with its fellow, is wedged in between the incisive and the palatine elements beneath the vomer, thus explaining the Y-shaped arrangement of the foramina of Stensen, which open into the anterior palatine canal.

The *premaxillæ*, which in most vertebrates are independent bones lying in front of the maxillæ, constitute in man and apes the portions of the maxilla which lie in front of the anterior palatine foramen, and support the superior incisor teeth. Each premaxilla is developed from two centres: a *facial*, which ultimately contains the incisor and canine teeth, and forms the front part of the hard palate, as well as the anterior half of the frontal process of the complete maxilla (Fawcett); and a *palatine centre* (supra vomerine of Rambaud and Renault) which forms the medial wall of the corresponding canal of Stensen. The former develops very early, either before or after the maxilla (Mall), and fuses almost at once with the maxilla along the alveolar margin; the latter appears about the twelfth week, and soon fuses with the facial centre. The line of fusion of the premaxillæ with the maxillæ proper can be readily seen in young skulls, and occasionally also in the adult. It corresponds to a suture which passes on the palate obliquely laterally and forwards, from the anterior palatine foramen to the interval between the lateral incisor and the canine tooth. In cases of alveolar cleft palate the adjacent bones fail to unite along the line of the suture. In some instances, however, the cleft passes outwards between the central and lateral incisor teeth, and this condition suggests the explanation that the premaxillary element is derived from two centres—a lateral and a medial. The researches of Albrecht and Warinski support this view. The latter anatomist further observes that the lateral cleavage may lead to a division of the dental germ of the lateral incisor tooth, and so explain the occurrence of the supernumerary incisor which is occasionally met with. In this way the different varieties of cleft palate are readily explained; medial cleft palate being due to failure of union between the two premaxillary bones. Lateral cleft palate may be of two types: the cleft in one case passing forward between the central and lateral incisor, and being due to the non-union of the two elements from which the premaxilla is primarily developed; the other, in which the cleft passes between the lateral incisor and the canine, or between the lateral incisor and a supernumerary incisor, owing to the imperfect fusion of the premaxilla laterally with the maxilla.

Ossa Palatina.

The *palate bone*, of irregular shape, assists in the formation of the lateral wall of the posterior part of the nasal cavity, the posterior portion of the hard palate, the orbit, the pterygo-palatine, the infra-temporal, and the pterygoid fossæ. It consists of *horizontal* and *vertical parts*, united to each other like the limbs of the letter L. At their point of union there is an irregular outstanding process, called the *pyramidal process*, whilst capping the summit of the vertical part and separated by a deep cleft are two irregular pieces of bone, called the *sphenoidal* and *orbital processes*.

FIG. 159.—OSSIFICATION OF THE MAXILLA.

A, Lateral side; B, Medial side; C, Under side. *a*, Nasal process; *b*, Orbital plate; *c*, Anterior nasal spine; *d*, Infra-orbital groove; *e*, Infra-orbital foramen; *f*, Anterior palatine groove; *g*, Palatine process; *h*, Premaxillary suture; *i*, Alveolar process.

The **pars horizontalis** (horizontal part) has two surfaces and four borders. As its name implies, it is horizontal in position, and forms the posterior third of the hard palate. Its **superior surface**, which is smooth, is slightly concave from side to side, and forms the floor of the posterior part of the nasal cavity. Its **inferior surface**, rougher, is directed towards the mouth, and, near its posterior edge, often displays a transverse ridge for the attachment of a part of the aponeurosis of the tensor veli palatini muscle. The **anterior border** articulates by means of an irregular suture with the posterior edge of the palatine process of the maxilla. The **posterior margin** is free and concave from side to side; by its sharp edge it furnishes attachment to the aponeurosis of the soft palate. The **medial border** is upturned, and when it articulates with its fellow of the opposite side it forms superiorly a central crest continuous in front with the nasal crest of the maxilla; it supports the posterior part of the inferior border of the vomer, and projecting beyond the line of the posterior border forms the **spina nasalis posterior** (posterior nasal spine). The **lateral border** fuses with the vertical part, forming with it a right angle. The posterior extremity of this edge is grooved by the lower end of the **foramen palatinum majus** (greater palatine canal).

FIG. 160.—RIGHT PALATE BONE.

A, As seen from the Lateral Side; B, As viewed from the Medial Side.

The **pars perpendicularis** (perpendicular part) is very much broader below than above. Composed of thin bone, particularly at its superior part, it is liable to be broken in the process of disarticulation, so that it is somewhat uncommon to meet with a perfect specimen. It may be described as possessing two surfaces and four borders. Its **medial surface**, which is directed towards the cavity of the nose, is crossed horizontally, about its middle, by the **crista conchalis** (conchal crest) with which the posterior end of the superior border of the inferior conchal bone articulates; above and below this, it enters into the formation of the lateral wall of the middle and inferior meatuses of the nose, respectively. Near the superior extremity of the perpendicular part, and below the processes which spring from it, there is another ridge more or less parallel to that already described. This is the **crista ethmoidalis** (ethmoidal crest), and with this the posterior extremity of the middle concha articulates. The **lateral surface**, which forms the medial wall of the pterygo-palatine fossa, is channelled by a vertical groove (**sulcus pterygopalatinus**), converted into the **pterygo-palatine canal** by articulation with the maxilla. This canal, called at its lower end the **larger palatine foramen**, transmits the posterior palatine nerve and greater palatine vessels. Anteriorly the lateral surface projects forwards to a variable extent, and helps to close in the maxillary sinus by its **maxillary process**. The **anterior border** is a thin edge, of irregular outline, which articulates above with the ethmoid, with the posterior edge of the maxillary process of the inferior conchal bone about its middle, and below with the maxilla. The **posterior border**, thin above,

where it articulates with the anterior part of the medial pterygoid lamina, expands below into the pyramidal process. The inferior border of the vertical part is confluent with the lateral edge of the horizontal part; posteriorly, and immediately in front of the tuberosity, it is notched by the lower extremity of the larger palatine foramen.

FIG. 161.—THE RIGHT PALATE BONE.

As seen from behind.

The superior border supports the orbital and sphenoidal processes; the former—the anterior—is separated from the latter by a notch (*incisura spheopalatina*), which is converted into the **spheno-palatine foramen** by the articulation of the palate bone with the inferior surface of the sphenoid. Through this communication between the pterygo-palatine fossa and nasal cavity pass the spheno-palatine artery and the nasal branches of the spheno-palatine ganglion. The **processus pyramidalis** (pyramidal process) is directed backwards and laterally from the angle formed by the perpendicular and horizontal parts, and presents, on its posterior surface, a central smooth vertical groove, bounded on either side by rough articular furrows which unite above in a V-shaped manner with the upper thin posterior edge. These latter articulate with the anterior parts of the lower portions of the medial and lateral pterygoid laminae, while the central groove fits into the wedge-like interval between the two pterygoid laminae, thus entering into the formation of the pterygoid fossa. The lateral surface of the pyramidal process is rough above, where it is confluent with the lateral surface of the perpendicular part which articulates with the tuberosity of the maxilla; below, there is a small, smooth, triangular area which appears between the tuberosity of the maxilla and the lateral surface of the lateral pterygoid lamina, and so enters into the medial wall of the infra-temporal fossa. Passing through the pyramidal process in a vertical direction are the **foramina palatina minora** (lesser palatine foramina) for the transmission of the smaller palatine nerves and vessels.

The **processus orbitalis** (orbital process), shaped like a hollow cube, surmounts the anterior part of the vertical plate. The open mouth of the cube is usually directed backwards and medially towards the anterior part of the body of the sphenoid, with the cavity of which it commonly communicates; the anterior part of the cube articulates with the medial end of the angle formed by the orbital plate and infra-temporal surface of the maxilla. Of the remaining four surfaces, one directed forwards and medially articulates with the ethmoid. The others are non-articular: the **superior** enters into the formation of the floor of the orbit; the **lateral** is directed towards the pterygo-palatine fossa; whilst the **inferior**, which is confluent with the medial surface of the vertical part, is of variable extent, and overhangs the superior meatus of the nose.

The **processus sphenoidalis** (sphenoidal process), much smaller than the orbital, curves upwards, medially, and backwards from the posterior part of the summit of the perpendicular part. Its **superior surface**, which is grooved, articulates with the anterior part of the inferior surface of the body of the sphenoid and the root of the medial pterygoid lamina, thereby converting the groove into the **pharyngeal canal**, which transmits an artery of the same name together with a pharyngeal branch from the spheno-palatine ganglion. Its **lateral side** enters into the formation of part of the medial wall of the pterygo-palatine fossa. Its **medial curved aspect** is directed towards the nasal cavity, whilst its medial edge is in contact with the ala of the vomer.

Connexions.—The palate bone articulates with its fellow of the opposite side, with the ethmoid, vomer, sphenoid, maxilla, and inferior concha.

Ossification.—The palate bone ossifies in membrane at the side of the nasal segment of the bucco-nasal cavity, medial to the descending palatine nerves, at a time when each half of the developing palatine shelf is hanging down by the side of the tongue. When the palatine shelf becomes horizontal, as it does in the fifth week, bone extends into it to form the horizontal plate. From this common centre all parts of the palate bone develop but the orbital process may be ossified from an independent centre, which either fuses with the palate bone, or with the sphenoid, or with the ethmoid.

Ossa Zygomatica.

The **zygomatic bone** (O.T. malar) underlies the most prominent part of the cheek, and is hence often called the cheek-bone. Placed to the lateral side of the orbital cavity, it forms the sharp lateral border of that hollow, and serves to separate that space from the temporal and infra-temporal fossæ which lie behind; below, it rests upon and is united to the maxilla; behind, it enters into the formation of the zygomatic arch, which bridges across the temporal fossa.

As viewed from the lateral side, the bone is convex from side to side, and has four processes, of which three are prominent. These are the **fronto-sphenoidal**

FIG. 162.—THE RIGHT ZYGOMATIC BONE. A, Lateral Side; B, Medial Side.

(processus frontosphenoidalis), the marginal or pointed extremity of the maxillary border, and the temporal (processus temporalis). The most elevated part of the convex malar surface (facies malaris) forms the **malar tuberosity**.

The **temporal process** ends posteriorly in an oblique edge, which articulates with the extremity of the zygomatic process of the temporal bone. The **fronto-sphenoidal** process, the most prominent of the three, is united superiorly to the zygomatic process of the frontal bone. The edge between the frontal and temporal processes is thin and sharp; it affords attachment to the temporal fascia, and near its upper end there is usually a pronounced angle (**processus marginalis**), formed by a sudden change in the direction of the border of the bone. It is just below this point that the zygomatico-temporal branch of the zygomatic nerve becomes cutaneous. The inferior margin of the temporal process is somewhat thicker and rounded; it extends downwards and forwards towards the inferior angle, where the bone articulates with the maxilla, and is there confluent with the ridge which separates the facial from the infra-temporal aspect of the maxilla. This edge of the bone is sometimes called the **masseteric border**, since it affords attachment to the fibres of origin of the masseter muscle. Sweeping downwards, in front of the fronto-sphenoidal process, is a curved edge which terminates inferiorly in a pointed process. This border forms the lateral and, in part, the inferior margin of the orbital cavity. Between the anterior extremity of the masseteric edge and the pointed anterior angle there is an irregular suture by which the bone is joined to the maxilla. The opening of the **foramen zygomaticofaciale** (zygomatico-

facial foramen) is seen on the lateral surface of the bone; its size and position are very variable.

The medial aspect of the bone is distinguished by a curved elevated crest, called the orbital process, which extends medially and backwards, and is confluent laterally with the orbital margin. This process has two surfaces—one anterior, which forms a part of the lateral and lower wall of the orbit, and one posterior, which is directed towards the temporal fossa above and the infra-temporal fossa below. The free edge of the orbital process is thin and serrated; a little below its middle it is usually interrupted by a non-articular notch, which corresponds to the anterior extremity of the inferior orbital fissure. The part above this articulates with the great wing of the sphenoid, the portion below with the orbital surface of the maxilla. Behind the orbital process the medial surface of the bone is concave from side to side, and extends backwards along the medial aspect of the temporal process and upwards over the posterior half of the medial side of the frontal process, thus entering into the formation of the infra-temporal and temporal fossæ respectively. The orbital surface of the orbital process usually displays the openings of two canals (foramina zygomatico-orbitalia)—one which traverses the bone below the orbital margin and appears on the front of the bone as already described, the other which passes obliquely upwards and laterally through the orbital process and appears in the temporal fossa, to the medial side of the frontal

FIG. 163.—MEDIAL SURFACE OF THE ZYGOMATIC BONE AT BIRTH.

process (foramen zygomaticotemporale). The former transmits the zygomatico-facial branch, the latter the zygomatico-temporal branch of the zygomatic nerve. Just under the orbital margin and a short distance below the zygomatico-frontal sutures there is usually a small tubercle serving for the lateral attachment of the ligamentum palpebrarum. (Whitnall, J. A. and P., vol. xlv.)

Below the orbital process there is a rough triangular area, bounded laterally by the maxillary border. This articulates with the zygomatic process of the maxilla, and occasionally forms the lateral wall of the maxillary sinus.

Connexions.—The zygomatic bone articulates with the frontal, sphenoid, maxilla, and temporal bones.

Ossification.—The zygomatic ossifies in membrane. Its basis appears about the tenth week as a thin ossifying lamina which corresponds to the orbital margin, attached to which there is a backward expansion corresponding to the body of the bone; from this posteriorly there extends the element of the temporal process. On the medial side, and lying within the angle formed by the orbital and temporal elements, there appears a secondary thickening, which develops into a cup-shaped layer which fits into the recess and ultimately forms the surface of the bone directed to the temporal fossa. Below the orbital margin on the medial side, and extending backwards towards the temporal process, is another secondary thickening, which forms a club-shaped nodule, the thick end of which is directed forwards, whilst posteriorly it forms, in part, the lower margin of the body and temporal process. The overlap of these several parts leads to the formation of grooves which may persist in the adult as sutures. (Karl Toldt, junr., *Sitzsbr. des Akad. des Wiss.*, Wien, July 1902.) Regarding the ossification of this bone there are great differences of opinion; not a few anatomists describe it as developed from a single centre. Support, however, is given to its origin from multiple centres owing to the frequency with which in the adult it is met with in a divided condition.

Mandibula.

The mandible or lower jaw, of horse-shoe shape, with the extremities upturned, is the only movable bone of the face. Stout and strong, it supports the teeth of the lower dental arch, and articulates with the base of the cranium, by the joints, on either side, between its condyles and the mandibular fossæ of the

temporal bones. The anterior or horizontal part, which contains the teeth, is called the *corpus mandibulæ* (body); the posterior or vertical portions constitute the *rami mandibulæ*.

The body displays in the median plane, in front, a faint vertical ridge, the *symphysis*, which indicates the line of fusion of the two symmetrical halves from which the bone is primarily developed. Inferiorly this ridge divides so as to enclose, in well-marked specimens, a triangular area—the *protuberantia mentalis* (mental protuberance), the centre of which is somewhat depressed, thus emphasising the inferior angles, which are known as the *tubera mentalia* (mental tubercles). The *lateral surface* is crossed by a faint, elevated ridge, the *linea obliqua* (oblique line), which runs upwards and backwards from the mental tubercle to the lower part of the anterior border of the ramus, with which it is confluent. From this ridge arise the *m. quadratus labii inferioris* and the triangular muscle. A little above this, midway between the upper and lower borders of the mandible, and in line with the root of the second premolar tooth, the bone is pierced by the *mental foramen*; this is the anterior opening of the inferior

FIG. 164.—THE MANDIBLE AS SEEN FROM THE LEFT SIDE.

alveolar canal, which traverses the body of the bone. Through this aperture the mental vessels and nerves reach the surface. The *upper border* supports the sixteen teeth of the mandible. It is thick behind and thinner in front, in correspondence with the size of the roots of the teeth. Anteriorly the sockets of the incisor and canine teeth produce a series of vertical elevations (*juga alveolaria*), of which that corresponding to the canine tooth is the most prominent. When this is outstanding it gives rise to a hollowing of the surface between it and the symphysis, often referred to as the *incisor fossa*; frequently, however, this is only faintly marked. Below the oblique line the bone is full and rounded, and ends below in the *basis mandibulæ* (base). This slopes laterally at the sides, and forwards in front, where it is thick and hollowed out on either side of the symphysis to form the *digastric fossæ*, to which the anterior bellies of the digastric muscles are attached; narrowing somewhat behind this, the base again expands opposite the molar teeth, and finally becoming reduced in width, terminates posteriorly at the *angle* formed between it and the posterior border of the ramus. The *medial surface* of the body is crossed by the *linea mylohyoidea* (mylo-hyoid line). This slants from above downwards and forwards towards the lower part of the symphysis. It serves for the origin of the mylo-hyoid muscle, and also, just behind the last molar tooth, furnishes an attachment to the superior constrictor of the pharynx. Below the posterior part of this ridge the surface is hollowed to form a *fossa* for the lodgment of the submaxillary gland. Above the anterior part of the mylo-hyoid line the bone is smooth and usually convex. Here the sublingual gland lies in relation to it. In the angle formed by the convergence of the two mylo-hyoid lines, and in

correspondence with the back of the lower part of the symphysis, there is a raised tubercle surmounted by two laterally placed spines, the *spinæ mentales* (mental spines). Occasionally these are again subdivided into an upper and lower pair, or it may be that the lower pair may fuse to form a rough median ridge. To the upper pair of spines the *genio-glossi* muscles are attached, whilst the lower pair serve for the origin of the *genio-hyoid* muscles. Immediately above the tubercle there is a median foramen for the transmission of a nutrient vessel, and close to the alveolar border opposite the intervals between the central and lateral incisors, there are two little vascular canals.

The *ramus mandibulæ* passes upwards from the posterior part of the bone, forming by the junction of its posterior border with the base of the body the *angulus mandibulæ* (angle), which is usually rounded and more or less everted. The lateral surface of the ramus affords attachment to the *masseter* muscle, and when that muscle is powerfully developed the bone

is usually marked by a series of oblique curved ridges, best seen towards the angle. About the middle of the deep or medial surface is the large opening (*foramen mandibulare*) of the *inferior alveolar canal*, which runs downwards and forwards to reach the body, and transmits the *inferior alveolar* vessels and nerves. This aperture is overhung in front by a pointed scale of bone, the *lingula mandibulæ*, to the edges of which the *spheno-mandibular ligament* of the mandibular articulation is attached. Behind the lingula and leading downwards and forwards for an inch or so from the opening of the *inferior alveolar canal* is the *sulcus mylohyoideus* (*mylo-hyoid groove*), along which the *mylo-hyoid artery* and nerve pass. Behind and below this groove the medial surface of the angle is rough for the attachment of the *internal pterygoid muscle*. Superiorly the ramus supports the *coronoid process* in front, and the *condyloid process* behind, the two being separated by the wide *incisura mandibulæ* (*mandibular notch*), over which there pass in the recent condition the vessels and nerve to the *masseter* muscle. The *coronoid process*, of variable length and beak-shaped, is limited behind by a thin curved margin, which forms the anterior boundary of the *mandibular notch*. In front its anterior edge is convex from above downwards and forwards, and becomes confluent below with the anterior border of the ramus and the oblique line. To the medial side of this edge there is a grooved elongated triangular surface, the medial margin of which, commencing above near the summit of the *coronoid process*, leads downwards along the medial side of the root of the last molar tooth towards the *mylo-hyoid line*. Behind this ridge the thickness of the ramus is much reduced. The *temporal muscle* is inserted into the margins and medial surface of the *coronoid process*. The posterior border of the ramus is continued upwards to support the *capitulum mandibulæ* (*condyle*), below which it is somewhat constricted to form the *collum mandibulæ* (*neck*), which is compressed from

	9. Angle.	

before backwards, and bounds the mandibular notch posteriorly. To the medial side of the neck, immediately below the condyle, there is a little depression (*fovea pterygoidea*) for the insertion of the external pterygoid muscle. The convex surface of the condyle is transversely elongated, and so disposed that its long axis is inclined nearly horizontally from within laterally and a little forwards. The convexity of the condyle is more marked in its antero-posterior than in its transverse diameter, and tends slightly to overhang the mandibular notch. The medial and lateral ends of the condyle terminate in tubercles which serve for the attachment of part of the capsular ligament of the joint.

Ossification.—Its development is intimately associated with Meckel's cartilage, the cartilaginous bar of the first visceral or mandibular arch. Meckel's cartilages, of which there are two, are connected proximally with the periotic capsule and cranial base. These distal ends meet but do not

fuse in the region of the symphysis. Ossification takes place chiefly from membrane, in part from primordial cartilage (Meckel's cartilage), and also in part from accessory (metaplastic) cartilages, which have no connexion with Meckel's cartilage, but arise in the membrane from which the greater part of the bone is formed. Before ossification commences three structures are seen lying side by side in the mandibular arch of the embryo. These are, from within laterally, Meckel's cartilage, the inferior alveolar nerve which anteriorly divides into its two terminal branches, viz., the incisor and mental nerves, and a dense connective tissue which stretches from before backwards from close to the mid-line anteriorly to near the acoustic region posteriorly. *Ossification in membrane* commences about the fortieth to forty-fifth day in the angle between the incisor and mental nerves; it extends rapidly backwards under the mental nerve which grooves its upper surface, and is ultimately enclosed within the mental foramen. At the same time the outer alveolar wall is formed by the extension of this ossifying membrane bone, from which later, about the third month, is developed by backward growth the angle and ramus, the latter surmounted by a well-defined coronoid process. About the forty-fifth day the inner alveolar wall, the so-called splenial element, is formed by an ingrowth from the anterior part of the floor of the mental groove. This passes below the incisor nerve and passes up between it and Meckel's cartilage, which it subsequently overlaps, extending rapidly forwards and backwards to end posteriorly in the lingula anterior to the point of origin of the mylo-hyoid nerve. The mandible, in point of time, is the second bone to ossify, being preceded only by the clavicle. *Ossification in Meckel's cartilage.*—This commences a little later than the first formation of the coronoid process, opposite the first and second incisor with germs, not by independent ossification, but by invasion of osteoblasts from the neighbouring membrane bone. The cartilage becomes surrounded by shelves of bone projected medially both above and below it from the main membrane bone. A bony tube is thus formed which extends from near the mid-line anteriorly to the second milk tooth posteriorly. Within these limits Meckel's cartilage becomes incorporated within the mandible. The extreme anterior end of the cartilage does not, however, undergo ossification, and the hinder end, save that part concerned in the formation of the malleus and incus, degenerates and ultimately disappears. *Ossification in accessory cartilages.*—These appear at the following sites: one,

FIG. 166.—DEVELOPMENT OF THE MANDIBLE.

A, As seen from the medial side; B, from the lateral side; C, showing accessory (metaplastic) cartilages (blue).

(In A and B Meckel's cartilage is coloured blue.)

a carrot-like mass, at the condyle; the large end forms the condyle; the tapering end is wedged into the ossifying ramus under the root of the coronoid process. This cartilage appears about the eleventh week. About the thirteenth week a strip of cartilage appears along the anterior border of the coronoid process. Along the anterior end of the alveolar walls close to the middle line, and turning down the symphyseal surface of the mandible to end below in the region of the future digastric impression, another mass of cartilage appears about the fourteenth week. All the above cartilages are ossified by invasion from the surrounding membrane bone and are not therefore independent centres. It is possible that the symphyseal cartilages may be occasionally independently ossified and thus give rise to the ossa mentalia when they exist. From what has been stated it thus appears that under normal conditions each half of the mandible ossifies from one centre only. The above account is based on the researches of Low¹ and Fawcett.²

In a third or fourth month foetus the cartilage can be traced from the under surface of the fore part of the tympanic ring downwards and forwards to reach the jaw, to which it is attached at the opening of the mandibular canal; from this it may be traced forwards as a narrow strip applied to the medial surface of the mandible, which it sensibly grooves. The proximal end of this furrow remains permanently as the mylo-hyoid groove. The part of the cartilage between the tympanic ring and the jaw disappears, and its sheath becomes converted into fibrous tissue, and persists in the adult as the so-called internal lateral (spheno-mandibular) ligament of the temporo-maxillary articulation, its proximal end through the Gaserian fissure being continuous with the slender process of the malleus, with the development of which bone it is intimately associated. I. Chaine (*Comptes Rendus, Biologie*, 1903) takes exception to this view and regards the spheno-mandibular ligament as the remnant of a muscular slip.

At birth the mandible consists of two lateral halves united at the symphysis by fibrous tissue; towards the end of the first, or during the second year, osseous union between the two halves is complete. In infancy the jaw is shallow and the rami proportionately small; further, owing to the obliquity of the ramus the angle is large, averaging about 150°. The mental foramen lies near the lower border of the bone. Coincident with the eruption of the teeth and the use of the jaw in mastication, the rami rapidly increases in size, and the angle becomes more acute. After the completion of the permanent dentition it approaches more nearly a right angle varying from 110° to 120°. The body of the bone is stout and deep, and the mental foramen usually lies midway between the upper and lower borders. As age advances, owing to the loss of the teeth and the consequent shrinkage and absorption of the alveolar border of the bone, the body becomes narrow and attenuated, and the mental foramen now lies close to the upper border. At the same time the angle opens out again (130° to 140°), in this respect resembling the infantile condition. In old age the coronoid process and the condyle form a more open angle with each other than in the adult.

Os Hyoideum.

The hyoid bone, though placed in the neck, is developmentally connected with the skull. It lies between the mandible above and the larynx below,

FIG. 167.—THE HYOID BONE AS SEEN FROM THE FRONT.

and is connected with the root of the tongue. Of U-shaped form, as its name implies (Greek *ν* and *ἶδος*, like), it consists in the adult of a central part, or **body**, with which are united two long processes extending backwards—the **greater cornua**—one on either side. At the point where these are ossified with the body, the **lesser cornua**, which project upwards and backwards, are placed.

The **body** is arched from side to side and compressed from before backwards, so that its surfaces slope downwards and forwards. Its **anterior surface** displays a slight median ridge, on either side of which the bone is marked by the attachment of the mylo-hyoid muscles. Its **posterior surface**, deeply hollowed, is concave from side to side and from above downwards. Herein lie a quantity of

¹ *Journal of Anatomy and Physiology*, vol. xlv. p. 82.

² *Graduation Thesis*, Edinburgh, 1906.

fat and a bursa which separates this aspect from the thyreo-hyoid membrane. The upper border, usually described with the anterior surface, is broad; it is separated from the anterior aspect by a transverse ridge, behind which are the impressions for the attachment of the genio-hyoid muscles. Its posterior edge is thin and sharp; to this, above, are attached the genio-glossi, whilst behind and below the thyreo-hyoid membrane is connected with it. The inferior border is well defined and narrow; it serves for the attachment of the omo-hyoid, sterno-hyoid, thyreo-hyoid, and stylo-hyoid muscles.

The **greater cornua** are connected on either side with the lateral parts of the body. At first, union is effected by synchondroses, which, however, ultimately ossify. These cornua curve backwards, as well as upwards, and terminate in more or less rounded and expanded extremities. Compressed laterally, they serve for the attachments laterally of the thyreo-hyoid and hyo-glossi muscles, and the middle constrictor of the pharynx from below upwards, whilst medially they are connected with the lateral expansions of the thyreo-hyoid membrane, the free edges of which are somewhat thickened, and connect the extremities of the great cornua with the ends of the superior cornua of the thyroid cartilage below.

The **lesser cornua**, frequently cartilaginous in part, are about the size of grains of wheat. They rest upon the upper surface of the bone at the junctions of the greater cornua with the body. In youth they are separated from, but in advanced life become ossified with, the rest of the bone, from which they are directed upwards, backwards, and a little laterally. Their summits are connected with the stylo-hyoid ligaments; they also serve for the attachment of muscles.

Connexions.—The hyoid is slung from the styloid processes of the temporal bones by the stylo-hyoid ligaments. Inferiorly it is connected with the thyroid cartilage of the larynx by the thyreo-hyoid ligaments and membrane. Posteriorly it is intimately associated with the epiglottis.

Ossification.—In considering the development of the hyoid bone it is necessary to refer to the arrangement and disposition of the cartilaginous bars of the second and third visceral arches. That of the second visceral arch, the hyoid bar—or Reichert's cartilage, as it is sometimes called—is united above to the petrous part of the temporal, whilst ventrally it is joined to its fellow of the opposite side by an independent median cartilage. Chondrification of the third visceral arch only occurs towards its ventral extremity, forming what is known as the thyreo-hyoid bar. This also unites with the median cartilage above mentioned. In these cartilaginous processes ossific centres appear in certain definite situations. Towards the end of foetal life a single centre (by some authorities regarded as primarily double) appears in the median cartilage, and forms the body of the bone (**basihyal**). About the same time ossification begins in the lower ends of the thyreo-hyoid bars, and from these the greater cornua are developed (thyreo-hyals). During the first year the lower ends of the hyoid bars begin to ossify and form the lesser cornua (cerato-hyals). The cephalic ends of the same cartilages meanwhile ossify to form the styloid process (stylohyal) on either side and one of the auditory ossicles called the stapes, whilst the intervening portions of cartilage undergo resorption and become converted into the fibrous tissue of the stylo-hyoid ligaments, which in the adult connect the lesser cornua with the styloid processes of the temporal bone. The greater cornua fuse with the body in middle life; the lesser cornua only at a more advanced period. Variations in the course of development lead to interesting anomalies of the hyoid apparatus. The lesser cornua may be unduly long or the stylo-hyoid ligament may be bony; in this case the cartilage has not undergone resorption, but has passed on to the further stage of ossification, thus forming an epihyal element comparable to that in the dog. The ossified stylo-hyoid ligament, as felt through the pharyngeal wall, may be mistaken for a foreign body. (Farmer, G. W. S., *Brit. Med. Journ.* 1900, vol. i. p. 1405.)

THE SKULL AS A WHOLE.

The skull as a whole may be studied as seen from the front (**norma frontalis**), from the side (**norma lateralis**), from the back (**norma occipitalis**), from above (**norma verticalis**), and from below (**norma basalis**).

The Skull from the Front (Norma Frontalis).

In front, the smooth convexity of the frontal bone limits this region above, whilst inferiorly, when the lower jaw is disarticulated, the teeth of the upper jaw form its lower boundary. The large openings of the orbits are seen on either side; whilst placed centrally, and at a somewhat lower level, is the *apertura piriformis* (anterior nasal aperture) leading into the nasal cavity.

The frontal region, convex from above downwards and from side to side, is limited laterally by two ridges, which are the anterior extremities of the temporal lines. Superiorly the fulness of the bone blends with the convexity of the vertex. Inferiorly the frontal bone forms on either side the arched superior border of the orbit (*margo supraorbitalis*). The space between these borders corresponds to the root of the nose, and here are seen the sutures which unite the frontal with the nasal bones medially, and with the frontal process of the maxilla on either side, called the *naso-frontal* and *fronto-maxillary* sutures, respectively. The supra-orbital margin is thin and sharp laterally, but becomes thick and more rounded towards its medial side, where it forms the *medial angular process* and unites with the frontal process of the maxilla and the lacrimal bone on the medial wall of the orbit. This arched border is interrupted towards the medial side by a notch (*incisura supraorbitalis*), sometimes converted into a foramen, for the transmission of the supra-orbital nerve and artery. In the median plane, just above the naso-frontal suture, there is often the remains of a median suture (*sutura frontalis*), which marks the fusion of the two halves from which the bone is primarily ossified. Here also a prominence, of variable extent—the *glabella*—is met with; from this there passes out on either side above and over the orbital margin a projection called the *superciliary arch*.

The *orbital fossæ*, of more or less conical form, display a tendency to assume the shape of four-sided pyramids by the flattening of the superior, inferior, and lateral walls. The *base*, which is directed forwards and a little laterally, corresponds to the orbital aperture. The shape of this is liable to individual and racial variations, being nearly circular in the Mongoloid type, whilst it displays a more or less quadrangular form in Australoid skulls. The superior margin, as has been already stated, is formed by the frontal bone between the zygomatic and medial angular processes. The lateral and about half the inferior margins are formed by the sharp curved edge between the facial and orbital surfaces of the zygomatic bone. The medial border and the remainder of the inferior margin are determined by the lateral surface of the frontal process of the maxilla, and the sharp edge separating the facial from the orbital surface of the same bone. Three sutures interrupt the continuity of the orbital margin—*zygomatiko-frontal* laterally, the *fronto-maxillary* medially, both lying about the same level, and the *zygomatiko-maxillary* inferiorly. The *apex* of the space is directed backwards and medially, so that the medial walls of the two orbits lie nearly parallel to each other, whilst the lateral walls are so disposed as to form almost a right angle with each other. The depth of the orbit measures, on an average, about two inches (5 cm.). At the apex there are two openings; the larger, known as the *superior orbital fissure* (O.T. *sphenoidal*), passes from the apex of the space laterally and a little upwards for the distance of three-quarters of an inch or so, between the roof and lateral wall of the orbit. The medial third of this fissure is broad and of circular form. Laterally it is considerably reduced in width. Through this the oculomotor, trochlea, ophthalmic division of the trigeminal, and the abducent nerves enter the orbit, whilst the ophthalmic veins pass backwards through it. Above and medial to the medial end of the sphenoidal fissure there is a smaller circular opening, the *optic foramen*, for the transmission of the optic nerve and ophthalmic artery.

The *roof of the orbit*, which is very thin and brittle towards its centre, is formed in front by the orbital part of the frontal bone and behind by a small triangular piece of the small wing of the sphenoid, which surrounds the optic foramen and forms the upper border of the superior orbital fissure. Laterally

this surface is separated from the lateral wall by the superior orbital fissure

FIG. 168.—THE FRONT OF THE SKULL.

The nasal bones, lamina papyracea of the ethmoid, vomer, inferior conchæ, zygomatic, and parietal bones are coloured red. The sphenoid, lacrimal, perpendicular part and middle conchæ of the ethmoid, and inferior conchæ are coloured blue. The maxillæ are coloured yellow. The frontal and temporal bones are left uncoloured.

1. Mental protuberance.	14. Ethmoidal foramina.	26. Left nasal bone.
2. Body of mandible.	15. Temporal line.	27. Zygomatic bone.
3. Ramus of mandible.	16. Supra-orbital notch.	28. Inferior orbital fissure.
4. Anterior nasal spine.	17. Glabella.	29. Zygomatic arch.
5. Canine fossa.	18. Frontal tuberosity.	30. Apertura piriformis, displaying nasal septum and inferior and middle conchæ.

11. Superior orbital fissure.	24. Orbital surface of great wing of sphenoid.	
12. Lacrimal bone and groove.	25. Squamous part of the temporal.	
13. Optic foramen.		

posteriorly, anteriorly by an irregular suture between the orbital part of the

frontal and the upper margin of the orbital surface of the great wing of the sphenoid, lateral to which the zygomatic process of the frontal articulates with the zygomatic bone, often forming a ridge which limits the fossa for the lodgment of the lacrimal gland inferiorly (Whitnall). Medially the roof is marked off from the medial wall by a suture, more or less horizontal in direction, between the orbital plate of the frontal and the following bones in order from before backwards, viz., the frontal process of the maxilla, the lacrimal bone, and the lamina papyracea of the ethmoid. In the suture between the last-mentioned bone and the frontal there are two foramina, the **anterior** and **posterior ethmoidal foramina**; both transmit ethmoidal vessels—the anterior affording passage to the anterior ethmoidal branch of the naso-ciliary nerve as well. The roof is concave from side to side, and to some extent also from before backwards. About midway between the fronto-maxillary suture and the supra-orbital notch or foramen, but within the margin of the orbit, there is a small **depression**, occasionally associated with a spine (*fovea vel spina trochlearis*), for the attachment of the cartilaginous pulley of the superior oblique muscle of the eyeball. Under cover of the zygomatic process the roof is more deeply excavated, forming a shallow **fossa** for the lodgment of the lacrimal gland (*fossa glandulæ lacrimalis*). In front, the roof separates the orbit from the **frontal sinus**, and along its medial border it is in relation with the **ethmoidal air-cells**. The relation to these air spaces is variable, depending on the development and size of the sinuses. The rest of the roof, which is very thin, forms by its upper surface part of the floor of the anterior cranial fossa, in which are lodged the frontal lobes of the cerebrum.

The **floor of the orbit** is formed by the **orbital surface** of the **maxilla**, together with part of the **orbital surface** of the **zygomatic bone**, and a small triangular piece of bone, the **orbital process** of the **palate**, which is wedged in posteriorly. Laterally, for three-quarters of its length posteriorly, it is separated from the lateral wall, which is here formed by the great wing of the sphenoid, by a cleft called the **inferior orbital fissure**. Through this there pass the maxillary division of the trigeminal nerve on its way to the infra-orbital canal, the zygomatic branch of the maxillary nerve, the infra-orbital vessels, a branch connecting the inferior ophthalmic vein with the pterygoid plexus, and some twigs from the sphenopalatine ganglion. By means of this fissure the orbit communicates with the pterygo-palatine fossa behind, and the infra-temporal fossa to the lateral side, though in the recent condition the fissure is bridged over by the involuntary orbitalis muscle of Müller. Medially the floor is limited from behind forwards by the suture between the following bones, viz., the orbital process of the palate below with the body of the sphenoid above and behind, and the lamina papyracea of the ethmoid above and in front—**anterior** to which the orbital surface of the maxilla below articulates with the lamina papyracea of the ethmoid and the lacrimal above and in front. At the anterior extremity of this line of sutures the medial edge of the orbital plate of the maxilla is notched and free between the point where it articulates with the lacrimal posteriorly and the part from which its frontal process rises. Here it forms the lateral edge of a canal, down which the membranous naso-lacrimal duct passes to the nose. The floor of the orbit is thin behind and at the sides, but thicker in front, where it blends with the orbital margin. Passing in a sagittal direction through its substance is the infra-orbital canal, the roof of which is usually deficient behind, where it becomes continuous with a broad, shallow groove, which leads forwards from the anterior margin of the inferior orbital fissure. This canal (**canalis infraorbitalis**) opens on the anterior surface of the maxilla immediately below the orbital margin (**foramen infraorbitale**) and transmits the maxillary division of the trigeminal nerve, together with the infra-orbital vessels. The floor forms a thin partition which separates the orbit from the maxillary sinus, which lies beneath it. Medially it completes the lower ethmoidal air-cells, and separates the orbit from the middle meatus of the nasal cavity.

The **lateral wall of the orbit**, which is the strongest, is formed by the orbital surface of the **great wing** of the **sphenoid** and the superior part of the **orbital surface** of the **zygomatic bone**. Above it, behind, is the **superior orbital fissure**, whilst below,

and extending much farther forward, is the **inferior orbital fissure**. The posterior portion of this wall, formed by the great wing of the sphenoid, serves as a partition between the orbit and the anterior extremity of the middle cranial fossa, in which is lodged the pole of the temporal lobe of the cerebrum. In front of this, and behind the line of the spheno-zygomatic suture, this wall is strengthened on its outer aspect by its confluence with the cranial wall. Still more anteriorly, the lateral wall separates the orbit from the temporal fossa. The anterior margin of the lateral wall is stout and formed by the **zygomatic bone**, behind which, formed in part by the orbital process of the zygomatic bone and the zygomatic edge of the great wing of the sphenoid, it forms a fairly thick partition between the orbit in front and the temporal fossa behind. Crossing this surface from above downwards, close to the anterior extremity of the inferior orbital fissure, is the suture between the zygomatic bone and the great wing of the sphenoid (**sutura sphenozygomatica**). This wall is pierced in front by one or two small canals (**foramina zygomatico-orbitalia**), which traverse the zygomatic bone and allow the transmission of the zygomatico-temporal and zygomatico-facial branches of the zygomatic portion of the maxillary division of the trigeminal nerve. A small tubercle, which can be more readily felt than seen, is situated just within the orbital margin near the middle of the fore part of this wall, and indicates the site of attachment of the *ligamentum palpebrarum laterale* (Whitnall).

The **medial wall of the orbit** is formed from before backwards by a small part of the **frontal process** of the maxilla, by the **lacrimal**, and by the **lamina papyracea** of the **ethmoid**, posterior to which is a small part of the lateral aspect of the **body** of the **sphenoid** in front of the optic foramen. Above, the orbital part of the frontal bone forms a continuous suture from before backwards with the bones just enumerated; whilst below, the lacrimal and the lamina papyracea of the ethmoid articulate with the orbital plate of the maxilla; posteriorly the hinder extremity of the lamina papyracea and the anterior part of the body of the sphenoid articulate with the orbital process of the palate. The orbital surface of the lacrimal bone is divided into two by a vertical ridge—the **lacrimal crest** (**crista lacrimalis posterior**)—which forms in front the posterior half of a hollow, the **fossa sacci lacrimalis** (lacrimal fossa), the anterior part of which is completed by the channelled posterior border of the **frontal process** of the maxilla. In the lacrimal fossa is lodged the lacrimal sac, whilst passing from it and occupying the canal, of which the upper opening is at present seen, is the membranous nasolacrimal duct. The lower part of the lacrimal fossa separates the orbit from the anterior part of the middle meatus of the nasal cavity. To the medial side of the upper part of the lacrimal fossa lie the anterior ethmoidal cells, the passage leading from the nose to the frontal sinus (**infundibulum ethmoidale**), whilst the part of the bone behind the lacrimal crest forms the thin partition between the orbit and the ethmoidal cells. Behind, where the body of the sphenoid forms part of the medial wall of the orbit, the **sphenoidal air sinus** is in relation to the apex of that space, though here the partition wall between the two cavities is much thicker.

The **skeleton of the face** on its *anterior surface* is formed by the two maxillæ, the frontal processes of which have been already seen to pass up to articulate with the medial angular processes of the frontal bone, thus forming the lower halves of the medial margins of the orbit. Joined to the maxillæ laterally are the **zygomatic bones**, which are supported by their union with the temporal bones posteriorly through the medium of the zygomatic arches. The suture which separates the zygomatic from the maxilla (**sutura zygomaticomaxillaris**) commences above about the centre of the inferior orbital margin and passes obliquely downward and laterally, its inferior end lying in vertical line with the lateral orbital margin. The two maxillæ are separated by the nasal cavities, which here open anteriorly. Above, the two nasal bones are wedged in between the frontal processes of the maxillæ: whilst below the *apertura piriformis*, the maxillæ themselves are united in the middle line by the *internaxillary suture* (**sutura intermaxillaris**).

The **apertura piriformis** (**piriform aperture**) (**O.T. nasal aperture** or **anterior nares**), which lies below and in part between the orbits, is of variable

shape and size—usually piriform, it tends to be long and narrow in Europeans, as contrasted with the shorter and wider form met with in the negroid races. Its edges are formed below and on either side by the free curved margin of the body and the frontal process of the maxilla; and above, and partly at the sides, by the free border of the nasal bones. In the median plane, inferiorly, corresponding to the upper end of the intermaxillary suture there is an outstanding process—the **anterior nasal spine**, formed by the coalescence of spicules from both maxillæ; arising from this, and passing backwards and upwards, is a thin bony partition—the osseous septum of the nose. Often deflected to one or other side, it divides the cavity of the nose (**cavum nasi**) into a right and left half. Projecting into these chambers from their lateral walls can be seen the medial surfaces and free borders of the **middle and inferior conchæ**, the spaces below and between which form the **inferior and middle meatuses** of the nose, respectively.

Below the orbit, and to the lateral side of the piriform aperture, the anterior or facial surface of the body of the maxilla is seen; this is continuous inferiorly with the lateral surface of the alveolar process, in which are embedded the roots of the upper teeth.

A horizontal line drawn round the jaw on the level of a point midway between the lower border of the piriform aperture and the alveolar edge corresponds to the plane of the **hard palate**. Below that the alveolar process separates the cavity of the mouth from the front of the face; whilst above, the large air space, the **maxillary sinus**, lies within the body of the maxilla.

The **zygomatic bone** forms the lower half of the lateral and lateral half of the lower border of the orbit. Its lateral aspect corresponds to the point of greatest width of the face, the modelling of which depends on the flatness or projection of this bone.

When the **mandible** or lower jaw is in position, and the teeth in both jaws are complete, the lower dental arch will be seen to be smaller in all its diameters than the upper, so that when the jaws are closed the upper teeth slightly overlap the lower both in front and at the sides. Exceptionally, a departure from this arrangement is met with.

Lateral Aspect of the Skull (*Norma Lateralis*).

Viewing the lateral aspect of the skull, in the first instance without the lower jaw, it is seen to be formed in part by the bones of the cranium, and in part by the bones of the face. A line drawn from the fronto-nasal suture to the tip of the mastoid process serves to define roughly the boundary between these portions of the skull. Of ovoid shape, the cranium is formed above by the **frontal, parietal, and occipital bones** from before backwards; whilst below, included within these are the **sphenoid and temporal bones**. The sutures between these several bones are arranged as follows: Commencing at the zygomatic process of the frontal, the suture between that bone and the zygomatic bone is first seen; tracing this backwards and a little upwards, the lower edge of the frontal next articulates with the upper margin of the great wing of the sphenoid for a distance varying from three-quarters of an inch to one inch. Here the posterior border of the frontal turns upwards and slightly backwards, forming with the parietal the **sutura coronalis (coronal suture)**. The lower border of the parietal bone, which is placed immediately behind the frontal, articulates anteriorly with the posterior part of the superior border of the great wing of the sphenoid. The extent of this suture (**sutura sphenoparietalis**) is liable to very great individual variation—at times being broad, in other instances being pointed and narrow, whilst occasionally the parietal does not articulate with the sphenoid at all. Behind the spheno-parietal suture the parietal articulates with the squamous part of the temporal (**sutura squamosa**), the posterior extremity of which is about one inch behind the **external acoustic meatus**. Here the suture alters its character and direction, and in place of being scaly, becomes toothed and irregular, uniting, for the space of an inch or so, the mastoid angle of the parietal with the mastoid process of the temporal bone. This suture (**sutura parietomastoidea**) is more or less horizontal in direction, and lies in line and on a level with the superior border of the zygomatic arch. At a point about two inches behind the external acoustic

meatus the posterior border of the parietal bone turns obliquely upwards and backwards, and forms with the squamous part of the occipital bone the strongly denticulated *sutura lambdoidea* (lambdoid suture). Inferiorly this suture is continued obliquely downwards between the occipital bone and the posterior border of the mastoid portion of the temporal, where it forms the *sutura occipitomastoidea*

FIG. 169.—NORMA LATERALIS OF THE SKULL.

The occipital, sphenoid, ethmoid, and lacrimal bones and the mandible are coloured blue. The parietal, zygomatic, and nasal bones are coloured red. The temporal, frontal, and maxillary bones are left uncoloured.

1. Mental foramen.	12. Lambdoid suture.	22. Stephanion.
2. Body of the mandible.	13. Occipital bone.	23. Frontal bone.
3. Maxilla.	14. Lambda.	24. Pterion.
4. Ramus of mandible.	15. Obelion placed between the two parietal foramina.	25. Temporal fossa.
5. Zygomatic arch.	16. Parietal bone.	26. Great wing of sphenoid.
6. Styloid process.	17. Lower temporal line.	27. Zygomatic bone.
7. External acoustic meatus.	18. Upper temporal line.	28. Zygomatico-facial foramen.
8. Mastoid process.	19. Squamous part of temporal bone.	29. Lacrimal bone.
9. Asterion.	20. Bregma.	30. Nasal bone.
10. Superior nuchal line of occipital bone.	21. Coronal suture.	31. Infra-orbital foramen.
11. External occipital protuberance.		32. Piriform aperture and anterior nasal spine.

(occipito-mastoid suture), much simpler and less serrated than the two previously mentioned. These three sutures just described meet in triradiate fashion at a point called the **asterion**.

Anteriorly the curve of the squamous suture is continued downward between the anterior edge of the squamous part of the temporal and the posterior border of the great wing of the sphenoid; inferiorly it lies in plane with the middle of the zygomatic arch.

The sutures around the summit of the great wing of the sphenoid are arranged like the letter H placed obliquely, the cross-piece of the H corresponding to the spheno-parietal suture. When this is short, and becomes a mere point of contact, the arrangement then resembles the letter X. This region is named the **pterion**.

Curving over the lateral region of the calvaria in a longitudinal direction is the **temporal line**. This is often double. The lower line marks the limit of the attachment of the temporal muscle, whilst the upper ridge defines the attachment of the temporal fascia. Commencing in front at the **zygomatic process** of the frontal, the line sweeps upwards and backwards across the inferior part of that bone, and then crossing the coronal suture—at a point called the **stephanion**—it passes on to the parietal, over which it curves in the direction of its mastoid angle. Here it is continued on to the temporal bone, where it sweeps forward to form the **supra-mastoid crest**, which serves to separate the squamous from the mastoid portion of the temporal bone laterally. Carried forwards, this ridge is seen to become continuous with the upper border of the zygomatic arch over the external acoustic meatus. In front, the temporal ridge separates the temporal fossa from the region of the forehead; above and behind, it bounds the **temporal fossa** which lies within its concavity, and serves to separate that hollow from the surface of the calvaria which is overlain by the scalp. Above the level of the temporal lines the surfaces of the frontal and parietal bones are smooth, the latter exhibiting an elevation of varying prominence and position, but usually situated about the centre of the bone, called the **tuber parietale** (**parietal tuberosity**). A slight hollowing of the surface of the parietal behind and parallel to the coronal suture is not uncommon, and is referred to as the post-coronal depression.

As seen in profile, the part of the calvaria behind and below the lambdoid suture is formed by the squamous part of the occipital bone. In line with the zygomatic arch this outline is interrupted by the **external occipital protuberance** or **inion**. The projection of this point is variable; but its position can usually be easily determined in the living. Passing forwards from it, and blending anteriorly with the posterior border of the mastoid process of the temporal bone, is a rough crest, the **linea nuchæ superior** (**superior or nuchal curved line**), a little above which there is often a much fainter line, the **linea nuchæ suprema** (**highest curved line**); this affords attachment to the galea aponeurotica. These two lines serve to separate the part of the cranium above, which is covered by scalp, from that below, which serves for the attachment of the fleshy muscles of the back of the neck, the latter surface (**planum nuchale**) being rough and irregular as contrasted with the smooth superior part (**planum occipitale**). The fulness of these two parts of the occipital bone varies much. There is frequently a pronounced bulging of the **planum occipitale**, and the position of the lambda can often be easily determined in the living; similarly the **planum nuchale** may be either comparatively flat or else full and rounded. These differences are of course associated with corresponding differences in the development of the cerebral and cerebellar lobes, which are lodged in relation to the cerebral aspect of these parts of the bone. The further description of the **planum nuchale** is best deferred till the external aspect of the base of the skull is studied.

Fossa Temporalis.—Within the limits of the temporal lines the side of the cranium slopes forwards, inwards, and downwards, thus leaving a considerable interval between its lower part and the **zygomatic arch**. This space or hollow is called the **temporal fossa**; bounded above and behind by the temporal lines, its inferior limit is defined by the level of the zygomatic arch. Deepest opposite the angle formed by the frontal and temporal processes of the zygomatic bone, the fossa becomes shallow towards its circumference.

Its floor or **medial wall**, which is slightly concavo-convex from before backwards about mid-level, is formed above by the temporal surface of the frontal, behind by the sphenoidal angle of the parietal, as well as the lower portion of that bone, below the temporal line; below and in front by the temporal surface of the great wing of the sphenoid, and behind and below by the squamous portion of the temporal bone. Inferiorly, the floor is limited in front by the free inferior border of the great wing of the sphenoid, which forms the upper boundary of the **pterygo-**

palatine fossa; behind that, by a rough ridge, the **infra-temporal crest**, which crosses the lateral surface of the great wing of the sphenoid, to become continuous posteriorly with a ridge on the lower surface of the squamous part of the temporal, from which the anterior root of the zygomatic process springs. **Anteriorly** the temporal fossa is separated from the orbit by the zygomatic process of the frontal above, and by the orbital process of the zygomatic and its junction with the lateral border of the great wing of the sphenoid between its orbital and temporal surfaces.

Laterally and in front, the fossa is overhung by the backward projection of the fronto-sphenoidal process of the zygomatic bone, and it is under cover of this, and within the angle formed by the frontal and orbital processes of the zygomatic bone, that we see the opening of the **zygomatico-temporal foramen**, which pierces the orbital plate of the zygomatic bone and transmits the zygomatico-temporal branch of the zygomatic nerve—a filament of the maxillary division of the trigeminal nerve. The anterior part of the **inferior orbital fissure** opens into the lower part of the temporal fossa, and thus establishes a communication between it and the orbit. If the floor of the fossa be carefully examined, some more or less distinct **vascular grooves** may be seen. One passing upwards over the posterior part of the squamous temporal, immediately in front of and above the external acoustic meatus, is for the middle temporal artery; two others, usually less distinct, pass up, one over the temporal surface of the great wing of the sphenoid, the other over the anterior part of the squamous part of the temporal; these are for the anterior and posterior deep temporal branches of the internal maxillary artery. **Inferiorly** the temporal fossa communicates with the infra-temporal fossa, beneath the zygomatic arch, the two being separated by an imaginary horizontal plane passing medially at the level of that bony bridge. The fossa contains the temporal muscle with its vessels and nerves, together with the zygomatico-temporal branch of the zygomatic nerve and some fat; all of which are enclosed by the fascia which stretches over the space from the upper temporal line above to the superior border of the zygomatic arch below. The extent and depth of the fossa depends on the size of the temporal muscle, the development of which is correlated with the size and weight of the lower jaw.

Springing from the front and lower part of the squamous part of the temporal is the **zygomatic process** of that bone; it has two roots, an anterior and a posterior, between and below which are placed the fossa **mandibularis** (mandibular fossa) in front, and the opening of the **external acoustic meatus** behind. Of compressed triangular form, the process at first has its surfaces directed upwards and downwards, but curving laterally and forwards, it twists on itself, so that its narrowed surfaces are now turned laterally and medially, and its edges upwards and downwards; passing forwards, it expands somewhat, and ends in an oblique serrated surface, which unites with the temporal process of the zygomatic bone completing the **zygomatic arch**. It is the superior edge of this bridge of bone which forms the posterior root. The inferior border, turning medially, forms the anterior root, and serves to separate the temporal from the infra-temporal surface of the squamous part of the temporal, blending in front with the **infra-temporal crest** on the lateral surface of the great wing of the sphenoid. The under surface of this root is convex from before backwards, and is thrown into relief by the **mandibular fossa**, which passes up behind it. In this way a downward projection, which is called the **tuberculum articulare** (O.T. *eminentia articularis*), is formed.

The **spina angularis** of the sphenoid (angular spine) lies immediately to the medial side of the articular part of the mandibular fossa. Its size and projection vary. It is well to remember its relation to the condyloid process of the mandible when that bone is in position; lying, as it does, to the medial side and a little in front of that process, it affords attachment to the speno-mandibular ligament of the mandibular articulation. As will be seen hereafter, the anterior extremity of the osseous part of the auditory tube lies just to its medial side.

A noteworthy feature about the articular part of the mandibular fossa is the thinness of the bony plate which serves to separate it from the middle cranial fossa above. The **vaginal process** is a crest of bone which runs obliquely forwards from the front and medial side of the mastoid process, just below the

external acoustic meatus, to the angular spine of the sphenoid. Passing downwards and slightly forwards from the centre of this, and ensheathed by it in front and at the sides, is the pointed **styloid process**, the length of which is extremely variable.

In the recess between the posterior root of the zygoma and the upper curved edge of the meatus there is usually a depression, though in some instances this may be replaced by a slight bulging of the bone. If from the posterior root of the zygoma a vertical line be let fall, tangential to the posterior edge of the meatus, a small triangular area is mapped off which has been named by Macewen the **supra-meatal triangle**. Surgically this is of importance, as it is the spot selected in which to trephine the bone to reach the **tympanic antrum**.

In the suture between the posterior border of the mastoid part of the temporal and the squamous part of the occipital, there is usually a **foramen (mastoid)** for the transmission of an emissary vein from the transverse sinus within the cranium to the cutaneous occipital vein of the scalp; this opening, which may be double, varies greatly in size, and is usually placed on a level with the external acoustic meatus.

Fossa Infratemporalis.—The side of the cranium in front of the anterior root of the zygomatic process of the temporal bone is deeply hollowed, forming the **infra-temporal fossa**. The student must bear in mind that, in examining this space, the ramus and coronoid process of the mandible form its lateral wall; but this bone for the present being withdrawn, enables us to get a better view of the boundaries of the space. In front its **anterior wall** is formed by the convex posterior or **infra-temporal surface** of the **maxilla**, which rises behind the socket for the last molar tooth to form the **tuber maxillare** (maxillary tuberosity). Anteriorly, the infra-temporal surface of the maxilla is separated from its anterior aspect by the rounded inferior margin of the zygomatic process which supports the zygomatic bone. This latter curves laterally and backwards, forming part of the upper and anterior wall of the fossa. On the medial surface of this wall will be seen the suture uniting the zygomatic and maxillary bones (*sutura zygomaticomaxillaris*), which runs obliquely upwards and medially to reach the lateral extremity of the inferior orbital fissure, the inferior border of which forms the superior boundary of the infra-temporal surface of the maxilla. On this aspect of the bone are to be seen the openings of the **foramina alveolaria**, two or more in number, which transmit the nerves and vessels to the upper molar teeth. The **medial wall** of the infra-temporal fossa is formed by the lateral surface of the **lateral pterygoid lamina**, the width and shape of which varies greatly; its posterior border is thin and sharp, and often furnished with spiny points, to one of which the pterygo-spinous ligament, which stretches from this border to the angular spine of the sphenoid, is attached. It occasionally happens that this ligament becomes ossified. Anteriorly the lateral pterygoid lamina is separated from the maxilla above by an interval called the **pterygo-maxillary fissure**. Below this the bones are apparently fused, but a careful inspection of the skull, together with an examination of the disarticulated bones, will enable the student to realise that, wedged in between the two bones at this point, is a part of one of the smaller bones of the face, the **pyramidal process** of the **palate bone** (O.T. tuberosity of palate bone).

The inferior border of the lateral pterygoid lamina is usually curved and slightly everted. Superiorly, where the lateral pterygoid lamina is generally narrower, it sweeps upwards to become continuous with the broad inferior surface of the great wing of the sphenoid; this, which overhangs in part the infra-temporal fossa superiorly, is limited laterally by the **infra-temporal crest**, which separates its infra-temporal from its temporal surface. The infra-temporal surface of the great wing of the sphenoid is limited in front and below by the edge which forms the superior boundary of the inferior orbital fissure, whilst behind it reaches as far back as the medial extremity of the petro-tympanic fissure, where it terminates in the angular spine. It is from this point that the suture (*sutura sphenosquamosa*) curves forward and upwards to reach the region of the pterion. The infra-temporal surface of the great wing of the sphenoid, and the lateral surface of the lateral pterygoid plate, alike afford extensive attachments for the external pterygoid muscle, whilst the former is pierced by minute canals for the transmission of emissary veins. Occasionally a larger vascular foramen is present (**foramen Vesalii**),

through which a vein runs from the cavernous sinus within the cranium to the pterygoid venous plexus situated in the infra-temporal fossa. Immediately behind the root of the external pterygoid plate there is a large oval hole, the **foramen ovale**, and behind that, and in line with the angular spine, is the smaller **foramen spinosum**. These two foramina cannot usually be seen in a side view of the skull, and are better studied when the base is examined; they are mentioned, however, because they transmit structures which here pass to and from the cranium, viz., the mandibular division of the trigeminal nerve, together with its motor root, and the accessory meningeal artery through the foramen ovale, and the middle meningeal artery and its companion vein through the foramen spinosum. A part of the squamous part of the temporal also forms a small portion of the roof of this fossa; it consists of a triangular area immediately in front of the tuberculum articulare, and between it and the anterior root of the zygomatic process of the temporal, which is here curving medially and forwards, to become continuous with the infra-temporal crest. Medially this surface is continuous with the infra-temporal surface of the great wing of the sphenoid, separated from it, however, by the posterior part of the sphenosquamosal suture.

When the mandible is in position, the **infra-temporal fossa** is concealed by the **ramus** of the mandible, the medial surface of which, in its upper half, forms the lateral wall of that space. Viewed from the lateral side, the ramus of the mandible displays considerable differences in different skulls. These are mainly due to variations in its width and in the nature of the angle which it forms at its fusion with the body of the bone. A considerable interval separates the posterior border of the ramus from the front of the mastoid process. Within this space may be seen the free inferior edge of the **tympanic plate** (vaginal process), from which, just below the external acoustic meatus, the **styloid process** of the temporal bone is observed passing downwards and slightly forwards. The width and height of the **coronoid process** vary much, oftentimes reaching the level of the top of the condyle. Its extremity, when the lower jaw is closed, lies just within the anterior part of the zygomatic arch; at other times it rises to a much higher level, so that its point may be seen above the level of the upper border of the zygomatic arch. The posterior edge of the coronoid process forms the anterior border of the mandibular notch, and limits in front the interval left between the lower border of the posterior half of the zygomatic arch and the upper hollowed edge of the ramus. On looking into this interval, the **floor of the infra-temporal fossa** may be seen, formed anteriorly by the lateral pterygoid lamina; whilst posteriorly it is possible to pass a probe right across the base of the skull from one mandibular notch to the other, the shaft of the probe lying immediately behind the pterygoid processes of the sphenoid, and crossing the foramina ovalia, through which the mandibular divisions of the trigeminal nerves pass.

The **ramus** and **coronoid process** are so placed as to occupy a position intermediate between the zygomatic arch laterally and the lateral pterygoid lamina medially; their medial surface, therefore, forms the lateral wall of the infra-temporal fossa. On a level with the surface of the crowns of the teeth of the mandible, and situated about the middle of this aspect of the ramus, is the **mandibular foramen**, the superior opening of the **canalis mandibulæ** (mandibular canal), which traverses the body of the bone. Through this foramen there pass the inferior alveolar branch of the mandibular division of the trigeminal nerve, together with the inferior alveolar artery and its veins. As will now be seen, when the mandible is in position, the infra-temporal fossa is closed in laterally by the ramus of the mandible. In front there is an interval between the anterior border of the ramus and the infra-temporal surface of the maxilla, through which pass the buccinator branch of the trigeminal nerve and the communicating vein between the pterygoid plexus and the anterior facial vein. Above, in the interval between the mandibular notch and the inferior border of the zygomatic arch, there pass from the fossa the vessels and nerves which supply the masseter muscle. Between the posterior border of the ramus and the styloid process there enter and leave the large vessels which are found within the space. **Superiorly**, under cover of the zygomatic arch, the infra-temporal fossa communicates with the

temporal fossa, whilst inferiorly it is continuous with the infra-maxillary region. **Medially**, on the floor of the fossa there is an Γ -shaped fissure, the horizontal limb of which corresponds to the **inferior orbital fissure**, forming a channel of communication between the fossa and the orbit, through which passes the zygomatic branch of the maxillary division of the trigeminal nerve; whilst the vertical cleft is the **pterygo-maxillary fissure**, which leads into a small fossa placed between the front of the root of the pterygoid process of the sphenoid and the back of the maxilla, called the **pterygo-palatine fossa**.

The following foramina open into the infra-temporal fossa—the foramen ovale, foramen spinosum, foramina alveolaria, mandibular foramen, minute foramina for the transmission of emissary veins; of these one of large size is occasionally present, the foramen of Vesalius.

Fossa Pterygopalatina.—This space, which corresponds to the angular

FIG. 170.—CORONAL SECTION THROUGH THE PTERYGO-PALATINE FOSSA OF THE RIGHT SIDE.

The sphenoid is coloured red. The maxilla, vomer, middle, and inferior conchæ are coloured blue. The palate bone is left uncoloured.

interval between the pterygo-maxillary and inferior orbital fissures, and which lies between the maxilla in front and the root of the pterygoid process behind, is bounded medially by the perpendicular part of the palate bone, which separates it from the nasal cavity, with which, however, it communicates by means of the spheno-palatine foramen, which lies between the orbital and sphenoidal processes of the palate bone and the inferior surface of the body of the sphenoid. Opening into this fossa, above and behind, are the foramen rotundum, the pterygoid canal and the pharyngeal canal, in that order from lateral to medial side, whilst below is the superior orifice of the pterygo-palatine canal, together with openings of the lesser palatine canals. Its roof is formed by the under surface of the body of the sphenoid and the orbital process of the palate bone. Anteriorly it lies in relation to the apex of the orbit, with which it communicates by means of the inferior orbital fissure; whilst laterally, as already stated, it communicates with the infra-temporal fossa through the pterygo-maxillary fissure.

Posterior Aspect of the Skull (Norma Occipitalis).

The view of the cranium as seen from behind includes the posterior halves of the two parietal bones above, the squamous part of the occipital bone below, and the mastoid portions of the temporal bones on either side, inferiorly. The shape of this aspect of the skull varies much, but ordinarily the greatest width corresponds to the level of the parietal tuberosities. The sutures on this view of the calvaria display a triradiate arrangement, one limb of which is vertical, and corresponds to the posterior part of the interparietal or **sagittal suture**. The other two limbs pass laterally and downwards in the direction of the mastoid processes, uniting the two parietal bones in front with the occipital bone behind; these constitute the Λ -shaped **lambdoid suture**. The point of confluence of the sagittal and lambdoid sutures is called the **lambda**. This can generally be felt in the living, owing to the tendency of the squamous part of the occipital to project slightly, immediately below this spot. About one inch and a quarter above the lambda the two small **parietal foramina** are seen, through which pass the small emissary veins of Santorini, which connect the intra-cranial venous system with the superficial veins of the scalp. These small holes lie about $\frac{1}{16}$ of an inch apart on either side of the sagittal suture, which here, for the space of about an inch, displays a simplicity of outline in striking contrast with its serrated arrangement elsewhere. The term **obelion** is applied to a point on the sagittal suture in line with the two parietal foramina. The **lambdoid suture** is characterised by great irregularity of outline, and not infrequently chains of separated ossicles are met with in it, the *ossa suturarum* (sutural bones). The squamous part of the occipital bone is divided into two parts by the **superior nuchal or curved line**, the central part of which forms the **external occipital protuberance or inion**. The part above, called the **planum occipitale** or occipital surface comes within our present consideration; the part below, called the **planum nuchale** or the nuchal surface, though seen in perspective, had best be considered when the base is examined. A little above the level of the superior curved line the occipital surface is crossed on either side by a faint lunated line, the **linea nuchæ suprema** (highest nuchal or curved line), to which are attached the occipitales muscles and the galea aponeurotica. The projection of the occipital surface varies much in individual skulls; most frequently it overhangs the external occipital protuberance, forming a distinct boss; exceptionally, however, the latter may be the most projecting part of the bone. The extremity of the superior nuchal line on either side corresponds to the position of the **asterion** (p. 285). Lateral to these points the outline of the skull is determined by the downward projection of the mastoid processes, the medial surfaces of which are deeply grooved by the **mastoid notches** for the attachment of the posterior bellies of the digastric muscles, thus causing these processes to appear more pointed when viewed from this aspect.

Upper Aspect of Skull (Norma Verticalis).

This is the view of the calvaria as seen from above. It is liable to great diversities of form. Thus its shape may vary from an elongated oval to an outline more nearly circular. These differences have been classified, and form important distinctions from a craniometrical standpoint, the rounder varieties being termed the **brachycephalic**, whilst the elongated belong to the **dolichocephalic** group. Another noteworthy point in this view is the fact that in some instances the zygomatic arches are seen, whilst in others they are concealed by the overhang and bulge of the sides of the anterior part of the cranium. The former condition is described as **phanozygous**, the latter as **cryptozygous**, and each is more or less closely associated with the long or round varieties of head-form respectively.

The sutures displayed have a T-shaped arrangement. Placed medially between the two parietal bones is the **sagittal suture**. This is finely denticulated, except in the region of the obelion, though, of course, this will not be apparent if obliteration of the suture has taken place through fusion of the two parietal bones. Posteriorly the sagittal suture unites with the lambdoid suture at the **lambda**, which marks in the adult the position of the posterior fontanelle of the fœtus. Anteriorly it terminates by joining the transverse suture which separates the frontal bone

anteriorly from the parietals posteriorly; this latter is called the **coronal suture**, and the point of junction between the sagittal and coronal sutures is known as the **bregma**; this corresponds in position to the anterior fontanelle of the fœtus. The summit of the vault of the calvaria corresponds to a variable point in the line of the sagittal suture, and is named the **vertex**. The **coronal suture** is less denticulated centrally than laterally. Occasionally there is a persistence of the suture (**metopic**) which unites the two halves of the frontal bone; under these conditions the line of the sagittal suture is carried forward to the fronto-nasal suture, and a skull displaying this peculiarity is described as **metopic**. Behind the coronal suture may occasionally be seen the **post-coronal depression**, and in some instances the vault of the calvaria forms a broad, slightly elevated crest along the line of the sagittal suture. On either side the temporal ridges can be seen curving over the lateral and superior aspects of the parietal bones. As the lower of these crosses the coronal suture in front it marks a spot known as the **stephanion**, useful as affording a fixed point from which to estimate the bi-stephanic diameter. The interval between the temporal ridges on either side will vary according to the form of the skull and the development of the temporal muscle. In this view of the calvaria a small part of the lambdoid suture on either side of the lambda is visible posteriorly.

Basis Cranii Externa (Norma Basalis).

The external or inferior aspect of the base of the cranium—*i.e.* the skull without the mandible—includes a description of the under surfaces of the **skeleton of the face** (**cranium viscerale**) and the **cranium** (**cranium cerebrale**). The former includes the **hard palate** formed by the maxillæ and palate bones, the **superior alveolar arch**, and the **bodies of the maxillæ** as seen from below; whilst laterally, and united with the bodies of the maxillæ, the **zygomatic bones** are displayed, curving backwards to form the anterior halves of the **zygomatic arches**. In the median plane, passing from the upper surface of the hard palate, is the osseous septum of the nose, here formed by the vomer, which is united above to the under surface of the body of the sphenoid.

The under surface of the cranium is pierced by the **foramen occipitale magnum** for the transmission of the spinal medulla and its membranes. In front of this a stout bar of bone extends forwards in the median plane, formed by the union of the body of the sphenoid in front with the basilar part of the occipital bone behind. In adult skulls all trace of the fusion of these two bones has disappeared; when union is incomplete, it indicates that the skull is that of a person below the age of twenty-five. The sphenoid comprises that part of the calvaria which forms the roof and sides of the apertures which lie on either side of the nasal septum above the hard palate—the **choanæ**. Laterally the under surfaces of the great wings of the sphenoid extend as far forward as the posterior border of the **inferior orbital fissure**; whilst posteriorly they reach as far as the **angular spine**, lateral to which the speno-squamosal suture, separating the great wing of the sphenoid from the squamous portion of the temporal, curves forwards and upwards, medial to the tuberculum articulare, to reach the floor of the temporal fossa, along which its course has been already traced (p. 168). On a level with the front of the foramen magnum the **jugular process** of the occipital bone forms an irregular curved border, which sweeps laterally to terminate at a point just medial to the root of the styloid process. Here, in line with the speno-squamosal suture, from which, however, it is separated by a considerable interval, its extremity turns backwards, and may be traced at first medial to, and then turning upwards, behind the mastoid process of the temporal bone, separated from this latter by the occipito-mastoid suture. The bone behind the foramen magnum, which is included between the two occipito-mastoid sutures, comprises the **nuchal surface** of the squamous portion of the occipital bone, an area which is limited behind by the **superior nuchal line**, which separates it from the occipital surface of the same bone. The remaining portions of the base of the calvaria, as at present exposed, are formed by the **squamous** and **tympanic portions** of the **temporal bone**, together with the **petro-mastoid part** of the same bone, the latter of which is wedged in between the great wing of

FIG. 171.—INFERIOR SURFACE OF BASE OF SKULL.

the sphenoid in front and the occipital bone behind. Stretching forwards from the squamous part of the temporal in front is seen the **zygomatic process** which, by its union with the zygomatic bone, completes the formation of the zygomatic arch.

Palatum Durum.—Studying next the various parts in detail, the **hard palate** may be first examined. Of horse-shoe shape as a rule, it presents many varieties of outline and size. Formed by the **palatine processes** of the maxillæ in front and the **horizontal parts** of the palate bones behind, its circumference in front and at the sides corresponds to the **superior alveolar arch**, in which are embedded the sixteen teeth of the two maxillæ; posteriorly the edge of the hard palate is thin, presenting in the median plane a pointed process, the **posterior nasal spine**, on either side of which the posterior free border is sharp and lunated. The vault of the palate, which is concave from side to side, and from before backwards, varies in depth according to the projection and development of the alveolar processes. When the teeth are shed and the alveoli are absorbed, the palate becomes shallow and flat. Running throughout its entire length in the median plane is the **median palatine suture**, which separates the palatine processes of the maxillæ in front and the horizontal parts of the palate bones behind. A little behind the central incisor teeth, and in the line of this suture, is a little pit, the **foramen incisivum**. At the bottom of this may be seen the openings of some small canals, varying in number from one to four; these are usually described as arranged in two pairs, the one pair placed side by side, the other lying in the median plane in front and behind. The former are called the **foramina of Stenson**, and transmit the terminal twigs of the greater palatine arteries which ascend to reach the nasal cavities. The latter, called the **foramina of Scarpa**, open, the anterior into the left, the posterior into the right nasal cavity, and afford passage for the fine filaments of the left and right naso-palatine nerves, respectively. About half an inch (12 mm.) in front of the posterior nasal spine the median palatine suture is crossed at right angles by the **transverse palatine suture**. This, which indicates the line of union of the palatine processes of the maxillæ with the horizontal parts of the palate bones, passes transversely laterally on either side until it reaches the medial aspect of the base of the alveolar process, along which it turns backward, to disappear within the **foramen palatinum majus** (**greater palatine foramen**), the aperture of which lies just medial to the root of the *dens serotinus* (wisdom molar). Through this there pass the greater palatine artery and the large posterior palatine nerve. Leading from this foramen is a groove which curves forward immediately to the medial side of the alveolar arch; not infrequently the medial edge of this groove forms a thin and sharp ridge on the surface of the palate. In this groove are lodged the afore-mentioned vessels and nerves. The surface of the palate in front of the transverse suture is rough, pitted for the palatine glands, and pierced by numerous small vascular foramina; the part of the palate behind the suture, formed by the under surface of the horizontal part of the palate bone, is much smoother. From this there rises, just posterior to the greater palatine foramen, a thin sharp crest, which curves medially immediately in front of the posterior free edge; to this are attached some of the tendinous fibres of the tensor veli palatini muscle.

Pterygoid Processes.—Buttressed against the posterior extremities of the alveolar arch are the pterygoid processes of the sphenoid. If carefully examined, these will be seen not to lie in actual contact with the maxillæ, but to be separated from them by the triangular wedge-shaped **pyramidal processes** of the palate bones. It is these latter which are pierced by the **foramina palatina minora** (**lesser palatine canals**), which lie just behind the greater palatine foramen, and through which pass the lesser palatine nerves. As here displayed, the **pterygoid processes** of the sphenoid lie on either side of the opening of the choanæ (O.T. posterior nares); each consists of two **laminæ**, a **medial** and a **lateral**; the latter is the broader, and is directed backwards and slightly laterally. Its lateral surface has been already studied in connexion with the infra-temporal fossa (p. 168). Medially it is separated from the medial pterygoid lamina by the **pterygoid fossa**, wherein is lodged a considerable part of the internal pterygoid muscle. The floor of the fossa is formed in greater part by the coalescence of the two pterygoid laminæ; but at the level of

the hard palate the pyramidal process of the palate bone appears wedged in between the two plates, and so enters into the formation of the floor of the pterygoid fossa. The medial pterygoid lamina separates the nasal cavity from the pterygoid fossa; to the posterior edge of the medial pterygoid lamina are attached the pharyngeal aponeurosis, the superior constrictor of the pharynx, and the pharyngopalatinus muscle. Above, the posterior border of this plate is channelled to form the small **fossa scaphoidea** (**scaphoid fossa**), which curves laterally over the summit of the pterygoid fossa, and furnishes a surface for the origin of the tensor veli palatini muscle. The sharp medial margin of this fossa, continuous below with the posterior border of the medial pterygoid lamina, extends upwards, and on either side of the body of the sphenoid forms a blunt pointed process, the **pterygoid tubercle**, which extends backwards towards the apex of the petrous part of the temporal bone. Just lateral to this, and concealed by it, is the posterior extremity of the **canalis pterygoideus**, through which pass the artery and nerve of the canal. The medial surface of the medial pterygoid lamina is directed towards the nasal cavity. Superiorly this surface curves medially to meet the inferior surface of the body of the sphenoid, forming on either side a lipped edge, the **vaginal process**, between which the alæ of the vomer, which here forms the nasal septum, are wedged. Between the two a small interval, however, is occasionally left, which forms on either side the **basi-pharyngeal canal**. A little lateral to the line of union of the vaginal process with the vomer is the opening of the **pharyngeal canal**. This lies between the inferior surface of the vaginal process and the sphenoidal process of the palate bone, which here articulates with the inferior surface of the body of the sphenoid. The pharyngeal branch of the spheno-palatine ganglion and the pterygo-palatine artery pass through this canal. Inferiorly the pterygoid processes project below the level of the hard palate. The medial plate ends in a slender recurved process, called the **hamulus pterygoideus**, which turns backwards and laterally (this is frequently broken off in skulls which have been roughly handled). It reaches as low as the level of the alveolar margin, and lies just within and behind the posterior extremity of the alveolar process. It can readily be felt in the living by placing the finger against the soft palate behind and just within the gum around the root of the dens serotinus (O.T. wisdom tooth). On the front of and below this process the tendon of the tensor veli palatini muscle glides in a groove.

The **choanæ** (O.T. **posterior nares**) lie between the two pterygoid processes. Of a shape much resembling two Gothic windows, their bases or inferior boundaries are formed by the horizontal part of the palate bone. Laterally they are bounded by the medial surfaces of the medial pterygoid laminae, whilst above, the lateral side of the arch is formed by the vaginal processes of the same laminae; medially they are separated by the thin vertical posterior border of the vomer, whilst above the everted alæ of the same bone form the medial sides of the arch. The plane of these apertures is not vertical but oblique, corresponding usually to a line drawn from the bregma above through the last molar tooth of the upper jaw below. Their size varies considerably, but the height is usually equal to twice the width.

The region of the cranium which lies lateral to the maxilla and lateral pterygoid lamina corresponds to the **infra-temporal fossa**, which has been already described, as it is seen from the side (*Lateral Aspect of the Skull*, p. 168). Viewed from below, the infra-temporal fossa is bounded in front by the infra-temporal surface of the body of the maxilla and the medial surface of the zygomatic bone. The roof, which is traversed by the spheno-squamosal suture, is formed in front by the inferior surface of the great wing of the sphenoid, and behind by a small triangular surface of the under side of the squamous part of the temporal bone, immediately in front of the tuberculum articulare.

Circumscribed laterally and behind by the anterior root of the zygoma, which curves forward to become continuous in front with the infra-temporal crest crossing the lateral surface of the great wing of the sphenoid, the roof of the fossa is separated from its anterior wall by the **inferior orbital fissure**, which is so inclined that with its fellow of the opposite side it forms an angle of 90°. Superiorly the infra-temporal fossa communicates freely with the temporal fossa medial to the

zygomatic arch, though the student must bear in mind the fact that when the mandible is in position the lateral limits of the space are very much reduced (p. 168).

The under surface of the great wing of the sphenoid is here V-shaped. The angle corresponds to the spine, the lateral limb to the speno-squamosal suture, whilst the medial limb corresponds to a narrow cleft, the *fissura speno-petrosa*, which separates it from the petrous portion of the temporal bone, to which it is united in the recent condition by a synchondrosis. Along the line of this latter fissure the edges of the adjacent bones (sphenoid and petrous part of the temporal) are bevelled so as to form a groove, which extends from the root of the medial pterygoid lamina medially, to the medial side of the base of the angular spine laterally, where the groove ends by entering an osseous canal. In the groove (*sulcus tubæ auditivæ*) the cartilaginous part of the **auditory tube** is lodged, whilst the osseous canal includes the bony part of the same tube, together with the tensor tympani muscle, which is lodged in a separate compartment immediately above it. The anterior extremity of the cartilaginous part of the auditory tube is supported by the posterior edge of the medial pterygoid lamina, which is often notched for its reception. Between the root of the lateral pterygoid lamina and the angular spine there are two foramina which lie immediately in front of the *sulcus tubæ auditivæ*. Of these the larger and anterior is the **foramen ovale**, through which pass the motor root and mandibular division of the trigeminal nerve, together with the accessory meningeal artery. The smaller, which, from its position immediately in front of the angular spine, is called the **foramen spinosum**, transmits the middle meningeal artery and vein, and sympathetic plexus surrounding the artery. The lesser superficial petrosal nerve here passes through the base of the skull to join the otic ganglion either through a small foramen (*canalis innominatus*) placed between the foramen ovale and the foramen spinosum, or through the foramen ovale or through the speno-petrosal fissure. The position of the suture between the basi-occipital and basi-sphenoid corresponds to a line connecting the tips of the pterygoid tubercles at the root of the medial pterygoid laminae.

Occasionally in the centre of this line there is a small pit with a foramen leading from it. This probably represents the lower end of the cranio-pharyngeal canal.

The under surface of the basilar part of the occipital bone (**basi-occipital**) stretches between the body of the sphenoid in front and the anterior margin of the foramen magnum behind; projecting from its centre is a slight elevation, the **pharyngeal tubercle**, to which the pharyngeal raphe, together with the central part of the anterior atlanto-occipital membrane, is attached. It should be noted, that when the atlas is in position the pharyngeal tubercle lies in line with the tubercle on the anterior arch of that bone. Curving laterally and backwards from the pharyngeal tubercle, on either side, is an irregular ridge (*crista muscularis*), in front and behind which are attached the longus capitis and rectus capitis anterior muscles. On either side of the basi-occipital, in front, there is an irregular opening of variable size; this is placed between the root of the pterygoid process anteriorly, the apex of the petrous portion of the temporal bone laterally, and the lateral edge of the basi-occipital and basi-sphenoid medially. It is called the **foramen lacerum**. Opening into it in front, just lateral to the pterygoid tubercle, is the **pterygoid canal**, whilst, in correspondence with the apex of the petrous part of the temporal, the large orifice of the **carotid canal** may be seen entering it behind and from the lateral side. In the recent condition the lower part of the foramen lacerum is occupied by fibro-cartilage, over the upper surface of which the internal carotid artery and greater superficial petrosal nerve pass to reach their respective foramina, whilst a small meningeal branch of the ascending pharyngeal occasionally enters the cranium through it. Leading laterally from the foramen lacerum in the direction of the angular spine of the sphenoid is the speno-petrosal fissure, which lies at the bottom of the *sulcus tubæ auditivæ*, and disappears from view within the **bony part of the auditory tube**. Passing backwards from the foramen lacerum there is a fissure between the lateral side of the basi-occipital and the posterior and medial border of the petrous part of the temporal bone. This, which is called the **petro-occipital fissure**, opens posteriorly into the jugular foramen. In the recent

condition the fissure is filled up with cartilage. The under surface of the petrous bone included between these two fissures is rough and irregular, and affords attachments near its apex to two small muscles, the levator veli palatini and the tensor tympani. Immediately behind the angular spine the petrous part of the temporal is pierced by a circular hole, the inferior opening of the **canalis caroticus** (carotid canal). This passes upwards, and then turns medially and forwards towards the apex of the bone, where it may again be seen opening into the lateral and upper side of the foramen lacerum. Laterally the wall of the vertical part of this canal, which is usually very thin, separates it from the cavity of the tympanum, as may be seen by holding the skull up to the light and looking into the external acoustic meatus. The carotid canal transmits the internal carotid artery, together with the sympathetic plexus around it. It is noteworthy that the two carotid canals lie in line with the anterior edges of the two external acoustic meatuses.

The **jugular foramen** is an opening of irregular shape and variable size placed between the petrous part of the temporal in front and the jugular process of the occipital bone behind. The former is excavated into a hollow called the **jugular fossa**, which forms a roof to the upper and lateral part of the space, whilst the latter, by a curved edge, either rounded or sharp, constitutes its posterior border. There is often considerable difference in the size of the jugular foramina; that on the right side (with the skull in its normal position) is usually the larger. The foramen is occasionally subdivided into two by spicules of bone which bridge across it. Lodged within the fossa is the bulb of the internal jugular vein, in front of which the inferior petrosal sinus passes down to join the internal jugular vein below the foramen. Effecting an exit between the two veins, in order from before backwards, are the glosso-pharyngeal, vagus, and accessory nerves. Small meningeal branches from the ascending pharyngeal and occipital arteries also enter the foramen. The two jugular foramina lie in line with a line drawn through the centres of the two external acoustic meatuses. Following the direction of a line connecting the angular spine of the sphenoid and the mastoid process of the temporal, and placed immediately lateral to the apertures of the carotid canal and jugular foramen, is the **vaginal process** of the tympanic plate of the temporal bone, the edge of which is sharp and thin, and serves to separate the inferior surface of the petrous part of the temporal from the non-articular part of the mandibular fossa. Springing from this crest immediately lateral to the jugular fossa, and in line with the middle of the external acoustic meatus, is the **styloid process** of the temporal bone. *Its relation to the jugular foramen is of great importance as the internal jugular vein lies close to its medial side.*

Immediately behind the root of the styloid process, medial to and in line with the front of the mastoid process, is the **stylo-mastoid foramen**, which is the inferior aperture of the canalis facialis. Through it the facial nerve passes out and the stylo-mastoid branch of the posterior auricular artery passes in. The medial surface of the mastoid process is deeply grooved at its base for the origin of the posterior belly of the digastric muscle. Medial to this, and running along, just wide of the occipito-mastoid suture, is a shallow groove in which the occipital artery is lodged. Just medial to the stylo-mastoid foramen is the synchondrosis between the extremity of the **jugular process** of the occipital bone and the petrous part of the temporal. The jugular process is a bar of bone which limits the jugular fossa posteriorly and abuts on the occipital condyles medially; its under surface is convex from before backwards and affords attachment to the rectus capitis lateralis muscle. The **occipital condyles** are placed between the jugular processes and the foramen magnum. Limited in front by a rounded thickening which becomes confluent with the anterior border of the foramen magnum, they form by their medial sides the lateral boundaries of that aperture on its anterior half. Laterally they are continuous with the jugular processes, in front of which they overhang a fossa which is pierced behind by the **canalis hypoglossi**, through which passes the hypoglossal nerve, together with a small vein and occasionally a small meningeal branch derived from the ascending pharyngeal artery.

The **posterior condylic fossæ** are situated just behind the posterior extremities of the condyles. Not infrequently the floor of each is pierced by the **condyloid canal**,

through which the posterior condylic vein emerges. The base of the skull behind the jugular processes and condyles of the occipital bone is formed by the nuchal surface of the squamous part of that bone. Posteriorly this surface is bounded by the **superior nuchal or curved line**, in the centre of which is placed the projecting external occipital protuberance. Laterally the squamous part of occipital bone is separated from the mastoid portion of the temporal bone by the occipito-mastoid suture, which curves backwards and laterally, from the extremity of the jugular process in front, around the base of the mastoid process behind. In front and in the median plane this plate of bone is pierced by the **foramen occipitale magnum**, the anterior half of which has been already seen to lie between the occipital condyles. Usually of oval form, though in some cases it tends to approach the circular, the plane of this opening is inclined downwards and slightly forwards. The extreme anterior edge of the foramen is sometimes called the **basion**, whilst the extreme posterior margin is termed the **opisthion**. The lower border of the medulla oblongata, where it becomes continuous with the spinal medulla, is lodged within the foramen, together with the meninges which cover it, whilst the vertebral arteries and the spinal portions of the accessory nerves pass upwards through it. The anterior and posterior spinal arteries, some small veins, and the roots of the first cervical nerves, also traverse it from above downwards.

The student will, no doubt, experience considerable difficulty in bearing in mind the relative positions of the various foramina and processes which he has studied on the under surface of the base of the skull.

If a line be drawn on either side from the incisive foramen in front, through the stylo-mastoid foramina posteriorly, it will be found to cut or pass near to the following objects:—On the hard palate it will lie close to the greater and smaller palatine foramina. It will then pass between the hamulus and the lateral pterygoid lamina, overlying the foramen ovale, the foramen spinosum, the opening of the osseous part of the auditory tube and the angular spine of the sphenoid; behind this it will cut through the root of the styloid process and define laterally the limits of the jugular fossa. After passing through the stylo-mastoid foramen, if the line be prolonged backwards it will usually be found to pass over the mastoid foramen in the occipito-mastoid suture. Another line of much value is one drawn across the base of the skull from the centre of one external acoustic meatus to the other. This will be found to pass through the root of the styloid process, the jugular foramen, the hypoglossal canal; it then crosses the front of the occipital condyles, and corresponds with the anterior edge of the foramen magnum.

A line which may be found useful is one drawn from the stylo-mastoid foramen of one side to the greater palatine foramen of the opposite side. This will be seen to overlie, from behind forwards, the lateral part of the jugular foramen and the inferior opening of the carotid canal. The line indicates the direction of the carotid canal, and cuts the foramen lacerum anteriorly; in front of this it usually corresponds to the position of the posterior aperture of the pharyngeal canal.

Mandible and Atlas in Position.—The examination of the base of the skull is incomplete unless the student examines it with the mandible and atlas in position. The relation of the ramus of the mandible to the infra-temporal fossa has been already sufficiently studied (p. 169); one or two points, however, may be emphasised. The **angular spine** of the sphenoid lies just medial to the condyle of the mandible when that structure is in position in the articular part of the mandibular fossa, and it is noteworthy that immediately to the medial side of the angular spine is the commencement of the osseous part of the auditory tube. The root of the **styloid process** occupies the centre of the interval between the mandibular ramus and the front of the mastoid process.

Anteriorly the arcade formed by the **body** of the mandible adds greatly to the depth of the hard palate. In this space are lodged the tongue and the structures which form the floor of the mouth. The medial surface of each side of the body of the mandible is traversed by the **mylo-hyoid line**, which commences posteriorly just behind the root of the last molar tooth and runs downwards and forwards towards the symphysis in front.

When the atlas is in articulation with the occipital bone it is well to recognise the relation of its **transverse processes** to the surrounding structures. The extremities of these processes lie in line with the ends of the jugular processes of the occipital bone, and thus come to be placed just medial to and immediately below and slightly in front of the tips of the **mastoid processes**. They can thus be easily felt in the living subject. Anteriorly they are separated by a short interval from the **styloid processes**, and the **stylo-mastoid foramina** lie immediately in front and

slightly to the lateral side of their extremities. The student will note that there is no hole in the jugular process of the occipital bone corresponding to the arterial foramen in the transverse process of the atlas through which the vertebral artery passes. The course of this vessel over the upper surface of the posterior arch behind the superior articular processes of the atlas will be seen to coincide with the posterior condylic fossæ and the margins of the foramen magnum immediately medial thereto, where a slight grooving of the edge often indicates the course of the artery. In front the anterior tubercle of the atlas falls in line with the **pharyngeal tubercle** on the under surface of the basi-occipital, and the student must not overlook the fact that the anterior surface of the cervical column does not coincide with the anterior margin of the foramen magnum, but lies nearly half an inch in front of that, in a frontal plane passing immediately in front of the external acoustic meatuses. Behind, the upper surface of the posterior arch of the atlas overlaps the posterior margin of the foramen magnum, and it is by the apposition of these two surfaces that extension is checked at the occipito-atlantal articulation.

THE SKULL IN SECTION.

By the removal of the skull-cap the cerebral aspect of the cranial cavity is exposed. The deep surface of the cranial vault is grooved medially for the **superior sagittal sinus**, on either side of which are seen numerous depressions for the lodgment of arachnoidal granulations. On holding the bone up to the light, the floor of these little hollows is oftentimes seen to be very thin. A short distance in front of the lambda, and on either side of the sagittal suture, are the cerebral openings of the **parietal foramina**. The inner tables of the frontal and parietal bones are grooved for the meningeal arteries. The principal branch of the **middle meningeal** runs more or less parallel to and at a variable distance behind the line of the coronal suture. Along the bottom of these grooves small foramina may be seen for the passage of nutrient arteries to the bone, and the floor of the sagittal sinus is likewise pierced by small apertures for the transmission of veins.

Basis Cranii Interna.

Cranial Fossæ.—The upper surface of the base of the skull is divided into three fossæ, of which the cerebrum occupies the anterior and middle, whilst in the posterior is lodged the cerebellum.

The **anterior fossa** is defined posteriorly by the sharp, thin edge of the small wings of the sphenoid, which curve laterally and slightly upwards, as well as backwards, to reach the region of the **pteryon** laterally. The floor is formed from before backwards, in the median plane, by the superior surface of the ethmoid and the anterior part of the body of the sphenoid; laterally it is constituted by the orbital parts of the frontal and the small wings of the sphenoid. On these the inferior surface of the frontal lobes of the cerebrum rests. In front the fossa is divided in the median plane by the **frontal crest**, to which the falx cerebri is attached. This is confluent below with the anterior part of the **crista galli**, from which, however, it is separated by the **foramen cæcum**, which usually transmits a small vein from the nose. On either side of the crista galli there are grooves which vary considerably in depth and width: therein are lodged the olfactory lobes. The floor and sides of the groove are pierced by numerous foramina; of these the largest number transmit the olfactory nerves to the nasal cavity. In front an elongated slit, placed on either side of the crista, affords a passage to the nose for the anterior ethmoidal branch of the naso-ciliary nerve and a small branch of the anterior ethmoidal artery which accompanies it. To the lateral side of the olfactory groove and the cribriform plate, the anterior fossæ communicate on either side by means of the two **ethmoidal foramina** with the cavities of the orbits. The anterior foramen transmits the anterior ethmoidal nerve and the anterior ethmoidal artery; the posterior affords passage to the posterior ethmoidal artery and nerves (O.T. spheno-ethmoidal nerve of Luschka). Lateral to the olfactory groove, the floor of the fossa, which here corresponds to the roof of the orbit, is very thin, as may

be seen by holding the skull up to the light; it is convex from side to side, and bears the impress of the gyri of the under surface of the frontal lobes of the cerebrum, which rest upon it. In front and at the side there are a number of vascular grooves for the branches of the anterior and middle meningeal arteries respectively.

The **middle fossa**, which in form may be compared to the wings of a bird united by the body, is bounded in front by the curved thin posterior edge of the small wings of the sphenoid; posteriorly, by the line of attachment of the tentorium cerebelli, extending from the **posterior clinoid process** along the superior angle of the petrous portion of the temporal bone. The median part of the fossa, which is narrow, corresponds to the **sella turcica** and the **tuberculum sellæ** of the **sphenoid**. It is limited anteriorly by a line connecting the anterior margins of the two optic foramina, and is overhung behind by the **dorsum sellæ**. In this area are lodged the structures which lie within the **interpeduncular fossa** on the base of the brain. The floor of the lateral parts of the fossa on each side is formed by the great wing of the sphenoid in front, the squamous part of the temporal bone to the lateral side, and the superior surface of the petrous part of the temporal behind. In the hollows so formed the temporal lobes of the cerebrum are lodged. On either side of the **tuberculum sellæ** are seen the **optic foramina**; these pass into the orbital cavities and transmit the optic nerves and ophthalmic arteries. Immediately behind these openings the anterior and middle clinoid processes are sometimes united, so as to enclose a foramen. Through this the internal carotid artery passes upwards. Leading backwards from this, along the side of the body of the sphenoid, is the **carotid groove**, which turns downwards near the apex of the petrous part of the temporal, to become continuous with the **carotid canal**, which here opens on the posterior wall of an irregular aperture, placed between the side of the body of the sphenoid and the summit of the petrous part of the temporal, called the **foramen lacerum**. Through the medial angle of this opening the carotid artery accompanied by its plexus of veins and sympathetic nerves passes upwards. Running through the fibrous tissue, which in life blocks up this opening, the greater superficial petrosal nerve coming from the hiatus facialis passes downwards and forwards to reach the posterior orifice of the **canalis pterygoideus**, which is placed on the anterior and inferior border of the foramen lacerum. A small meningeal branch of the ascending pharyngeal artery also passes upwards through this foramen. In front and to the lateral side of the foramen lacerum, and separated from it by a narrow bar of bone, is the **foramen ovale**; through this pass both roots of the mandibular nerve, the accessory meningeal artery, and some emissary veins. Somewhat lateral and posterior to this is the **foramen spinosum** for the transmission of the middle meningeal vessels, together with a recurrent branch (*nervus spinosus*) from the mandibular nerve. Leading from the lateral extremity of the foramen lacerum there is a groove which passes laterally, backwards, and slightly upwards on the superior surface of the petrous part of the temporal to end in the **hiatus facialis** (a cleft opening into the **canalis facialis**), which gives passage to the greater superficial petrosal branch derived from the ganglion geniculi on the facial nerve, together with the small petrosal branch of the middle meningeal artery. Just lateral to the hiatus facialis there is another small foramen for the transmission of the lesser superficial petrosal nerve. Overhung by the posterior border of the lesser wing of the sphenoid is the **superior orbital fissure**, the cleft which separates the small from the great wings of the sphenoid, and which opens anteriorly into the hollow of the orbit; through this pass the oculomotor, trochlear, ophthalmic division of the trigeminal, and abducent nerves, together with the ophthalmic veins as well as the sympathetic filament to the ciliary ganglion and the small orbital branch of the middle meningeal artery. Just below its medial extremity is the **foramen rotundum** for the passage of the maxillary nerve to the pterygo-palatine fossa. Behind this, and between it and the foramen ovale, the **foramen Vesalii** may occasionally be seen, through which a vein passes to reach the pterygoid plexus.

The lateral parts of the middle fossa are moulded in conformity with the gyri of the temporal lobes, but towards its medial part the splitting of the dura mater in the region of the cavernous sinus serves to separate the cranial base from the under surface of the cerebrum. As may be seen by transmitted light,

FIG. 172.—BASE OF THE SKULL SEEN FROM ABOVE.

The frontal and occipital bones are coloured red ; the ethmoidal and temporal bones, blue ; the parietal, orange ; and the sphenoid is left uncoloured.

37. Anterior cranial fossa for lodgment of frontal lobes of the brain.
38. Cribriform plate of ethmoid.
39. Crista galli of ethmoid.
40. Foramen cæcum.
41. Crest for attachment of falx cerebri.

the floor of the lateral parts of the fossa is thin as it overlies the **temporal, infra-temporal, and mandibular fossæ**. The grooves for the lodgment of the branches of the middle meningeal artery leading from the foramen spinosum are readily seen; one, coursing backwards a little below the line of the squamoso-parietal suture, is specially well marked. Amongst other features may be noticed the depression for the lodgment of the **semilunar ganglion** overlying the apex of the petrous part of the temporal; behind and to the lateral side of the hiatus facialis, the **arcuate eminence**, indicating the position of the superior semicircular canal; and immediately anterior and slightly to the lateral side of this the **tegmen tympani**, which roofs in the cavity of the tympanum, the thinness of which can readily be demonstrated if light be allowed to fall through the external acoustic meatus.

The **posterior fossa** is larger and deeper than the others. In front it is limited by a line on either side leading backwards and laterally from each **posterior clinoid process** along the superior border of the petrous part of the temporal bone, where laterally and posteriorly it becomes confluent with the superior lip of the transverse groove for the **transverse sinus**, ending posteriorly in the middle line at the **internal occipital protuberance**. Along the line thus indicated the process of dura mater called the **tentorium cerebelli**, which roofs in the posterior fossa, is attached. The floor of the fossa, in which the cerebellar lobes, the pons, and medulla oblongata are lodged, is formed by the petrous and mastoid portions of the temporal bone, with part of the body of the sphenoid and the basilar portion of the occipital bone wedged in between them. Above the mastoid part of the temporal a small part of the mastoid angle of the parietal enters into the constitution of the lateral wall of the fossa. Behind and within these the lateral parts and inferior portions of the squamous part of the occipital complete the floor. In the median plane the floor of the fossa is pierced by the **foramen magnum**, in which lies the lower part of the medulla oblongata, together with its membranes, and through which pass upwards the vertebral arteries and the accessory nerves. On either side of the foramen magnum, and a little in front of a transverse line passing through its centre, is the opening of the **canalis hypoglossi** for the passage of the hypoglossal nerve, a small meningeal branch from the ascending pharyngeal artery and an emissary vein. Overhanging the opening of the canalis hypoglossi there is a thickened rounded bridge of bone, to the lateral side of which is placed the irregular opening of the **jugular foramen**. The size of this is apt to vary on the two sides, and the lumen is frequently subdivided by a spicule of bone which runs across it; the posterior and lateral rounded part of the foramen is occupied by the transverse sinus, which here joins the internal jugular vein. A meningeal branch from the ascending pharyngeal or occipital artery also enters the skull through this compartment. The anterior and medial part of the foramen is confluent with the groove for the **inferior petrosal sinus**, which turns downwards in front of the spicule above referred to. The interval between the portions of the foramen occupied by the two veins allows the transmission of the glosso-pharyngeal, vagus, and accessory nerves in this order from before backwards. About a quarter of an inch above and to the lateral side of the anterior part of the foramen jugulare the posterior surface of the petrous portion of the temporal bone is pierced by the **internal acoustic meatus**, through which the facial and acoustic nerves, together with the nervus intermedius, and the auditory branch of the basilar artery, leave the cranial cavity. Behind the jugular foramen and close to the margin of the foramen magnum the opening of the **canalis condyloideus**, when present, may be seen. This gives passage to a vein which joins the vertebral vein inferiorly. The inner aperture of the **mastoid foramen** is noticed opening into the groove for the transverse sinus, a little below the level of the superior border of the petrous part of the temporal. Through it passes an emissary vein which joins the occipital vein laterally; the mastoid branch of the occipital artery also enters the cranial cavity through this foramen.

The posterior fossa is divided into two halves posteriorly by the **internal occipital crest**, to which the falx cerebelli is attached, the floors of the hollows on either side of which are often exceedingly thin and are for the lodgment of the hemispheres of the cerebellum. The grooves for the following blood sinuses are usually distinct—the **superior petrosal** running along the superior angle of the petrous part of the

temporal, the **inferior petrosal** lying along the line of suture between the petrous part of the temporal and the basilar part of the occipital bone; the **occipital sinus** grooving the internal occipital crest; and the **transverse sinus** curving forwards and laterally from the internal occipital protuberance, across the cerebral surface of the squamous part of the occipital, to reach the mastoid angle of the parietal bone, in front of which it turns downwards and medially to reach the jugular foramen, describing a sigmoid curve, and grooving deeply the inner surface of the mastoid and posterior aspect of the petrous portions of the temporal bone. Before it terminates at the jugular foramen it again reaches the occipital bone and channels the upper surface of the jugular process of that bone. Slight grooves for meningeal arteries are also seen—some pass upwards, whilst others turn downwards and are occupied by branches from the posterior offsets of the middle meningeal arteries.

Median Sagittal Section of the Skull.

Such a section should be made a little to one or other side of the median plane, so as to pass through the nasal cavity lateral to the septum; one-half will then display the nasal septum in position, whilst in the other the lateral wall of the nasal cavity of that side will be exposed.

The form of the cranial cavity is, of course, subject to many variations dependent on individual and racial peculiarities. The following details are, however, worthy of note. The posterior border of the foramen magnum (**opisthion**), and consequently the floor of the posterior cranial fossa, occupies the same horizontal plane as the hard palate. The anterior border of the foramen magnum (**basion**) lies a little higher, so that the plane of the foramen is, in the higher races at least, oblique, and is directed downwards and slightly forwards. From the basion a line passing upwards and forwards to reach the suture between the sphenoid and ethmoid passes through the **basi-cranial axis** formed by the basi-occipital, the basi-sphenoid, and the presphenoid. The basi-cranial axis is wedge-shaped on section posteriorly, whilst anteriorly it is of considerable width, and has within it the large sphenoidal air sinus. Its upper surface leads upwards and forwards with a varying degree of obliquity from the basion to the overhanging edge of the dorsum sellæ, in front of which the **sella tuncica**, the floor of which is quite thin, is well seen in the section.

From the tuberculum sellæ the floor of the anterior fossa follows a more or less horizontal direction, corresponding pretty closely to the level of the axis of the orbital cavity. The roof of the orbit is seen to bulge upwards to a considerable extent into the floor of the anterior fossa; whilst the floor of the middle fossa sinks to a level corresponding to that of the under surface of the basi-cranial axis, where it forms the roof of the choanæ. The maximum length of the skull is measured from the **glabella** (a point between the superciliary arches) to the occipital point posteriorly. It is noteworthy that the maximum occipital point does not necessarily correspond to the external occipital protuberance (**inion**). The greatest vertical height usually corresponds to the distance from the **basion** to the **bregma** (point of union of the sagittal with the coronal suture), though to this rule there are many exceptions. On looking into the posterior fossa the hypoglossal canals and jugular foramina and the internal acoustic meatus are seen in line, sloping from below upwards. The **internal acoustic meatus** lies in a vertical plane, passing through the basion. The grooves for the middle meningeal artery and its branches are very obvious. The anterior groove curves forwards and laterally, and reaching the cerebral surface of the pterion, passes towards the vertex at a variable distance behind and more or less parallel to the coronal suture. From this groove pass forwards across the suture to reach the frontal bone. Another groove curves upwards and backwards a little below the line of the parieto-squamosal suture. From this an upwardly directed branch radiates on the cerebral surface of the parietal bone, in the region of the parietal tuberosity, whilst a lower branch passes backwards some little distance above the lambdoid suture, and gives offsets which curve downwards and medially over the cerebral surface of the squama occipitalis of the occipital bone.

Cavum Nasi.—In the section through the **nasal cavity** the structures which form its **lateral wall** can now be studied. These are—the nasal bone; the frontal process of the maxilla; the lacrimal bone; the labyrinth of the ethmoid, comprising the superior and middle conchal bones; the perpendicular part of the palate bone; the inferior conchal bone; and the medial surface of the medial pterygoid lamina.

The **roof** as seen in the section is formed by the nasal and frontal bones, the cribriform plate of the ethmoid, the body of the sphenoid and the sphenoidal conchæ, the sphenoidal process of the palate and the ala of the vomer. The **floor**, which is

FIG. 173.—MEDIAL ASPECT OF THE LEFT HALF OF THE SKULL SAGITTALLY DIVIDED.

The frontal, maxillary, and sphenoid bones are coloured red ; the parietal nasal and palate bones, blue ; the basilar part of occipital, yellow, and squama occipitalis, purple. The ethmoid and inferior concha, together with the left ala of the vomer, are left uncoloured.

22. Palatine process of maxilla.	
23. Horizontal part of palate bone.	

nearly horizontal from before backwards, is formed by the palatine processes of the maxillæ and palate bones. On sagittal section the **nasal cavity** appears somewhat triangular in shape with the angles cut off; the base corresponds to the floor; the apertura piriformis and choana to the truncated anterior and posterior

angles, respectively; the superior angle is cut off by the cribriform plate; whilst the sides correspond to the frontal and nasal bones anteriorly, and the sphenoidal conchæ, sphenoidal process of the palate, and the ala of the vomer posteriorly. The cavity is therefore deep towards its middle, but gradually becomes shallower in front and behind where the piriform aperture and choana are situated. The piriform opening of the **nose**, which is of half-heart shape, is larger than that of the **choanæ** (O.T. **posterior nares**), and is directed forwards and downwards; the choanæ are of rhomboidal form, and slope backwards and downwards. The **inferior meatus** is the channel which is overhung by the inferior concha, and its floor is formed by the side-to-side concavity of the upper surface of the hard palate. Opening into it above, under cover of the anterior part of the inferior concha, is the **canal** for the **naso-lacrima duct**; whilst its floor is pierced in front near the middle line by the **canalis incisivus**. The **middle meatus** is the hollow between the middle and inferior conchæ; it slopes from above downwards and backwards, and is overhung by the free curved edge of the middle conchæ, beneath which there is a passage called the **infundibulum**, leading upwards and forwards to open superiorly into the frontal sinus, as well as into some of the anterior ethmoidal cells. Under cover of the centre of the middle concha and continuous with the infundibulum in front there is a curved groove, the **hiatus semilunaris**, into which open one or more orifices from the **maxillary sinus**. Above this groove there is a rounded eminence, the **bullæ ethmoidalis**, overlying the middle ethmoidal cells, which usually open on its surface. The **superior meatus**, about half the length of the middle meatus, is placed between the superior and middle conchæ in the posterior and upper part of the cavity; it receives the openings of the **posterior ethmoidal cells**. Near its posterior extremity the **spheno-palatine foramen** pierces its lateral wall, and brings it in relation with the pterygo-palatine fossa. The **sphenoidal sinus** opens on the roof of the nose, above the level of the superior conchæ, into a depression called the **spheno-ethmoidal recess**.

Septum Nasi.—If the opposite half of the section in which the osseous **nasal septum** is retained be now studied, it will be seen to be formed by the crests of the maxillary and palate bones below, on which rests the vomer, the posterior border of which being free, forms the posterior edge of the nasal septum, which slopes obliquely upwards and backwards towards the inferior surface of the body of the sphenoid. Here the vomer articulates with the rostrum of the sphenoid. In front of this the vomer articulates with the perpendicular part of the ethmoid, and between them anteriorly there is an angular recess into which the cartilaginous septum fits. Superiorly and anteriorly the osseous septum is completed by the articulation of the perpendicular part of the ethmoid with the nasal spine of the frontal, together with the nasal crest formed by the union of the nasal bones; whilst posteriorly and superiorly the perpendicular plate of the ethmoid articulates with the median ethmoidal crest of the sphenoid. In most instances the osseous septum is not perfectly vertical, but is deflected towards one or other side.

Air-sinuses in Connexion with the Nasal Cavities.—Connected with the nasal cavities are a number of air-sinuses. These are found within the body of the sphenoid, the labyrinth of the ethmoid, the orbital process of the palate bone, the body of the maxilla, and the superciliary arch of the frontal bone.

The **sphenoidal sinus**, of variable size, occupies the interior of the body of the sphenoid. In some cases it extends towards the roots of the pterygoid processes. In front it is formed in part by the absorption of the sphenoidal conchæ and is divided up into two cavities by a sagittally placed partition, which, however, is frequently displaced to one or other side. It opens anteriorly into the roof of the nose in the region of the spheno-ethmoidal recess.

The **ethmoidal sinuses** are placed between the lateral aspects of the upper part of the nasal cavities, and the cavities of the orbits, from which they are separated by thin and papery walls. These air-spaces are completed by the articulation of the ethmoid with the maxilla, lacrimal, frontal, sphenoid, and palate bones, and are divided into three groups—an anterior, middle, and posterior. The latter communicates with the superior meatus; the anterior and middle open either independently or in conjunction with the infundibulum into the middle meatus.

The sinus in the orbital process of the **palate bone** either communicates with the sphenoidal sinus, or else assists in closing in some of the posterior ethmoidal cells. Its communication with the nasal cavity is through one or other of these spaces.

The **maxillary sinus** lies to the lateral side of the nasal cavity, occupying the body of the maxilla. Its walls, which are relatively thin, are directed upwards to the orbit, forwards to the face, backwards to the infra-temporal and pterygo-palatine fossæ, and medially to the nose. In the latter situation the perpendicular part

FIG. 174.—THE NASAL SEPTUM AS SEEN FROM THE LEFT SIDE.

The frontal, maxillary, and sphenoid bones are coloured red; the nasal, vomer, and basi-occipital blue; the perpendicular part of the ethmoid and the horizontal part of the palate bone are left uncoloured.

may be deflected to one or other side. They communicate with the nose through a passage called the **infundibulum**, which opens inferiorly into the anterior part of the middle meatus, below the ethmoidal bulla and continuous with the hiatus semilunaris.

The fact should not be overlooked that the air-spaces within the temporal bone, viz., the tympanic cavity and the mastoid air-cells, are brought into communication with the naso-pharynx through the auditory tubes. Further details regarding the air-sinuses and the mode of their growth will be found under the description of the individual bones.

Frontal Sections.

The relations of many parts of the cranium are best displayed in a series of frontal (coronal) sections.

By sawing off a thin slice from the front of the lower part of the frontal bone above, and carrying the section downwards through the medial wall of the orbit and the frontal process of the maxilla, into the piriform aperture below, a number of important relations are revealed (see Fig. 175). In the frontal region the extent and arrangement of the **frontal sinuses** are displayed. The partition between the two sinuses, be it noted, is usually complete and central in position, though it may occasionally be perforated or oblique. The sinuses are hardly ever symmetrical, the right being usually the smaller of the two. (Logan Turner, *Edin. Med. Journ.* 1898.)

The **infundibulum** on either side, leading from the frontal sinus above to the middle

of the palate bone, the uncinat process of the ethmoid, the maxillary process of the inferior concha, and a small part of the lacrimal bone assist in the formation of the thin osseous partition which separates it from the nasal cavity. The floor corresponds to the alveolar border of the maxilla, and differs from the other walls in being stout and thick; it is, however, deeply pitted inferiorly by the alveoli for the teeth. The sinus opens by a narrow orifice in the floor of the hiatus semilunaris into the middle meatus. Occasionally there are two openings.

The **frontal sinuses** lie, one on either side, between the inner and outer tables of the frontal bone over the root of the nose, and extend laterally under the superciliary arches. The partition which separates them is usually central, though it

meatus below, is seen with the middle concha medial to it, and the anterior ethmoidal cells to its lateral side above. If the section passes through the **canal** for the **naso-lacrimal duct** the continuity of that channel leading from the orbit above to the inferior meatus of the nose below is clearly shown. Its medial wall above, by which it is separated from the cavity of the nose, is formed by the thin lacrimal bone; below, it passes under cover of the inferior concha to open into the anterior part of the inferior meatus. It is

FIG. 175.—PART OF THE FRONTAL, NASAL, AND MAXILLARY BONES REMOVED IN ORDER TO DISPLAY THE RELATION OF THE VARIOUS CAVITIES EXPOSED.

The frontal and maxillary bones, where cut, are coloured blue; the ethmoid and the inferior concha red; the lacrimal and vomer yellow.

	13. Anterior nasal spine.

separated from the maxillary sinus laterally by a thin lamina of bone. The cavity of the maxillary sinus is seen to extend upwards and forwards so as to pass over the lateral side as well as slightly in front of the canal for the naso-lacrimal duct.

The lower margins of the middle conchæ lie pretty nearly on a level with the most dependent parts of the orbital margins, whilst the lower borders of the inferior conchæ are placed a little above the lower margin of the piriform opening on a level with the lowest point of the zygomatico-maxillary suture.

Such a section will reveal any deflection of the nasal septum should it exist, and will also show that but a narrow cleft separates the upper part of the septum, on either side, from the medial surface of the superior conchæ.

The next section (Fig. 176) passes through the anterior part of the temporal fossa just

behind the zygomatic process of the frontal bone above; inferiorly it passes through the alveolar process of the maxilla in the interval between the first and second molar teeth.

FIG. 176.—FRONTAL SECTION PASSING INFERIORLY THROUGH THE INTERVAL BETWEEN THE FIRST AND SECOND MOLAR TEETH.

The frontal and maxillary bones, where cut, are coloured blue; the ethmoid, inferior concha, and zygomatics red; the vomer yellow.

14. Maxillary sinus.
15. Canal for the anterior alveolar nerve and vessels exposed.
16. Inferior concha.
17. Inferior meatus of nose.
18. Alveolar process of maxilla.
19. Groove for posterior palatine nerve and greater palatine vessels.
20. Palatine process of maxilla.
21. Maxillary crest forming part of nasal septum.
22. Vomer forming part of nasal septum.

The **anterior cranial fossa** is deepest in its centre, where its floor is formed by the cribriform plate of the ethmoid; this corresponds to the level of the zygomatico-frontal suture laterally. On either side the floor of the fossa bulges upwards, owing to the arching of the roof of the orbit. Of the orbital walls, the lateral is the thickest and stoutest; the superior, medial, and inferior walls, which separate the orbit from the cranial cavity, the ethmoidal cells, and the maxillary sinus, respectively, are all thin. The cavity of the **maxillary sinus** lying to the lateral side of the nasal cavity is well seen. Its roof, which separates it from the orbital cavity, is thin and traversed by the **infraorbital canal**. Its medial wall, with which the inferior concha articulates, is very slender, and forms the lateral walls of both the middle and inferior meatuses of the nose. Its lateral wall is stouter where it arches up to bracket the temporal process of the zygomatic bone. Its floor, which rests upon the superior surface of the alveolar border of the maxilla, sinks below the level of the hard palate. The fangs of the teeth sometimes project into the floor of the cavity.

The **nasal cavities** are narrow above, where they lie between the orbital cavities, from which they are separated by the cells within the labyrinth of the ethmoid. The roof which corresponds to the cribriform plate is narrow, and lies between the septum medially and the labyrinth on either side.

At the level of the orbital floor the nasal cavities expand laterally, the **middle meatus** running longitudinally in the angle formed by the labyrinth of the ethmoid with the body of the maxilla, the nasal cavities expand laterally, the **middle meatus** running longitudinally in the angle formed by the labyrinth of the ethmoid with the body of the maxilla, whilst its floor is formed by the superior surface of the inferior concha.

The **inferior meatus**, much more roomy, runs along under cover of the inferior

concha. Laterally it is related to the maxillary sinus, whilst its floor is formed by the concave superior surface of the hard palate.

The **hard palate** is arched below, whilst its superior surface is concave upwards on either side of the median crest which supports the nasal septum. The sides of the arch below correspond to the medial surfaces of the alveolar processes and fall in line with the lateral walls of the nasal cavities superiorly. The summit of the arch lies a quarter of an inch above the level of the floor of the maxillary sinus.

The next section (Fig. 177) passes through the pterygo-palatine and temporal fossæ inferiorly, and cuts the cranial vault about half an inch in front of the bregma. The floor of the **anterior cranial fossa** is seen to be formed by the upper surface of the body and small wings of the sphenoid, and is almost horizontal. At the median plane the sphenoidal sinuses are exposed, separated by a thin bony partition, on either side of which the openings by which they communicate with the nasal cavities are seen. The section passes in front of the optic foramen, the groove of which may be seen on the under surface of the small wing of the sphenoid close to the body, and lays open the superior orbital fissure which here leads forwards into the orbit, and which, inferiorly and laterally, is continuous with the cleft between the maxilla and the lower edge of the great wing of the sphenoid—the inferior orbital fissure. This also leads into the orbit.

The **nasal cavities**, now much diminished in height, are roofed in above by the under-surface of the body of the sphenoid and the alæ of the vomer, whilst the lateral walls are seen to be formed by the thin perpendicular parts of the palate bones, lateral to which the rounded posterior surface of the maxilla is directed backwards, here forming the anterior wall of the **pterygo-palatine fossa**—the space which lies between the anterior part of the pterygoid process behind and the maxilla anteriorly. As will be seen, the medial wall of this space is formed by the perpendicular part of the palate, which is, however, deficient above immediately below the inferior surface of the body of the sphenoid. In the interval between the orbital process, which lies in front of the section, and the sphenoidal process, which lies behind, this forms the **spheno-palatine foramen**. Laterally the section has passed through the inferior orbital fissure, which is continuous above with the pterygo-palatine fossa. Inferiorly the section passes through the line of fusion of the pterygoid processes with the pyramidal process of the palate

the line of fusion of the pterygoid processes with the pyramidal process of the palate

bone and the union of the latter with the maxilla. Just above this the opening of the **pterygo-palatine canal**, which leads from the pterygo-palatine fossa to the under surface of the hard palate, is visible; whilst inferiorly a small portion of the lower part of the

pterygoid fossa is cut through. Within the **choanæ** the middle and inferior conchæ are seen; the inferior border of the former corresponds to the level of the superior border of the zygomatic arch, whilst the attached edge of the latter to the perpendicular part of the palate lies in the same horizontal plane as the inferior margins of that arch. Note also that the medial pterygoid laminae lie considerably within the lines of the medial surfaces of the alveolar border, and reach some little distance below the level of the hard palate.

The next section (Fig. 178) passes through the mandibular fossa just behind the tuberculum articulare; superiorly, it cuts the vault half an inch behind the bregma. The **middle cranial fossa** is shown in section, the floor of which descends as low as the level of the inferior surface of the body of the sphenoid, corresponding laterally to a horizontal plane passing through the superior edge of the posterior root of the zygoma. The body of the sphenoid rises a finger's breadth above this in the median plane; the cavity within it is exposed, whilst on either side and below is seen the groove for the internal carotid artery, leading upwards from the medial part of the foramen lacerum, which is here divided. To the lateral side of the groove is seen the prominent edge of the lingula, immediately below which is the posterior aperture of the *pterygoid canal*, the inferior edge of which is in part concealed by the pterygoid tubercle. Immediately lateral to the foramen lacerum the *foramen ovale* is seen separated from the surface of the section by a narrow bridge of bone. Here it is seen to overlie the root of the lateral pterygoid lamina. The section passes just in front of the foramen spinosum, and here is visible the stout suture between the great wing of the sphenoid and the squamous part of the temporal bone. The **mandibular fossa** of the temporal bone is cut on either side, and in its deepest part is separated from the

middle cranial fossa by but a thin lamina of bone. The thinness of the squamous part of the temporal and the manner in which it is sutured to the parietal is also well displayed.

The next figure (Fig. 179) displays the anterior surface of the section immediately behind that above described. In the centre is seen the body of the sphenoid, and the posterior wall of the sinus is now exposed; on either side the apex of the petrous part of the temporal abuts upon the side of the body of the sphenoid, and the large orifice of the **carotid canal** is seen opening on to the posterior wall of the foramen lacerum, which is here divided. In the recess between the lateral wall of the carotid canal and the spine of the sphenoid is the groove leading into the osseous part of the auditory tube, in front of which the base is pierced by the foramen spinosum. Lateral to the angular spine, the mandibular fossa is divided and its thin roof displayed. Crossing it transversely is seen the petro-tympanic fissure which divides the fossa into an articular and non-articular part. The floor of the **middle cranial fossa** is here seen to be formed by the upward slope of the anterior surface of the petrous part of the temporal, which is pierced by the hiatus facialis, and the foramen for the lesser superficial petrosal nerve. On the upper surface of the summit of the petrous part of the temporal the depression for the lodgment of the semi-lunar ganglion is well seen on either side.

The last section, the anterior surface of which Fig. 180 is a representation, passes vertically through the base immediately in front of the root of the styloid process. In the median plane the basi-occipital is divided a little in front of the anterior extremities of the occipital condyles; its upper surface is concave from side to side and forms a wide groove for the medulla oblongata and pons. On either side there is a narrow interval between the lateral edge of the basi-occipital and the posterior border of the petrous part of the temporal, which in life is occupied by dense fibrous tissue; running along the upper surface of this suture is the inferior petrosal sinus. Laterally the section passes through the temporal bone, dividing the cavity of the **tympanum** and laying open the **external acoustic meatus**. To the medial side of the tympanic wall the **cochlea** is exposed, whilst above and lateral to it the canalis facialis is twice divided, the section passing posterior to the angle formed by its genu. Below the cochlea, and separated from it and the medial part of the floor of the tympanum, the carotid canal is in part exposed. Above the tympanum is the **epitympanic recess** ("attic") leading into the **tympanic antrum**, the whole being

	25. Occipital condyle.

roofed in by the thin **tegmen tympani**, which separates it from the middle cranial fossa. The obliquity of the medial end of the external acoustic meatus, together with the

groove for the attachment of the tympanic membrane is well seen, and the thickness of the upper wall of that passage is also noteworthy. The floor of the meatus, formed by the tympanic plate, which separates it from the mandibular fossa, is much thinner, but in the region of the root of the styloid process there is a massing together of dense bone.

HORIZONTAL SECTION.

Figure 181 represents a horizontal section passing through the face a little below the level of the inferior orbital margin, cutting through the root of each pterygoid process posteriorly. The nasal cavities and the maxillary sinuses are thus exposed. The **nasal cavity** is divided slightly below the inferior edge of the middle concha along the line of the middle meatus. The thin partition, which here separates the nose from the maxillary sinus, is cut through, and the aperture into the sinus laid open. In front of this, the canal for the naso-lacral duct is cut across, and its relations to the maxillary sinus in front and to the lateral side, and to the nose medially, are well displayed. The form of the **maxillary sinus**, as exposed, is triangular, the summit of the triangle being directed laterally towards the root of the zygomatic process. Its anterior wall, which is here stout, is

FIG. 180.—VERTICAL SECTION THROUGH THE SKULL IMMEDIATELY IN FRONT OF THE ROOT OF THE STYLOID PROCESS.

pierced obliquely by the infra-orbital canal which at this point reaches the facial surface of the maxilla at the infra-orbital foramen. Its posterior wall, thin and convex backwards, is directed towards the *infra-temporal fossa* laterally, and to the **pterygo-palatine fossa** medially, where it lies in front of the pterygoid processes. The latter fossa has been cut across and is seen to correspond to the interval between the posterior and superior surface of the maxilla, and the anterior aspect of the root of the pterygoid process. Laterally, it is seen to communicate with the infra-temporal fossa by means of the **pterygo-maxillary fissure** which is here cut across; medially, it opens into the nose by the **spheno-palatine foramen**, which is also divided. On one side the anterior orifice of the **pterygoid canal** is seen opening on to the posterior wall of the fossa. On the other side, the canal has been laid open, by removing its lower wall, so as to expose its whole length as it leads backward to the anterior edge of the foramen lacerum. In the middle line, the **nasal septum**, here formed by the vomer and perpendicular part of the ethmoid, is shown in section. A line passing through the inferior orbital fissures cuts the zygomatic arch where the zygomatic process of the temporal articulates with the zygomatic bone.

SEXUAL DIFFERENCES IN THE SKULL.

Whilst it is a matter of difficulty, in all cases, to determine with certainty the sex of a skull, the following points of difference are usually fairly characteristic. The female skull is, as a rule, smaller than the male. In point of cranial capacity it averages about a tenth less than the male of corresponding race. Undue stress must not be laid on these facts, since the female in bulk and stature measures on an average less than the male. It is lighter, smoother as regards the development of its muscular ridges, and possesses less prominent mastoid processes. In the frontal region, the superciliary arches are less pronounced, and this imparts a thinness and sharpness to the upper orbital margin, which is fairly characteristic, and can best be appreciated by running the finger along that edge of bone. For the same reason, the forehead appears more vertical and the projections of the

frontal tuberosities more outstanding, though it is stated that the frontal and occipital regions are less capacious proportionately than in the male. The vertex in the female is said to be more flattened, and the height of the skull consequently somewhat reduced. In the male the edge of the tympanic plate is generally sharp, and divides to form the sheath of the styloid process, whilst in the female the corresponding border is described as being rounder and more tubercular.

Whilst it is true that no one of these differences is sufficiently characteristic to enable us to pronounce with certainty on the matter of sex, it is the case that, taken together, they usually justify us in arriving at a conclusion which, as a rule, may be regarded as fairly accurate. In some instances, however, it is impossible to express any definite opinion.

THE SKULL AT BIRTH.

The skull at birth is remarkable for the small size of its *facial* portion and the proportionately great development of its *calvarial* part, the former constituting only about one-eighth of the mass of the latter.

The bones of the cranial vault have not as yet the serrated edges which they exhibit at a later stage of growth, but are at present separated from each other by a narrow linear membranous interval, corresponding in position to the lines of the sutures by which they are ultimately united. At certain points, where these membranous sutures meet or intersect, there are areas, of varying outline, in which the space between the edges of the surrounding bones is formed of membrane only. This membrane corresponds to the overlying pericranium and the underlying dura mater. The larger of these membranous intervals, called *fonticuli* or *fontanelles*, are met with in correspondence with the angles of the *parietal* bone. Of these, two are placed medially, at either end of the sagittal suture.

The *fonticulus frontalis*, or *anterior medial fontanelle*, formed by the convergence of four sutures, is the lozenge-shaped membranous interval between the rounded frontal angles of the parietal bones posteriorly and the sloping edges of the two halves of the frontal bone anteriorly, which are still separated from each other by the metopic suture. This space closes about the first half of the second year or later.

The *fonticulus occipitalis*, or *posterior medial fontanelle*, at this stage is represented by a triradiate membranous interval interposed between the two parietals in front and the more or less pointed angular superior extremity of the occipital squama behind and below. The anterior limb of the triradiate area corresponds to the posterior more open part of the sagittal suture, whilst the lateral extensions slope outwards and downwards between the edges of the occipital squama and the posterior margins of the parietal bones on either side; variations in the outline of this fontanelle may be met with, owing to the persistence of the suture which separates the interparietal elements of the occipital bone into two halves. *Closure of the occipital fonticulus* takes place about the second month after birth.

The *lateral fonticuli* are situated at the sphenoidal angles of the parietal bone. The *fonticulus sphenoidalis*, or *antero-lateral fontanelle*, corresponds to the region of the *pterion*, and is the irregular membranous interval between the sphenoidal angle of the parietal above, the posterior edge of the frontal anteriorly, and the margins of the great wing of the sphenoid and the *pars squamosa* of the temporal bone below; it closes from two to three months after birth.

The *fonticulus mastoideus*, or *postero-lateral fontanelle*, lies between the mastoid angle of the parietal superiorly and the mastoid portion of the petro-mastoid element of the temporal bone in front, the edge of the ex-occipital part of the occipital bone below, and the anterior margin of the supra-occipital element of the same bone behind. The site of this fontanelle corresponds to what is known as the asterion in the adult; it closes in from twelve months to two years after birth.

In any of these fonticuli independent ossicles of bone, called *ossa suturarum*, are liable to appear, and assist in the closure of the membranous area. At birth such an ossicle may appear in the fonticulus occipitalis, constituting what has been termed a *pre-interparietal*. And in the region of the pterion such ossicles have been described as *epipteric bones*; but it is doubtful if such independent ossicles have any

morphological significance, and are not more readily accounted for on the assumption that they are mere irregularities in the ossification of the occluding membrane.

The *sagittal fonticulus* is occasionally seen in the skull at birth as a transverse fissure or angular cleft, notching the sagittal margins of the parietal bones, transversely to the line of the sagittal suture, and in correspondence with the position of the parietal foramina, the medial margins of which may, as yet, be unossified and formed merely by the membranous layer uniting the two bones. Frequently at birth all evidence of the previous existence of this fonticulus is absent.

Most striking at birth is the occurrence of outstanding bosses, *tubera parietalia*, on the surface of the parietal bones. These overlie the position of the primary ossific centres from which these bones are originally developed, and correspond to

FIG. 182.—FRONTAL ASPECT OF THE SKULL AT BIRTH.

the greatest maximum width of the calvaria. They mark the position of what in the adult are known as the *tubera parietalia*, though, be it noted, that in the adult condition these reliefs need not necessarily correspond to the greater breadth of the head.

In like manner the sites of the centres from which the lateral portions of the frontal pad of the frontal bone are developed are readily recognised by the presence of the frontal bosses, which impart to the child's forehead its bulging appearance, and correspond in later life to the position of the frontal tuberosities. As yet the two halves of the frontal part of the frontal bone are ununited, being separated by the frontal or metopic suture (*sutura frontalis*), which lies in direct continuation anteriorly with the line of the sagittal suture. The frontal suture is, as a rule, more or less completely fused by the sixth year.

The size of the infant's skull at birth varies considerably, and is to a large extent dependent on the bulk and development of the child. The size of the skull in female infants is absolutely smaller than in the case of male children, though not necessarily proportionately smaller, since the weight of female children at birth is on the average absolutely less than male fetuses at full term.

In viewing the skeleton of the face the observer is struck with the large proportionate size of the orbital and nasal apertures. The former are circular in outline, with sharp crisp margins. Under cover of the zygomatic process of the frontal bone the roof and lateral wall of the orbit is deeply recessed. The *fossa sacci lacrimalis* is oftentimes directed more towards the facial aspect than towards the orbital cavity. The **superior and inferior orbital fissures** are proportionately large, and the latter, in the macerated skull, forms a wide channel of communication with the *fossa infratemporalis*. The nasal aperture, **apertura piriformis**, is cordate in form, and exhibits a greater proportionate width than is met with in the adult; its inferior margin is not far beneath the level of the inferior orbital margins. The vertical depth of the maxillæ is small, and as yet the **processus alveolaris** is imperfectly developed, its inferior edge lying but little below the level of the inferior border of the arcus zygomaticus. Sunk in the alveolar border at this

FIG. 183.—LATERAL ASPECT OF THE SKULL AT BIRTH.

stage may be seen the relatively large hollows in which the dental sacs are lodged. Within the body of the maxilla the **maxillary sinus** is represented by a shallow groove, disposed in relation to the middle meatus of the nose. For this reason the space separating the orbital floor from the palatine surface of the bone is small, but is later increased to its adult proportions by the enlargement of the maxillary sinus and the consequent expansion of the body of the maxilla.

Viewed from the inferior surface, the hard palate is shallow, owing to the poor development of the alveolar border. The sutures between the **ossa incisiva** and the **processus palatini** of the maxillæ are readily recognisable, and the vertical height of the **choanæ** is seen to be relatively small, owing to the perpendicular parts of the palate bones not having reached their adult proportions.

The **mandible** consists of two parts united, medially in front, by fibrous tissue to form the symphysis. The alveolar border is deeply grooved for the reception of the dental sacs, whilst the remaining substance of the body of the bone is but slightly developed. The **foramen mentale** pierces the bone about midway between its superior and inferior borders.

The **ramus** is proportionately wide, and forms with the body an *angle* which is very obtuse.

The **coronoid process** rises considerably above the level of the **capitulum**, and comes into close relationship with the *crista infratemporalis*.

The **capitulum**, which is proportionately more expanded than in the adult, occupies the somewhat laterally directed shallow **mandibular fossa** of the temporal bone.

On viewing the lateral aspect of the skull, the **meatus auditorius externus**, as such, is not seen; it is replaced by the slender **annulus tympanicus**, which supports the tympanic membrane. This ring of bone, incomplete above, is united by its extremities superiorly to the under surface and lateral aspect of the squamozygomatic part of the temporal bone. The ring itself is disposed so that it slopes downwards, forwards, and medially; as yet it fails to enter into the formation of the posterior wall of the *fossa mandibularis*, and only at a later stage does it grow laterally to form the floor of the external acoustic meatus. Through the ring the labyrinthine wall of the *cavum tympani* is seen; exposed on this surface are the promontory, the fenestra vestibuli, and the fenestra cochleæ.

Posterior to the tympanic ring the **sutura squamosomastoidea**, still open, is seen separating the *pars mastoidea* from the *squama temporalis* of the temporal bone. On turning the skull over so that its inferior surface is exposed, the *partes laterales* of the occipital bone are seen separated in front from the *pars basilaris* by a suture, which runs through the occipital condyle on either side. Posteriorly an open suture, which curves backward and laterally on each side of the posterior margin of the *foramen ovale*, separates them from that part of the *squama occipitalis* which is developed in cartilage. The *squama occipitalis* at this stage exhibits a lateral cleft on each side, passing backwards from the *fonticulus mastoidea*, which serves to indicate the line of union of the parts which are developed in cartilage and membrane respectively. The latter, the superior, sometimes separate, constitutes the *os interparietale*.

DIFFERENCES DUE TO AGE.

At birth the face is proportionately small as compared with the cranium, constituting about one-eighth of the bulk of the latter. In the adult the face equals at least half the cranium. About the age of puberty the development and expansion of some of the air-sinuses, more particularly the frontal sinus, lead to characteristic differences in form in both the head and face.

The eruption of the teeth in early life and adolescence enables us to determine the age with fair accuracy. After the completion of the permanent dentition, the wear of the teeth may assist us in hazarding an approximate estimate. The condition of the sutures, too, may guide us, synostosis of the coronal and sagittal sutures not as a rule taking place till late in life. Complete obliteration of the synchondrosis between the occipital bone and sphenoid may be regarded as an indication of maturity. In old age the skull usually becomes lighter and the cranial bones thinner. The alveolar borders of the maxillæ and mandibles become absorbed owing to the loss of the teeth. This gives rise to a flattening of the vault of the hard palate and an alteration in the form of the mandible, whereby the mandibular angle becomes more obtuse.

THE BONES OF THE UPPER EXTREMITY.

Clavicula.

The **clavicle**, or **collar bone**, one of the elements in the formation of the shoulder girdle, consists of a curved shaft, the extremities of which are enlarged. The medial end, since it articulates with the sternum, is called the *sternal extremity*; the lateral extremity, from its union with the acromion process of the scapula, is known as the *acromial end*.

The **extremitas sternalis** (sternal end) is enlarged, and rests upon the disc

of fibro-cartilage which is interposed between it and the clavicular facet on the upper and lateral angle of the manubrium sterni. It is also supported by a small part of the medial end of the cartilage of the first rib. Its *articular surface*, usually broader from above downwards than from side to side, displays an antero-posterior convexity, whilst tending to be slightly concave in a vertical direction. The edge around the articular area, which serves for the attachment of the capsule of the

FIG. 184.—THE RIGHT CLAVICLE SEEN FROM ABOVE.

sterno-clavicular articulation, is sharp and well defined, except below where it is rounded.

The shaft exhibits a double curve, being bent forwards in the medial two-thirds of its extent, whilst in its lateral third it displays a backward curve. Of rounded or prismatic form towards its sternal end, it becomes compressed and flattened at its acromial extremity. It may be described as possessing two surfaces, a superior and an inferior, separated by anterior and posterior borders, which

FIG. 185.—THE UPPER SURFACE OF THE RIGHT CLAVICLE WITH MUSCLE ATTACHMENTS.

are well defined towards the lateral extremity of the bone, but become wider and less well marked medially where they conform more to the cylindrical shape of the bone. The superior surface, which is smooth and subcutaneous throughout its whole length, is directed upwards and forwards. The anterior border,

which separates the superior from the inferior surface in front, is rough and tubercular towards its medial end for the attachment of the clavicular fibres of the pectoralis major, whilst laterally, where it becomes continuous with the anterior margin of the acromial end, it is better defined, and bears the imprint of the origin of the fibres of the deltoid muscle; here, not uncommonly, a projecting spur of bone, called the *deltoid tubercle*, may be seen. The posterior border is broad medially,

FIG. 186.—THE RIGHT CLAVICLE SEEN FROM BELOW.

where it is lipped superiorly to furnish an attachment for the clavicular fibres of the sterno-mastoid muscle; behind and below this the sterno-hyoid and sterno-thyroid muscles are attached to the bone. Laterally, the posterior border becomes more rounded, and is confluent with the posterior edge of the acromial end at a point where there is a marked outgrowth of bone from its inferior surface, the *tuberositas coracoidea*. Into the lateral third of this border are inserted the

upper and anterior fibres of the trapezius muscle. The inferior surface, inclined downwards and backwards, is marked close to the sternal end by an irregular elongated impression (*tuberositas costalis*), often deeply pitted, for the attachment of the costo-clavicular ligament, which unites it to the cartilage of the first rib. Lateral to this the shaft is channelled by a groove which terminates close to the coracoid impression; into this groove the subclavius muscle is inserted.

FIG. 187.—THE UNDER SURFACE OF THE RIGHT CLAVICLE WITH THE ATTACHMENTS OF THE MUSCLES MAPPED OUT.

The **acromial end** of the bone is flattened and compressed from above downwards, and expanded from before backwards; its anterior edge is sharp and well defined, and gives attachment to the deltoid muscle, which also spreads over part of its upper surface. Its posterior margin is rougher and more tubercular, and provides a surface for the insertion of the trapezius. The area between these two muscular attachments is smooth and subcutaneous. The lateral edge of this forward-turned part of the bone is provided with an oval facet (*facies articularis acromialis*) for articulation with the acromion of the scapula; the margins around this articular area serve for the attachment of the capsule of the joint. The inferior surface of the acromial end of the bone is traversed obliquely from behind forwards and laterally by a rough ridge or line called the **trapezoid ridge**. The posterior extremity of this ridge, as it abuts on the posterior border of the bone, forms a prominent process, the *tuberositas coracoidea*; to each of these, respectively, are attached the trapezoid and conoid portions of the coraco-clavicular ligament.

The morphology of the clavicle is of special interest. Its presence is associated with the freer use and greater range of movement of the fore-limb, such as are necessary for its employment for more specialised actions than those of mere progression. In consequence of these requirements, the limb, and with it the scapula, become further removed from the trunk, and so the support which the blade bone received through the union of its coracoid element with the sternum, as in birds and reptiles, and to some extent in the lowest mammals, is withdrawn. Some substitute, however, is necessary to meet the altered conditions, and in consequence a new element is introduced in the form of a clavicle. The origin of this bone appears to be intimately associated with the precoracoid element met with in amphibia or reptiles but whereas the precoracoid is always laid down in cartilage, which, however, not infrequently disappears, the clavicle develops in the membrane overlying the precoracoid cartilage. In the course of its development it may become intimately associated with the remains of that cartilage. Thus, it is probable that the articular discs at the sterno-clavicular and acromio-clavicular joints, as well as the sternal articular end of the clavicle, represent persistent portions of the primitive cartilage, whilst it is possible that the supra-sternal ossicles occasionally present may be also derived from it. In this way, in its most specialised form, a secondary support is established between the sternum and scapula, which serves as a movable fulcrum, and greatly enhances the range of movement of the shoulder girdle.

Nutrient Foramina.—The foramina for the larger nutrient vessels, offsets of the transverse scapular artery, of which there may be one or two directed laterally, are usually found about the middle of the posterior border, or, it may be, opening into the floor of the groove for the subclavius muscle.

Ossification.—The clavicle in man is remarkable in commencing to ossify before any other bone in the body; this occurs as early as the fifth or sixth week of foetal life. The shaft is ossified from two primitive centres (Mall). These are preceded by a curved rod of connective tissue on the interior of which are developed two masses of a peculiar precartilaginous nature, one, the sternal, placed medially, lies above and overlaps in front the acromial mass, which is placed laterally. In each of these near their approximated ends a centre of ossification appears. These, subsequent to the fusion of the

two independent precartilaginous masses, coalesce and form a bridge of bone uniting the two primary ossific centres. At a later stage cartilage cells appear in the medial

Sternal epiphysis ossifies about 20th year; fuses about 25th year

Primary centre appears about 5th or 6th week of fetal life

FIG. 188.—OSSIFICATION OF THE CLAVICLE.

extremity of the sternal precartilaginous mass and still later in the lateral end of the acromial mass. By the growth and subsequent ossification of the cartilage so formed the clavicle increases in length (Fawcett).

A secondary centre or epiphysis appears at the sternal end about the age of twenty or later, and fusion rapidly occurring between it and the shaft, ossification is completed at the age of twenty-five or thereabouts.

The Scapula.

The **scapula**, or **shoulder blade**, is of triangular shape and flattened form. It has two surfaces, costal or ventral, and dorsal. From the latter there springs a triangular process called the **spine**, which ends laterally in the **acromion**;

FIG. 189.—THE DORSAL SURFACE OF THE RIGHT SCAPULA.

whilst from its superior margin there arises a beak-like projection called the **coracoid process**. The bone overlies the postero-lateral aspect of the thoracic framework, reaching from the second to the seventh rib.

The **body** of the bone, which is thin and translucent, except along its margins and where the spine springs from it, has three margins and three angles. Of these margins the **vertebral** (*margo vertebralis*) is the longest; it stretches from the medial angle above to the inferior angle below. Of curved or somewhat irregular outline, it affords a narrow surface for the insertion of the levator scapulæ, rhomboideus minor, and rhomboideus major muscles.

The **superior margin**, which is thin and sharp, is the shortest of the three. It runs from the medial angle towards the root of the coracoid process, before reaching which, however, it is interrupted by the **scapular notch**, which lies very close to the medial side of the base of that process. This notch, which is converted into a foramen by a ligament, or occasionally by a spicule of bone, transmits the supra-scapular nerve, whilst the transverse scapular artery runs above it. Attached to the superior margin, close to the notch, is the posterior belly of the omo-hyoid. The **axillary margin**, so called from its relation to the hollow of the axilla (armpit), is much stouter than either of the others; it extends from the lateral angle above to the inferior angle below. The upper inch or so of this border, which lies immediately below the glenoid articular cavity, is rough and tubercular (*tuberositas infra-glenoidalis*), and affords attachment to the long head of the triceps. Below this it is usually crossed by a groove which marks the position of the circumflex scapular artery.

The **medial angle** is sharp and more or less rectangular; the **inferior angle** is blunter and more acute; whilst the **lateral angle** corresponds to that part of the bone which is sometimes called the **head**, and which supports the **glenoid cavity** and the **coracoid process**.

The **glenoid cavity** is a piriform articular area, slightly concave from above downwards and from side to side; its border is but slightly raised above the general surface and affords attachment in the recent condition to the labrum glenoidale, which helps to deepen the socket in which the head of the humerus rests. Below, the margin of the glenoid cavity is confluent with the **infra-glenoid tuberosity**, whilst, above, it blends with a tubercle (*tuberositas supraglenoidalis*), to which the long head of the biceps muscle is attached. Springing from the upper part of the head, in line with the superior margin, is the **processus coracoideus** (coracoid process). The base of this is limited laterally by the glenoid edge, whilst medially it is separated from the superior margin by the scapular notch. Rising upwards for a short space, it bends on itself at nearly a right angle, and ends in a process which is directed laterally and slightly forwards, overhanging the glenoid cavity above and in front. Compressed from above downwards, it has attached to its upper surface near its angle the conoid ligament, lateral to which there is a rough area for the trapezoid ligament. Attached to its dorsal border is the coraco-

FIG. 190.—THE DORSAL SURFACE OF THE RIGHT SCAPULA WITH THE ATTACHMENTS OF THE MUSCLES MAPPED OUT.

acromial ligament, whilst at its extremity and towards the front of its ventral border, is the combined origin of the biceps and coracobrachialis, together with the insertion of the pectoralis minor. The *collum scapulæ* (neck) is that somewhat constricted part of the bone which supports the head; it corresponds in front and behind to a line drawn from the scapular notch to the infra-glenoidal tuberosity.

The body of the bone has two surfaces, a dorsal (*facies dorsalis*) and a costal (*facies costalis*). The former is divided into two fossæ by an outstanding process of triangular form, called the *spina scapulæ*. The attached border of this crosses the dorsal surface of the body obliquely in a direction

FIG. 191.—THE RIGHT SCAPULA SEEN FROM THE FRONT.

FIG. 192.—COSTAL SURFACE OF THE RIGHT SCAPULA WITH THE ATTACHMENTS OF MUSCLES MAPPED OUT.

laterally and slightly upwards, extending from the vertebral border, near the lower limit of its upper fourth, towards the centre of the posterior glenoid edge, from which, however, it is separated by the **great scapular notch**, which here corresponds to the dorsal aspect of the neck. Within this notch the transverse scapular vessels and the supra-scapular nerve pass to the infra-spinous fossa. The surfaces of the spine, which are directed upwards and downwards, are concave, the upper entering into the formation of the supra-spinous fossa, which lies above it, the lower forming the upper wall of the infra-spinous fossa, which lies below it. The two fossæ are in communication

with each other round the free lateral concave border of the spine, where that curves over the great scapular notch. The dorsal free border of the spine is subcutaneous throughout its entire length. Its upper and lower edges are strongly lipped, and serve—the superior, for the insertion of the trapezius; the inferior, for the origin of the deltoid. The intervening surface varies in width—broad and triangular where it becomes confluent with the vertebral border, it displays a smooth surface, over which the tendinous fibres of the trapezius play; narrowing rapidly, it forms a surface of varying width which blends laterally with a flattened process, the two forming a compressed plate of bone which arches across the great scapular notch above and behind, and then curves, upwards, forwards, and laterally to overhang the glenoid cavity. The medial border of this process is continuous with the upper margin of the spine, and is gently curved. The lateral border, more curved than the medial, with which it is united in front, is confluent with the inferior edge of the spine, with which it forms an abrupt bend, termed the **acromial angle**. The bone included between these two borders is called the **acromion**. Of compressed form, it much resembles the acromial end of the clavicle, with which it articulates by means of a surface (*facies articularis acromii*) which is placed on its medial border near its anterior extremity. The superior surface of the acromion, which is broad and expanded, is subcutaneous, and is directed upwards and dorsally, and in the normal position of the bone laterally as well. Its medial edge, where not in contact with the clavicle, has attached to it the fibres of the trapezius, whilst its lateral margin affords origin to the central part of the deltoid. At its anterior extremity it is connected with the coracoid process by means of the coraco-acromial ligament. Its inferior surface is smooth and overhangs the shoulder-joint.

The **supra-spinous fossa**, of much less extent than the **infra-spinous**, is placed above the spine, the upper surface of which assists in forming its curved floor; in it is lodged the **supraspinatus** muscle. The scapular notch opens into it above, whilst below and laterally it communicates with the **infra-spinous fossa** by the great scapular notch, through which the transverse scapular artery and supra-scapular nerve pass to reach the **infra-spinous fossa**.

The **infra-spinous fossa**, overhung by the spine above, is of triangular form. The axillary margin of the bone limits it in front, whilst the vertebral margin bounds it behind; the greater part of this surface affords origin to the **infraspinatus** muscle, excepting a well-defined area which skirts the axillary margin and inferior angle of the bone, and which affords an attachment to the fibres of origin of the **teres minor**. This muscle extends along the dorsal surface of the axillary margin in its superior two-thirds, reaching nearly as high as the glenoid edge; whilst a crescentic surface, which occupies the inferior third of the axillary border and curves backward round the dorsal aspect of the inferior angle, furnishes an origin for the **teres major** muscle. Here also, near the inferior angle, are occasionally attached some of the fibres of the **latissimus dorsi** muscle.

The **facies costalis** (costal aspect) of the body is hollow from above downwards and from side to side, the greatest depth being in correspondence with the spring of the spine from the dorsal surface. Its medial boundary, which is formed by the anterior lipped edge of the vertebral margin, affords attachment to the fibres of insertion of the **serratus anterior** along the greater part of its extent. The area of insertion of this muscle is, however, considerably increased over the ventral aspects of the medial and inferior angles respectively. Running down from the head and neck above to the inferior angle below, there is a stout rounded ridge of bone, which imparts a fulness to the costal aspect of the axillary margin and increases the depth of the costal hollow; to this, as well as to the floor of the fossa, the sub-scapularis muscle is attached. The tendinous intersections of this muscle leave their imprint on this surface of the bone in a series of three or four rough lines which converge towards the neck.

The scapula of man is characterised by the greater proportionate length of its base or vertebral margin as compared with lower forms. This proportion is expressed by what is termed the **scapular index** (Appendix D). The greater size of the acromion is also a distinctive feature. The double ossification of the coracoid occurs only in mammals. It is probable that the centre for the upper and anterior part of the

coracoid process represents the epicoracoid or precoracoid of lower forms, whilst the subcoracoid centre (metacoracoid) which assists in the formation of the glenoid cavity is the reduced and vestigial remains of the stout coracoid element met with in *Ornithorhynchus*, which articulates with the sternum.

Nutrient Foramina.—Foramina for the passage of nutrient vessels are seen in different parts of the bone; the most constant in position is one which opens into the infra-spinous fossa, about an inch or so from the scapular notch. Others are met with on the upper and under surfaces of the spine, on the costal aspect near its deepest part, and also around the glenoid margin.

Connexions.—The scapula is not directly connected with the trunk, but articulates with the lateral end of the clavicle, in union with which it forms the shoulder girdle, supporting the humerus on its glenoid surface. Placed on the upper and back part of the thorax, it covers the ribs from the second to the seventh inclusive. Possessed of a wide range of movement, it alters its position according to the attitude of the limb, rising or falling, being drawn inwards or outwards, or being rotated upon itself according as the arm is moved in various directions. These changes in position can easily be determined by recognising the altered relations of the subcutaneous and bony prominences, more especially the former, which include the spine, the acromion, and the inferior half of the vertebral border.

Ossification.—Ossification begins in the body of the cartilaginous scapula about the end of the second month of foetal life. At birth the head, neck, body, spine, and base of the coracoid process are well defined; the vertebral margin, inferior angle, glenoid cavity, acromion, and coracoid process, are still cartilaginous. The centre for the upper and anterior part of the coracoid appears in the first year, and fusion along an oblique line leading from the upper edge of the glenoid cavity to the conoid tubercle is complete about the fifteenth year. A separate centre (subcoracoid), which ultimately includes the superior part

of the glenoid cavity and lateral part of the coracoid process, makes its appearance about the tenth year, and fuses with the surrounding bone about sixteen or seventeen. Up till the age of puberty the acromion remains cartilaginous; centres, two or more in number, then make their appearance, which coalesce and ultimately unite with the spine about the twenty-fifth year. Failure of union may, however, persist throughout life (see Appendix B—Variations).

Ossification commences in the cartilage in the inferior angle about puberty, and independently and a little later, along the vertebral margin, fusion with the body occurring at from twenty to twenty-five years.

Small scale-like epiphyses make their appearance on the superior surface and at the

extremity of the coracoid, and are completed about the twentieth year. A thin epiphysal plate develops over the inferior part of the glenoid cavity about sixteen or seventeen, fusion being complete about eighteen or twenty years of age.

The Humerus.

The humerus, or bone of the upper arm, articulates proximally with the scapula and distally with the bones of the forearm, the radius and ulna. Its proximal end comprises the head and larger and smaller tubercles; its shaft, which is longer than any of the other bones of the upper extremity, is cylindrical proximally and flattened distally. At the distal extremity, which is expanded to form the epicondyles on either side, it supports the trochlear and capitular articular surfaces for the ulna and radius respectively.

FIG. 193.—OSSIFICATION OF THE SCAPULA.

The proximal extremity is the thickest and stoutest part of the bone. The *caput humeri* (head), which forms about one-third of a spheroid and is covered with articular cartilage, is directed proximally, medially, and slightly dorsally, and rests in the glenoid cavity of the scapula; the convexity of its surface is most pronounced in its posterior half. Separating the head from the tubercles laterally is a shallow groove, which fades away on the surface of the bone which supports the articular part inferiorly. This is named the *collum anatomicum* (anatomical neck) and serves for the attachment of the capsule of the shoulder-joint. The

FIG. 194.—ANTERIOR VIEW OF THE RIGHT HUMERUS.

FIG. 195.—THE ANTERIOR SURFACES OF THE HUMERUS WITH MUSCULAR ATTACHMENTS MAPPED OUT.

articular edge of the groove opposite the smaller tubercle is usually notched for the attachment of the superior gleno-humeral ligament. The *tuberculum majus* (larger

tubercle) abuts on the lateral side of the head and becomes continuous with the shaft distally. Its proximal surface forms a quadrant, which is subdivided into

three more or less smooth areas of unequal size. Of these the proximal and anterior is for the insertion of the supraspinatus muscle, the middle for the infraspinatus, whilst the most distal and posterior serves for the insertion of the teres minor muscle. The lateral surface of this tubercle, which bulges beyond the line of the shaft, is rough and pierced by numerous vascular foramina. Anteriorly the larger tubercle is separated from the tuberculum minus (smaller tubercle) by a well-defined furrow, called the *sulcus intertubercularis* (intertubercular groove) (O.T. bicipital groove). The transverse humeral ligament stretches across the groove between the two tubercles, thus converting the groove into a canal in which the tendon of the long head of the biceps and the ascending articular branch of the anterior circumflex artery of the humerus are lodged. The smaller tubercle lies in front of the lateral half of the head; it forms a pronounced elevation, which fades into the shaft distally. The surface of this tubercle is faceted above and in front for the insertion of the subscapularis muscle, whilst laterally it forms the prominent medial lip of the inter-tubercular groove. Distal to the head and tubercles the shaft of the bone rapidly contracts, and is here named the *collum chirurgicum* (surgical neck) owing to its liability to fracture at this spot.

The *corpus humeri* (shaft, or body) is cylindrical in its proximal half. On it the inter-tubercular groove may be traced distally and slightly medially, along its anterior surface. The edges of the groove, which are termed its lips, are confluent proximally with the larger and smaller tubercles, respectively. Here they are prominent, and form the *cristæ tuberculi majoris et minoris* (crests of the larger and smaller tubercles). Distally the lips of the intertubercular groove gradually fade away, the medial more rapidly than the lateral, which latter may usually be traced distally to a rough elevation placed on the lateral anterior surface of the shaft about its middle, called the *deltoid tuberosity*. Into the lateral lip of the intertubercular groove are inserted the fibres of the pectoralis major muscle; hence it is sometimes described

FIG. 196.—POSTERIOR SURFACE OF THE RIGHT HUMERUS.

as the pectoral ridge. To the floor of the groove the latissimus dorsi is attached; whilst the teres major muscle is inserted into the medial lip.

The **tuberositas deltoidea** (deltoid tuberosity) to which the powerful deltoid muscle is attached, is a rough, slightly elevated V-shaped surface, placed on the lateral anterior surface of the shaft about its middle. The anterior limb of the V is parallel to the axis of the shaft, and is continuous proximally with the lateral lip of the intertubercular groove, whilst the posterior limb of the V winds obliquely round the lateral anterior surface of the bone towards the posterior surface, where it becomes continuous with a slightly elevated and occasionally rough ridge which leads proximally along the posterior of the bone towards the larger tubercle; from this latter ridge the lateral head of the triceps muscle arises.

The medial anterior surface of the shaft about its middle inclines to form a rounded border, on which there is often a rough linear impression marking the insertion of the coracobrachialis muscle. Distal to this the shaft becomes compressed and expanded laterally, ending distally on either side in the **epicondyles**. Its surfaces are now anterior and posterior, being separated from each other by two clearly defined borders, the **medial and lateral margins**, or **epicondylar ridges**. Of these, the medial (**margo medialis**) is the more curved and less prominent, and is continuous proximally with the surface to which the coracobrachialis is attached, whilst distally it ends by blending with the medial epicondyle. The lateral (**margo lateralis**) is straighter and more projecting; its edge is usually distinctly lipped. Confluent with the lateral epicondyle distally, it may be traced proximally to near the deltoid tuberosity, where it turns backwards more or less parallel to the posterior oblique border of that impression, to be lost on the posterior surface of the shaft. The interval between this border and the deltoid eminence is thus converted into a shallow oblique furrow, which winds round the lateral surface of the bone just distal to its middle; this constitutes the **sulcus n. radialis** (groove for the radial nerve) along which the radial (O.T. musculo-spinal) nerve, together with the profunda brachii artery, passes from the back to reach the front of the arm. To the epicondylar ridges are attached the intermuscular septa, whilst the lateral in its proximal two-thirds furnishes a surface for the origin of the brachioradialis muscle, and in its distal third for the extensor carpi radialis longus muscle.

The anterior surface of the distal half of the shaft is of elongated triangular form, the base corresponding to the distal extremity of the bone. Running down the centre of this is a broad, rounded, elevated ridge, most pronounced proximally, where it joins the deltoid tuberosity, and sloping on either side towards the epicondylar ridges; it is into the lateral of these slopes that the groove for the radial nerve flows. Distally the elevated surface spreads out, and becomes confluent with the epicondyles. The **epicondylus medialis** (medial epicondyle) is the more prominent of the two, and furnishes a surface for the origin of the pronator teres, and the superficial flexor muscles of the forearm. The **epicondylus lateralis** (lateral epicondyle), stunted and but little projecting, serves for the attachment of the common tendon of origin of the extensor muscles. The brachialis muscle has an extensive origin from the anterior surface of the distal half of the shaft, including between its proximal slips the insertion of the deltoid.

FIG. 197.—POSTERIOR SURFACE OF THE RIGHT HUMERUS WITH ATTACHMENTS OF MUSCLES MAPPED OUT.

The posterior surface of the distal half of the shaft is smooth and rounded from

FIG. 198.—PROXIMAL ASPECT OF THE HEAD OF THE RIGHT HUMERUS (with the outline of the distal extremity in relation thereto shown in dotted line).

The distal extremity of the humerus is furnished with two articular surfaces (the condyles proper), the lateral of which, called the *capitulum*, for articulation with the proximal surface of the head of the radius, is a rounded eminence, placed on the anterior surface and distal border, but not extending on to the posterior surface of the distal end of the bone. Proximal to it, in front, there is a shallow depression (*fossa radialis*), into which the margin of the head of the radius sinks when the elbow is strongly flexed. A shallow groove separates the capitulum medially from the *trochlea*, which is a grooved articular surface, with prominent edges winding spirally

FIG. 199.—DISTAL ASPECT OF THE DISTAL EXTREMITY OF THE RIGHT HUMERUS.

FIG. 200.—THE DISTAL END OF THE RIGHT HUMERUS SEEN FROM THE LATERAL SIDE.

round the distal extremity of the shaft. The spiral curves from behind forwards and medially, and its axis is slightly oblique to the long axis of the shaft. The medial lip is the more salient of the two, and forms a sharp and well-defined margin to the articular area; its cartilage-covered surface is slightly convex. The lateral lip, much less prominent, is rounded off into the articular groove which separates it from the capitulum, posterior to which, however, it is carried up as a more or less definite crest. It is by means of the trochlea that the humerus articulates with the semilunar notch of the ulna. On the anterior surface of the bone, immediately proximal to the trochlea, is a depression—the *fossa coronoidea* (*coronoid fossa*)—into which the coronoid process of the ulna slips in flexion of the joint, whilst in a corresponding position on the posterior aspect of the distal end of the shaft there is a hollow, called the *fossa olecrani* (*olecranon fossa*), just proximal to the trochlea posteriorly. Into this the olecranon process sinks when the elbow is extended. The two fossæ are separated by a thin translucent layer of bone which may be deficient, thus leading to the formation of a foramen between the two hollows in the macerated bone. The anterior part of the capsule of the elbow-joint is attached to the proximal margins of the radial and coronoid fossæ in front, whilst the posterior ligament is connected with the proximal border and lateral edges of the olecranon fossa behind. The strong

radial and coronoid fossæ in front, whilst the posterior ligament is connected with the proximal border and lateral edges of the olecranon fossa behind. The strong

ulnar and radial collateral ligaments of the elbow joint are attached proximally to the medial and lateral epicondyles respectively. The proportionate length of the humerus to the body height is as 1 is to 4.93-5.25.

Nutrient foramina are usually to be seen, one at or near the surface for the insertion of the coraco-brachialis, the other usually close to the posterior border of the deltoid tuberosity; both have a distal direction. Numerous vascular foramina are scattered along the line of the anatomical neck, the larger ones being situated near the proximal end of the inter-tubercular groove. The vascularity of the bone is here intimately associated with the activity of its growth in this situation.

Connexions.—The humerus articulates proximally with the scapula, and distally with the radius and ulna. Embedded, as the humerus is, in the substance of the arm, its shaft and head are surrounded on all sides. It is only at its distal part that it comes into direct relation with the surface, the medial epicondyle forming a characteristic projection on the medial side of the elbow; whilst the lateral epicondyle, less prominent, and the lateral epicondylar ridge can best be recognised when the elbow is bent.

FIG. 201.—OSSIFICATION OF THE HUMERUS.

1. Appears early in 2nd month fetal life.
2. For larger tubercle, appears 2 to 3 years.
3. For head, appears within first 6 months.
4. For medial epicondyle, appears about 5 years.
5. For capitulum, appears 2 to 3 years.
6. Appears about 12 years.
7. Centres for head and larger tubercle coalesce about 5 years.
8. Centre for smaller tubercle fuses with other centres about 7 years.
9. Appears about 11 or 12 years.
10. Inferior epiphysis fuses with shaft about 16 to 17 years.
11. Superior epiphysis fuses with shaft about 25 years.
12. Fuses with shaft about 17 to 18 years.

Sexual differences.—Dwight (*American Journ. of Anat.* vol. iv. 1904) has shown that the head of the humerus in the female is proportionately smaller than that of the male.

Ossification.—At birth the shaft of the humerus is usually the only part of the bone ossified, if we except the occasional presence (22 per cent) of an ossific centre in the head. (H. R. Spencer, *Journ. Anat. and Physiol.* vol. xxv. p. 552.) The centre for the **shaft** makes its appearance early in the second month of intra-uterine life. Within the first six months after birth a centre usually appears for the **head**; this is succeeded by one for the **larger tubercle** during the second or third year. These soon coalesce; and a third centre for the **smaller tubercle** begins to appear about the end of the third year, or may be delayed till the fourth or fifth year. These three centres are all blended by the seventh year, and form an **epiphysis**, which ultimately unites with the shaft about the age of twenty-five. It may be noticed that the proximal end of the diaphysis is conical and pointed in the centre, over which the epiphysis fits as a cap, an arrangement which thus tends to prevent its displacement before union has occurred. The first centre to appear in the *distal extremity* is that for the **capitulum** about the second or third year. This extends medially, and forms the lateral half of the **trochlear surface**, the centre for the medial half not making its appearance till the eleventh or twelfth year.

Separate centres are developed in connexion with the **epicondyles**; that for the lateral appears about the twelfth year, and, rapidly coalescing with the centres for the capitulum and trochlea, forms an **epiphysis**, which unites with the shaft about the sixteenth or seventeenth year. The centre for the **medial epicondyle** appears about the fifth year; it forms a separate **epiphysis**, which unites with the shaft about eighteen or nineteen. These two epiphyses at the distal end of the bone are separated by a down-growth of the shaft, which lies between the medial epicondyle and the trochlea, and forms part of the base and medial side of the latter process.

The epicondylar process when present is developed from the diaphysis, and has been observed to be already well ossified by the third year. ("Proc. Anat. Soc." *Journ. Anat. and Physiol.* 1898.)

The Ulna.

Of the two bones of the forearm, the **ulna**, which is placed medially, is the longer. It consists of a large proximal extremity supporting the **olecranon** and the **coronoid process**; a **body** or **shaft** tapering distally; and a small rounded distal end called the **head**.

Proximal Extremity.—The **olecranon** lies in line with the shaft. Its dorsal surface, more or less triangular in form, is smooth and subcutaneous and covered by a bursa. Its proximal aspect, which forms with the posterior surface a nearly rectangular projection—the tip of the elbow—furnishes a surface for the insertion of the tendon of the triceps brachii muscle, together with a smooth area which is overlain by the same tendon, but separated from it by a bursal sac. To the volar crescentic border of this process are attached the fibres of the posterior part of the capsule and a portion of the ulnar collateral ligament of the elbow-joint. The volar surface is articular, and enters into the formation of the **semilunar notch**.

The **processus coronoideus** (**coronoid process**) is a bracket-like process, which juts forwards from the volar and proximal part of the shaft, and is fused with the olecranon proximally. By its proximal surface it enters into the formation of the semilunar notch, whilst its volar aspect, which is separated from its proximal side by a sharp irregular margin, slopes distally and dorsally to become confluent with the volar surface of the shaft. Of triangular shape, this area, which is rough and tubercular, terminates inferiorly in an oval elevated tubercle (**tuberositas ulnæ**), into which the tendon of the brachialis muscle is inserted. Of the lateral margins of the coronoid process, the medial is usually the better defined. Proximally, where it joins the proximal border, there is generally a salient tubercle, to which one of the heads of origin of the flexor digi-

FIG. 202.—THE RIGHT ULNA AS VIEWED FROM THE LATERAL SIDE.

torum sublimis muscle is attached, whilst distal to this point the medial border furnishes origins for the pronator teres, and occasionally for the flexor pollicis

longus muscles, from above downwards. The smooth medial surface of the coronoid process merges with the olecranon dorsally, and with the medial surface of the shaft distally.

The *incisura semilunaris* (O.T. *greater sigmoid cavity*), for articulation with the trochlea of the humerus, is a *semicircular notch*, the proximal part of which is formed by the volar surface of the olecranon, whilst distally it is completed by the proximal surface of the coronoid process. Constricted towards its deepest part by the notching of its lateral borders, the articular surface is occasionally crossed by a narrow impression which serves to define the olecranon proximally from the coronoid distally. The articular area is divided into a medial portion, slightly concave transversely, and a lateral part, transversely convex to a slight degree, by a longitudinal smooth ridge which extends from the most prominent part of the border of the olecranon proximally to the most outstanding point of the coronoid process distally. The margins of the semilunar notch are sharp and well defined, and serve, with the exception of the area occupied by the radial notch, for the attachment of the capsule of the elbow-joint.

The *radial notch* (O.T. *lesser sigmoid cavity*), placed on the radial side of the coronoid process, is an oblong articular surface for the reception of the head of the radius. It encroaches on the distal and lateral part of the semilunar notch, so as to narrow it considerably. Separated from it by a rectangular curved edge, it displays a surface which is plane from above downwards, and concave from before backwards. Its volar extremity is narrower and more pointed than its dorsal, and becomes confluent with the anterior edge of the coronoid process, at which point the annular ligament, which retains the head of the radius in position, is attached in front. Its dorsal border, wider and more outstanding, lies in line, and is continuous with the interosseous margin of the shaft. Dorsal to this border, the annular ligament is attached posteriorly.

The *shaft* of the ulna (*corpus ulnæ*), which is nearly straight, or but slightly curved, is stout and thick proximally, gradually tapering towards its distal extremity. It may be divided into three surfaces, a *volar* (O.T. *anterior*), a *dorsal* or *posterior*, and a *medial*, by three well-defined borders, an *interosseous crest*, a *dorsal margin*, which latter is

FIG. 203.—THE RIGHT RADIUS AND ULNA SEEN FROM THE VOLAR ASPECT.

subcutaneous throughout its whole length, and a **volar margin** (O.T. anterior border).

The **crista interossea** (interosseous crest) is crisp and sharp in the proximal three-fourths of the shaft, but becomes faint and ill-defined in the distal fourth. To this, with the exception only of the part which forms the dorsal boundary of the hollow in which the tuberosity of the radius is disposed when the two bones are articulated, is attached the interosseous membrane which connects the two bones of the forearm. The **margo dorsalis** (dorsal margin), of sinuous outline, curving laterally above, and slightly medially below, is continuous proximally with the triangular subcutaneous area on the back of the olecranon, being formed by the confluence of the borders which bound that surface; well marked above, it becomes faint and more rounded below, but may be traced distally to the dorsal surface of the base of the styloid process. To this border is attached an aponeurosis common to the flexor carpi ulnaris, extensor carpi ulnaris, and flexor digitorum profundus muscles. A noteworthy feature in connexion with this part of the shaft is the fact that it is subcutaneous, and can easily be felt beneath the skin throughout its whole length.

The **volar or anterior surface** corresponds to the front and medial side of the shaft. It is described as consisting of two surfaces, a volar and a medial, which are separated by a rounded **volar margin**, which extends from the tuberosity proximally towards the styloid process distally. The prominence of this ridge varies in different bones, being well marked in bones of a pronounced type, but corresponding merely to the rounding of the surfaces in poorly developed specimens. The volar aspect of the bone affords an extensive origin to the flexor digitorum profundus muscle, which clothes its volar and medial surfaces in its proximal three-fourths, reaching as far back as the dorsal border, and extending proximally as high as the medial side of the olecranon process. Immediately distal to the radial notch there is a hollow triangular area, limited dorsally by the proximal part of the interosseous crest, and defined in front by an oblique line which extends distally and backwards from the lateral margin of the coronoid process. In this hollow the tuberosity of the radius rests when the forearm is in the prone position, and to its floor are attached the fibres of origin of the supinator muscle. The distal fourth of the shaft is crossed by the fibres of the pronator quadratus muscle, which derives its origin from a more or less well-defined crest, which winds

FIG. 204.—VOLAR ASPECT OF BONES OF THE RIGHT FOREARM WITH MUSCULAR ATTACHMENTS MAPPED OUT.

spirally distally and backwards towards the volar surface of the root of the styloid process, and is continuous proximally with the volar margin.

The **dorsal surface** of the shaft lies dorsally between the dorsal margin and the interosseous crest. At its proximal part it is placed behind the semilunar and radial notches, extending on to the lateral side of the olecranon. Here an area corresponding to the proximal third of the length of the bone is marked off distally by an oblique ridge which leaves the interosseous crest about an inch or more distal to the dorsal edge of the radial notch. Into this somewhat triangular surface the fibres of the anconeus are inserted. Distal to this the

posterior surface is subdivided by a faint longitudinal ridge, the bone between which and the interosseous crest furnishes origins for the abductor pollicis longus, extensor pollicis longus, and extensor indicis proprius muscles, in order proximodistally. The surface of bone between the dorsal margin and the afore-mentioned longitudinal line is smooth and overlain by the extensor carpi ulnaris muscle, which does not arise from it.

The distal extremity of the ulna presents a rounded head (*capitulum ulnæ*), from which, on its medial and dorsal aspect, there projects distally a cylindrical pointed process called the *styloid process*. To the extremity of this latter is attached the ulnar collateral ligament of the carpus, whilst on the volar aspect it has connected with it the antero-medial portion of the capsule of the wrist-joint. The antero-lateral half of the circumference of the head is furnished with a smooth narrow convex articular surface, which fits into the ulnar notch of the radius. Its distal surface, flat and semilunar in shape, and separated from the root of the styloid process by a well-marked groove, rests on the upper surface of the triangular articular disc of the wrist, the apex of which is attached to the groove just mentioned. The margins of the head, to the volar side and dorsal to the radial articular surface, have attached to them the volar and dorsal inferior radio-ulnar ligaments. The dorsal and medial surface of the styloid process is channelled by a groove which separates it from the dorsal surface of the head, and extends proximally some little way upon the dorsal surface of the distal end of the shaft. In this is lodged the tendon of the extensor carpi ulnaris muscle. The proportionate length of the ulna to the body height is as 1 is to 6.26-6.66.

Nutrient Foramina.—A foramen, having a proximal direction, for the nutrient artery of the shaft opens on the volar surface of the bone from two to three inches distal to the tuberosity. Vascular canals of large size are seen proximal and dorsal to the radial notch, just dorsal to the notched lateral border of the semilunar notch. At the distal end of the bone similar openings are seen in the groove between the styloid process and the distal articular surface of the head.

Connexions.—The ulna articulates proximally with the trochlea of the humerus. On the lateral side it is in contact with the radius at both proximal and distal ends, the proximal radio-ulnar articulation being formed by the head of the radius and the radial notch of the ulna, the distal radio-ulnar joint comprising the head of the ulna, which fits into the ulnar notch of the radius. Between these two joints the shafts of the bones are united by the interosseous membrane. The distal surface of the head of the ulna does not articulate with the carpus, but rests on the proximal surface of the interposed articular disc. The ulna is superficial throughout its entire extent. Superiorly the olecranon process can be readily recognised, particularly when the elbow is bent, as in this position the olecranon is withdrawn from the olecranon fossa of the humerus in which it rests when the joint is extended. Distal to this the subcutaneous triangular area on the back of the olecranon can be easily determined, and from it the posterior border of the bone can readily be traced along the line of the "ulnar furrow" to the styloid process. With the hand supine this latter process can be felt to the medial side and slightly behind the wrist. When the hand is pronated, the distal end of the radius rolls round the distal extremity of the ulna, and the antero-lateral surface of the head of the latter bone now forms a well-marked projection on the dorsum of the wrist in line with the cleft between the little and ring fingers.

Ossification.—The ulna is ossified from one primary and two or more secondary centres. The centre for the shaft appears early in the second month of foetal life. At birth the shaft and a considerable part of the proximal extremity, including the coronoid process, are ossified, as well as part of the distal extremity. The olecranon and the distal surface of the head and the styloid process are cartilaginous. About ten

FIG. 205.—THE OSSIFICATION OF THE ULNA.

years of age a secondary centre appears in the cartilage at the proximal end of the bone, and

forms an epiphysis which unites with the shaft about sixteen. In this connexion Fawcett (*Proc. Anat. Soc. Great Britain and Ireland*, 1904, p. xxvii) has described the occurrence

of two ossific centres in the olecranon. One, the more volar, the "beak centre," enters into the formation of the proximal end of the articular surface of the semilunar notch, the other centre, not in any way forming it. A scale-like centre appears in the cartilage of the head about the sixth year, from which the distal surface of that part of the bone is developed, and by the extension of which the styloid process is also ossified; this epiphysis does not unite with the shaft till the twentieth or twenty-third year. Independent centres for the styloid process and for the extreme edge of the olecranon have also been described. The student may here be warned that the epiphysial line between the shaft and superior or olecranon epiphysis does not correspond to the constricted part of the semilunar notch, but lies considerably above it.

FIG. 206.—THE RIGHT RADIUS AND ULNA SEEN FROM THE DORSAL ASPECT.

The Radius.

The **radius**, or lateral bone of the forearm, is shorter than the ulna, with which it is united on the medial side. Proximally it articulates with the humerus, and distally it supports the carpus. It consists of a **head**, a **neck**, a **tuberosity**, a **shaft**, and an expanded **distal extremity**. The shaft is narrow proximally, but increases in all its diameters distally.

Proximal Extremity.

—The **capitulum** (head) is disc-shaped and provided with a shallow concave surface (**fovea capituli radii**) proximally for articulation with the capitulum of the humerus. The circumference of the head (**circumferentia articularis**) is smooth

and is embraced by the annular ligament. On the medial side it is usually much broader, and displays an articular surface, plane in the proximo-distal direction,

which rolls within the radial notch of the ulna in the movements of pronation and supination. The character of the lateral half of the circumference differs from the medial, in being narrower, and rounded from above downwards.

The *collum radii* (neck) is the constricted part of the shaft which supports the head, the overhang of the latter being greatest towards the lateral and dorsal side. Distal to the neck, on the medial side, there is an outstanding oval prominence, the *tuberositas radii* (radial tuberosity). The dorsal part of this is rough for the insertion of the biceps tendon, whilst the volar half is smooth and covered by a bursa which intervenes between it and the tendon.

The shaft (*corpus radii*), which has a lateral curve and is narrow proximally and broad distally, is wedge-shaped on section. The edge of the wedge forms the sharp medial interosseous crest of the bone (*crista interossea*), whilst its base corresponds to the thick and rounded lateral border over which the volar or anterior surface becomes confluent with the dorsal or posterior surface.

The *interosseous crest*, faint proximally where it lies in line with the dorsal margin of the tuberosity, becomes sharp and prominent in the middle third of the bone. Distal to this it splits into two faint lines, which lead to either side of the ulnar notch on the distal end of the bone, thus including between them a narrow triangular area into which the deeper fibres of the pronator quadratus muscle are inserted. To this crest, as well as to the dorsal of the two divergent lines, the interosseous membrane is attached.

The lateral surface (once described as the *lateral border*) is thick and rounded proximally, but becomes thinner and more prominent distally, where it merges with the base of the *styloid process*. About its middle the anterior and posterior oblique lines become confluent with it, and here, placed between them, is a rough elongated impression which marks the insertion of the pronator teres muscle. Proximal to this, and on the lateral surface of the neck, the supinator muscle is inserted, whilst distally this surface is overlain by the tendons of the brachio-radialis and the extensor carpi radialis longus and brevis muscles.

The volar or anterior surface (*facies volaris*) is crossed obliquely by a line which runs from the tuberosity proximally, distally, and laterally towards the middle of the lateral

FIG. 207.—DORSAL ASPECT OF BONES OF RIGHT FORE-ARM WITH ATTACHMENTS OF MUSCLES MAPPED OUT.

surface of the shaft. This, often called the *anterior oblique line*, serves for the attachment of the radial head of origin of the flexor digitorum sublimis muscle. Proximal to it, the volar aspect of the bone has the fibres of the supinator muscle inserted into it, whilst distally and medial to it, extending as far distally as the distal limit of the middle third of the bone, is an extensive surface for the origin of the flexor pollicis longus muscle. In the distal fourth of the bone, where the volar aspect of the shaft is broad and flat, there is a surface for the insertion of the pronator quadratus muscle, which also extends dorsally to the interosseous ridge.

The dorsal or posterior surface (*facies dorsalis*) is also crossed by an oblique line, less distinct than the anterior. This serves to define the proximal

limit of the origin of the abductor pollicis longus muscle. Proximal to this, the dorsal aspect of the neck and proximal part of the shaft is overlain by the fibres of the supinator muscle which become attached to this surface of the bone in its lateral half. Distal to the posterior oblique line the dorsal surface in the proximal part of its medial half gives origin to the abductor pollicis longus and the extensor pollicis brevis muscles in that order proximo-distally.

The distal extremity, which tends to be turned slightly forward, has a somewhat triangular form. Its distal carpal articular surface, concave from before backwards, and slightly so from side to side, is divided into two facets by a slight antero-posterior ridge, best marked at its extremities where the volar and dorsal margins are notched; the lateral of these areas, of triangular shape, is for articulation with the navicular, whilst the medial, quadrilateral in form, is for the os lunatum. The volar border, prominent and turned forward, is rough at its edge, where it serves for the attachment of the volar part of the capsule of the wrist-joint. The dorsal border is rough, rounded, and tubercular, and is grooved by many tendons; of these grooves the best marked is one which passes obliquely across its dorsal surface. This is for the tendon of the extensor pollicis longus muscle. The lateral lip of this groove is often very prominent, and forms an outstanding tubercle. To the medial side of this oblique groove there is a broad shallow furrow in which the tendons of the extensor digitorum communis and extensor indicis proprius muscles are lodged, whilst to its lateral side, and between it and the styloid process, there is another broad groove, subdivided by a faint ridge into two, for the passage of the tendons of the extensor carpi radialis brevis medially and the extensor carpi radialis longus laterally. The styloid process lies to the lateral side of the distal extremity; broad at its base, it becomes narrow and pointed distally where by its medial cartilage-covered surface it forms the summit of the distal triangular articular area. The lateral surface of this process is crossed obliquely distally and forwards by a shallow groove, the volar lip of which is sharp and well marked, and serves to separate it from the volar surface of the bone, whilst the dorsal lip is often emphasised by a small tubercle above. The tendon of the brachio-radialis muscle is inserted into the proximal part of either lip, and also spreads out on to the floor of the groove, whilst the tendons of the abductor pollicis longus and the extensor pollicis brevis muscles lie within the groove. To the tip of the styloid process is attached the radial collateral ligament of the wrist. On the medial side of the distal extremity is placed the *incisura ulnaris* (ulnar notch) for the reception of the head of the ulna. Concave from before backwards, and plane proximo-distally, it forms by its inferior margin a rectangular edge which separates it from the distal carpal surface. To this edge the base of the articular disc is attached, a structure which serves to separate the distal articular surface of the head of the ulna from the carpus. The volar and dorsal edges of the ulnar notch, more or less prominent, serve for the attachment of ligaments.

The proportionate length of the radius to the body height is as 1 is to 6·70–7·11.

Nutrient Foramina.—The openings of several small nutrient canals may be seen in the region of the neck. That for the shaft, which has a proximal direction, is usually placed on the volar surface of the bone, medial to the anterior oblique line, and from an inch and a half to two inches distal to the tuberosity. The dorsal surface of the distal extremity of the bone is pierced by many small vascular foramina.

Connexions.—The radius articulates with the capitulum of the humerus in the flexed position of the elbow, with the ulna to its medial side by the proximal and distal radio-ulnar joints, and with the navicular and lunate bones of the carpus distally. Proximally, the head of the bone can be felt in the intermuscular depression on the lateral side of the back of the elbow; here the bone is only covered by the skin, superficial fascia, and the thin common tendinous origin of the extensor muscles, as well as the ligaments which support it. Its position can best be ascertained by pronating and supinating the bones of the forearm, when the head will be felt rotating beneath the finger. The distal end of the bone is overlain on the volar and dorsal aspects by the flexor and extensor tendons, but its general form can be readily made out. The styloid process lying to the lateral side of the wrist in line with the extended thumb can easily be recognised; note that it reaches a more distal level than the corresponding process of the ulna. The lateral border of the lower third of the shaft can be distinctly felt, as here the bone is only overlain by tendons.

Ossification.—The centre for the shaft makes its appearance early in the second

FIG. 208.—THE OSSIFICATION OF THE RADIUS.

epiphysis capping the summit of the tuberosity has been described; this appears about the fourteenth or fifteenth year, and rapidly fuses with that process.

THE BONES OF THE HAND.

The bones of the hand, twenty-seven in number, may be conveniently divided into three groups:—

(1) The bones of the wrist or carpus—*eight* in number.

(2) The bones of the palm or metacarpus—*five* in number.

(3) The bones of the fingers and thumb or phalanges—*fourteen* in number.

The Carpus.

The ossa carpi (carpal bones) are arranged in two rows: the first, or proximal row, comprises from radial to ulnar side, the navicular (O.T. scaphoid), os lunatum (O.T. semi-lunar), os triquetrum (O.T. cuneiform), and os pisiforme or pisiform; the second or distal row includes the greater multangular (O.T. trapezium), lesser multangular (O.T. trapezoid), os capitatum (O.T. os magnum), and

month of intra-uterine life. At birth the shaft is well formed; its proximal and distal extremities are capped with cartilage, and the tuberosity is beginning to appear. A secondary centre appears in the cartilage of the distal extremity about the second or third year; this does not unite with the shaft until the twentieth or twenty-fifth year, somewhat earlier in the female. From this the carpal and ulnar articular surfaces are formed. The centre for the head appears from the fifth to the seventh year, and fuses with the neck about the age of eighteen or twenty. It forms the capitular articular surface and combines with the neck to form the area for articulation with the radial notch of the ulna. A scale-like

FIG. 209.—THE BONES OF THE RIGHT WRIST AND HAND SEEN FROM THE VOLAR ASPECT.

os hamatum (O.T. unciform). Irregularly six-sided, each of these bones possesses non-articular volar and dorsal surfaces. In addition, the marginal bones are non-articular along their ulnar and radial aspects according as they form the medial or lateral members of the series.

Navicular Bone (O.T. Scaphoid).—This is the largest as well as the most lateral

bone of the first row. Its *volar surface*, rough for the attachment of ligaments, is irregularly triangular. The distal angle on the lateral side forms a projection called the *tuberosity*; this can be felt at the base of the root of the thumb. Its *proximal surface*

is convex from side to side and before backwards for articulation with the radius. This area extends considerably over the dorsal surface of the bone. Its *distal surface* is convex from before backwards, and extends on to the dorsal aspect of the bone, slightly convex from

side to side; it is divisible into two areas, the lateral for articulation with the greater multangular, the medial for the lesser multangular. The *lateral surface* is narrow and rounded and forms a non-articular border, which extends from the radial articular surface proximally to the tuberosity distally. The *medial surface* is hollowed out in front for articulation with the head of the capitate bone. Proximal to this it displays a small semilunar-shaped facet for the os lunatum. The *dorsal non-articular surface* lies between the lateral articular surface proximally and the surface for the greater and lesser multangular bones distally. It is obliquely grooved for the attachment of the dorsal ligaments of the wrist. The navicular articulates with five bones—the radius, the os lunatum, the capitate, the lesser multangular, and the greater multangular.

Os Lunatum (O.T. Semilunar Bone).—So

called from its deeply excavated form, the os lunatum lies between the navicular on the lateral side and the os triquetrum on the medial. Its *volar surface*, of rhombic form and considerable size, is rough for the attachment of ligaments; its *proximal surface*, convex from side to side and from before backwards, articulates with the radius and in part with the distal surface of the articular disc of the wrist. Its *distal aspect*, deeply

FIG. 210.—VOLAR ASPECT OF BONES OF THE RIGHT CARPUS AND METACARPUS WITH MUSCULAR ATTACHMENTS MAPPED OUT.

FIG. 211.—DORSAL ASPECT OF BONES OF THE RIGHT CARPUS AND METACARPUS WITH MUSCULAR ATTACHMENTS MAPPED OUT.

hollowed from before backwards, is divided into two articular areas, of which the lateral is the larger; this is for the head of the capitate bone; the medial, narrow from side to side, articulates with the os hamatum. Its *lateral surface*, crescentic in shape, serves for articulation with the navicular, and also for the attachment of the interosseous ligaments which connect it with that bone. Its *medial surface*, of quadrilateral form, is cartilage-covered for articulation with the os triquetrum, and the edge which separates this from the proximal surface has attached to it the interosseous ligament which unites these two bones. The rough *dorsal non-articular surface* is much smaller than the volar; by this means the volar and dorsal surfaces of the bone can readily be determined. The os lunatum articulates with five bones—the navicular, the radius, the os triquetrum, the os hamatum, and the capitate bone.

Os Triquetrum (O. T. Cuneiform).—This bone may be recognised by the small oval or circular facet on its volar surface for the pisiform. This is placed towards the distal part of the *volar surface*, which is elsewhere rough for ligaments. The bone is placed obliquely, so that its surfaces cannot be accurately described as distal, proximal, etc.; but for convenience of description, the method already adopted is adhered to. The *proximal surface* has a convex rhombic surface for articulation with the distal surface of the articular disc in adduction of the hand, though ordinarily it does not appear to be in contact with that structure. To the medial side of this it is rough for ligaments. The *distal surface* is elongated and concavo-convex from radial to ulnar side; here the bone articulates with the os hamatum. The *lateral surface*, broader in front than behind, articulates with the os lunatum. The *medial surface*, rounded and rough, is confluent proximally and dorsally with the proximal and dorsal aspects of the bone. The *dorsal surface*, rounded and smooth laterally, is ridged and grooved medially for the attachment of ligaments. The os triquetrum articulates with three bones, viz., the pisiform, the os hamatum, and the os lunatum.

Os Pisiforme (O.I. Pisiform Bone).—About the size and shape of a large pea, the pisiform bone rests on the volar surface of the os triquetrum, with which it articulates by an oval or circular facet on its dorsal aspect. The rounded mass of the rest of the bone is non-articular, and inclines distally and laterally so as to overhang the articular facet in front and laterally. The mass of the bone is usually separated from the articular surface by a small but distinct groove. Into the summit of the bone the tendon of the flexor carpi ulnaris muscle is

FIG. 212.—THE BONES OF THE RIGHT WRIST AND HAND
SEEN FROM THE DORSAL ASPECT.

inserted, and here also the transverse carpal ligament is attached. The ulnar artery and nerve are in immediate relation with the lateral side of the bone.

FIG. 213.—THE RIGHT NAVICULAR BONE.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the right hand viewed from the volar aspect. The views on either side, and above and below, represent respectively the corresponding surfaces of the bone turned towards the reader.

concave proximo-distally, and very slightly convex from volar to dorsal side, and is for articulation with the lesser multangular; the distal, small and circular, and not always present, is for articulation with the lateral side of the base of the second metacarpal bone. The *dorsal surface*, of irregular outline, is rough for the attachment of ligaments. The greater multangular articulates with four bones, the navicular, lesser multangular, and the first and second metacarpal bones.

Lesser Multangular (O.T. Trapezoid Bone).—With the exception of the pisiform, this is the smallest of the carpal bones. Its rough *volar surface* is small and pentagonal in outline. By a small oblong surface on its *proximal aspect* it articulates with the navicular. *Distally*, by a somewhat saddle-shaped surface, it articulates with the base of the second metacarpal. Separated from this by a rough V-shaped impression prolonged from its volar aspect, is the surface on the *lateral side* for articulation with the greater multangular; this appears as if obliquely grooved from before backwards and distally.

The *medial facet* for articulation with the capitate is narrow proximo-distally, and deeply curved from before backwards. The *dorsal surface* of the bone, which is rough and non-articular, is much larger than the volar aspect. The mass of the bone,

Greater Multangular (O.T. Trapezium).—The greater multangular is the most lateral bone of the distal row of the carpus. It may be readily recognised by the oval saddle-shaped facet on its distal surface for articulation with the metacarpal bone of the thumb. From its *volar aspect* there rises a prominent *ridge*, medial to which is a groove along which the tendon of the flexor carpi radialis muscle passes. The ridge furnishes an attachment for the transverse carpal ligament, as well as for some of the short muscles of the thumb. The *proximal surface* has a half oval facet for the navicular, lateral to which it is rough, and becomes continuous with the non-articular *lateral aspect*, which serves for the attachment of ligaments. On its *medial surface* there are two facets; the proximal is a half oval,

FIG. 214.—THE RIGHT OS LUNATUM.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the right hand viewed from the volar aspect. The views on either side, and above and below, represent respectively the corresponding surfaces of the bone turned towards the reader.

dorsally, is directed distally and towards the medial side. The lesser multangular articulates with four bones—the greater multangular, navicular, and capitate bones, and the second metacarpal.

Capitate Bone (O.T. *Os Magnum*).

—This is the largest of the carpal bones. Its *volar surface* is rough and rounded. The *proximal portion* of the bone forms the *head*, and is furnished with convex articular facets which fit into the hollows on the medial surface of the navicular and distal surface of the *os lunatum*; that for the latter is medial to and separated by a slight ridge from the navicular articular area. The *distal surface*, narrow towards its volar border and broad dorsally, is subdivided usually into three facets by two ridges—that towards the lateral side is for the base of the second metacarpal;

FIG. 216.—THE RIGHT PISIFORM BONE.

NOTE.—The figure to the left represents the volar aspect of the bone; that to the right the dorsal view.

FIG. 217.—THE RIGHT GREATER MULTANGULAR BONE.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the right hand viewed from the volar aspect. The views on either side, and above and below, represent respectively the corresponding surfaces of the bone turned towards the reader.

FIG. 215.—THE RIGHT *OS TRIQUETRUM*.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the right hand viewed from the volar aspect. The views on either side, and above and below, represent respectively the corresponding surfaces of the bone turned towards the reader.

the intermediate facet is for the third metacarpal; whilst the medial facet of the three,

not always present, very small and placed near the dorsal side of the bone, is for the fourth metacarpal. The *lateral side* of the body has an articular surface for the small multangular, not infrequently separated from the navicular surface on the head by a rough line, to which the interosseous ligament connecting it with the navicular is attached. The *medial side* of the body has an elongated articular surface, usually deeply notched in front; or it may be divided anteriorly into a small circular area near the dorsal edge, and a larger posterior part. This latter articulates either singly or doubly with the *os hamatum*, the interosseous ligament which unites the two bones being attached either to the notch or to the surface separating the two articular facets. The *dorsal surface* is rough for ligaments; it is somewhat constricted below the head, the articular surface of which sweeps round its proximal border.

The capitate bone articulates with seven bones—the *os hamatum*, the *os lunatum*, the navicular, the small multangular, and the second, third, and fourth metacarpal bones; occasionally the fourth metacarpal does not articulate with the capitate.

Os Hamatum (O.T. *Unciform Bone*).

—The *os hamatum* can be readily distinguished by the hook-like process (*hamulus*) which projects from the distal and

medial aspect of its volar surface. To this is attached the transverse carpal

FIG. 218.—THE RIGHT LESSER MULTANGULAR BONE.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the right hand viewed from the volar aspect. The views on either side, and above and below, represent respectively the corresponding surfaces of the bone turned towards the reader.

slightly concave from before backwards, and are for articulation, the lateral with the fourth, and the medial with the fifth metacarpal bone. The dorsal surface, more or less triangular in shape, is rough for ligaments.

The os hamatum articulates with five bones—viz., the capitate, os lunatum, os triquetrum, and the fourth and fifth metacarpals.

The Carpus as a Whole.

When the carpal bones are articulated together they form a bony mass, the dorsal surface of which is convex from side to side. Anteriorly they present a grooved appearance, concave from side to side. This arrangement is further emphasised by the forward projection, on the medial side, of the pisiform and hamulus of the os hamatum, whilst laterally the tuberosity of the navicular and the ridge of the greater multangular help to deepen the furrow by their elevation. To these

ligament as well as some of the fibres of origin of the short muscles of the little finger. The medial side of the hamulus is sometimes grooved by the deep branch of the ulnar nerve. (Anderson, W., "Proc. Anat. Soc." Journ. Anat. and Physiol. vol. xxviii. p. 11.) The volar surface, rough for ligaments, is somewhat triangular in shape. Proximally and towards the medial side there is an elongated articular surface for the os triquetrum, convex proximally and concave distally. The lateral aspect of the bone is provided with a plane elongated facet, occasionally divided into two for articulation with the capitate bone (see above). Where the proximal and lateral surfaces meet, the angle is blunt, and has a narrow facet which articulates with the os lunatum. Distally there are two articular facets separated by a ridge; these are for articulation, the lateral with

FIG. 219.—THE RIGHT CAPITATE BONE.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the right hand viewed from the volar aspect. The views on either side, and above and below, represent respectively the corresponding surfaces of the bone turned towards the reader.

four points the transverse carpal ligament is attached, which stretches across from side to side, and thus converts the furrow into a canal through which the flexor tendons pass to reach the fingers.

FIG. 220.—THE RIGHT OS HAMATUM.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the right hand viewed from the volar aspect. The views on either side, and above and below, represent respectively the corresponding surfaces of the bone turned towards the reader.

FIG. 221.—RADIOGRAPH OF THE HAND AT BIRTH.

It will be noticed that whilst the primary centres for the metacarpus and phalanges are well ossified, the carpus is still entirely cartilaginous.

Compare this with the tarsus at birth, in which the tarsus is shown in part already ossified.

Ossification.—At birth the carpus is entirely cartilaginous. An exceptional case is figured by Lambertz, in which the centres for the capitate and triquetral bones were already present. The same authority states that it is not uncommon to meet with these centres in the second month after birth. According to Debierre (*Journ. de l'Anat. et de la Physiol.* vol. xxii. 1886, p. 285), ossification takes place approximately as follows:—

Capitate bone	11 to 12 months.
Os hamatum	12 to 14 months.
Os triquetrum	3 years.
Os lunatum	5 to 6 years.
Greater multangular.	6 years.
Navicular	6 years.
Lesser multangular	6 to 7 years.
Pisiform	10 to 12 years.

The same observer failed to note the appearance of a separate centre for the hamulus of the os hamatum, and records the occurrence of two centres for the pisiform.

The Metacarpus.

The **metacarpal bones** form the skeleton of the palm, articulating proximally with the carpus, whilst by their distal extremities or **heads** they support the bones of the digits. Five in number, one for each digit, they lie side by side and slightly divergent from each other, being separated by intervals, termed interosseous spaces. Distinguished numerically from the lateral to the medial side, they all display certain common characters; each possesses a **body** or shaft, a **base** or carpal extremity, and a **head** or phalangeal end.

The **shafts**, which are slightly curved towards the volar aspect, are narrowest towards their middle. The dorsal surface of each is marked by two divergent lines which pass distally from the dorsum of the base to tubercles on either side of the

head. The surface included between the two lines is smooth and of elongated triangular form. On either side of these lines two broad shallow grooves wind spirally on to the volar surface, where they are separated by a sharp ridge which is continuous with a somewhat triangular surface which corresponds to the volar aspect of the base. The grooved surfaces on either side of the shaft furnish origins for the interossei muscles. Close to the volar crest is the opening of the nutrient canal, which is directed towards the proximal extremity, except in the case of the first metacarpal bone.

FIG. 222.—FIRST RIGHT METACARPAL BONE.

they differ in size and shape according to their articulation.

Of the five metacarpal bones, the **first**, viz., that of the thumb, is the shortest and stoutest, the **second** is the longest, whilst the **third**, **fourth**, and **fifth** display a gradual reduction in length.

The four medial bones articulate by their bases with each other, and are united at their distal extremities by ligaments. They are so arranged as to conform to the hollow of the palm, being concave from side to side anteriorly, and convex posteriorly. The first metacarpal differs from the others in being free at its distal extremity, whilst its proximal end possesses only a carpal articular facet.

The **first metacarpal bone** is the shortest and stoutest of the series. Its shaft is compressed from before backwards. Its head, of large size, is but slightly convex from side to side, and is grooved on its volar aspect for the sesamoid bones. The base is provided with a saddle-shaped surface for articulation with the greater multangular, and has no lateral facets. Laterally there is a slight tubercle to which the abductor pollicis

The **capitulum** (head) is provided with a surface for articulation with the proximal phalanx. This area curves farther over its volar than its dorsal aspect. Convex from before backwards and from side to side, it is wider anteriorly than posteriorly; notched on its volar aspect, its edges form two prominent tubercles, which are sometimes grooved for the small sesamoid bones which may occasionally be found on the volar surface of the joint. On either side of the head of the bone there is a deep pit, behind which is a prominent tubercle; to these are attached the collateral ligaments of the metacarpo-phalangeal joints.

The **bases**, all more or less wedge-shaped in form, articulate with the carpus;

FIG. 223.—SECOND RIGHT METACARPAL BONE.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the right hand viewed from the volar aspect. The views on either side, and below, represent respectively the corresponding surfaces of the bone turned towards the reader.

and is grooved on its volar aspect for the sesamoid bones. The base is provided with a saddle-shaped surface for articulation with the greater multangular, and has no lateral facets. Laterally there is a slight tubercle to which the abductor pollicis

longus muscle is attached. The canal for the nutrient artery is directed towards the head of the bone.

The **second metacarpal bone** is recognised by its length and its broad and deeply notched base for articulation with the small multangular. It has a small half-oval facet for the large multangular on the lateral side of its base, whilst on its medial aspect it presents a narrow vertical strip for the capitate, in front of which there are two half-oval surfaces for the third metacarpal. To the dorsal aspect of the base is attached the tendon of the extensor carpi radialis longus muscle, whilst the flexor carpi radialis is inserted into the volar surface.

The **third metacarpal bone** can usually be recognised by the pointed **styloid process** which springs from the dorsum of its base, and is directed

FIG. 224.—THIRD RIGHT METACARPAL BONE.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the right hand viewed from the volar aspect. The views on either side, and below, represent respectively the corresponding surfaces of the bone turned towards the reader.

FIG. 225.—FOURTH RIGHT METACARPAL BONE.

FIG. 226.—FIFTH RIGHT METACARPAL BONE.

NOTE.—The bone in each figure is represented in the centre of the figure in the position which it occupies in the right hand viewed from the volar aspect. The views on either side, and below, represent respectively the corresponding surfaces of the bone turned towards the reader.

towards the radial side. Superiorly there is a facet on the base for the capitate. To the lateral side there are two half-oval facets for the second metacarpal. To the medial side there are usually two small oval or nearly circular facets for the

fourth metacarpal. The extensor carpi radialis brevis muscle is inserted into the dorsum of the base.

The **fourth metacarpal bone** may be recognised by a method of exclusion. It is unlike either the first, second, or third, and differs from the fifth, which it resembles in size, by having articular surfaces on both sides of its base. Proximally there is a quadrilateral surface on its base for articulation with the os hamatum. On its lateral side there are usually two small oval facets for the third metacarpal. Of these facets the dorsal one not infrequently has a narrow surface for articulation with the capitate. On the medial side there is a narrow articular strip for the base of the fifth metacarpal.

The **fifth metacarpal bone** can be recognised by its size and the fact that it has only one lateral articular facet on its base, namely, that on its lateral side for the fourth metacarpal. The carpal articular surface is saddle-shaped, and there is a **tubercle** on the medial side of the base for the insertion of the extensor carpi ulnaris muscle.

As has been already pointed out, the openings of the arterial canals are usually seen on the volar surfaces of the metacarpals, those of the four medial bones being directed proximally towards the base or carpal end, differing in this respect from that of the first metacarpal, which is directed distally towards the head or phalangeal extremity. The opening of the latter canal usually lies to the medial side of the volar aspect of the shaft.

Ossification.—The metacarpal bones are developed from primary and secondary centres; but there is a remarkable difference between the mode of growth of the first and the remaining four metacarpals, for whilst the **shaft** and **head** of the first metacarpal are developed from the primary ossific centre, and its **base** from a secondary epiphysis, in the case of the second, third, fourth, and fifth metacarpals the **shafts** and **bases** are developed from the primary centres, the **heads** in these instances being derived from the secondary epiphyses. In this respect, therefore, as will be seen hereafter, the metacarpal bone of the thumb resembles the phalanges in the manner of its growth, a circumstance which has given rise to considerable discussion as to whether the thumb is to be regarded as possessing three phalanges and no metacarpal, or one metacarpal and two phalanges. Broom (*Anat. Anz.* vol. 28), by a reference to reptilian forms, offers an explanation in regard to the difference in the mode of ossification of the first metacarpal on the ground that the most movable joint is that between the first metacarpal and the carpus, whereas on the other digits the most movable joints are those between the metacarpals and phalanges. In consequence those ends of the bones which enter into the formation of the joints where movement is most free are the ends where the epiphyses will appear. This is in accordance with the law to be suggested in connexion with the fibula. The primary centres for the shafts and bases of the second, third, fourth, and fifth metacarpals appear in that order during the ninth or tenth week of intra-uterine life, some little time after the terminal phalanges have begun to ossify; that for the shaft and head of the metacarpal bone of the thumb a little later. At birth the shafts of the bones are well formed. The secondary centres from which the heads of the second, third, fourth, and fifth metacarpals and the base of the first are developed, appear about the third year, and usually completely fuse with the shafts about the age of twenty. There may be an independent centre for the styloid process of the third metacarpal, and there is usually a scale-like epiphysis on the head of the first metacarpal which makes its appearance about eight or ten, and rapidly unites with the head. The occurrence of a basal epiphysis in the second metacarpal bone has been noticed.

Phalanges Digitorum Manus.

The **phalanges** or finger bones are fourteen in number—three for each finger, and two for the thumb.

Named numerically in order from the proximal toward the distal ends of the fingers, the **phalanx prima** (**first phalanx**), the longest and stoutest of the three, has a semi-cylindrical shaft which is curved slightly forwards. The volar surface is flat, and bounded on either side by two sharp borders to which the sheath of the flexor tendons is attached. The dorsal surface, convex from side to side, is overlain by the extensor tendons. The proximal end, considerably enlarged, has a simple oval concave surface, which rests on the head of its corresponding metacarpal bone. On either side of this the bone displays a tubercular form, and affords attachment to

the collateral ligaments of the metacarpo-phalangeal joint, and also to the interossei muscles. The distal end is much smaller than the proximal; the convex articular surface is divided into two condyles by a central groove running from before backward. The **phalanx secunda** (**second phalanx**) resembles the first in general form, but is of smaller size. It differs, however, in the form of its proximal articular surface, which is not a simple oval concavity, but is an oval area divided into two small, nearly circular concavities by a central ridge passing from volar to dorsal edge; these articulate with the condylic surfaces of the proximal phalanx. Into the margins of its volar surface near the proximal end are inserted the split portions of the tendon of the flexor digitorum sublimis, whilst on the dorsal aspect of the proximal end the central slip of the extensor digitorum communis muscle is attached. The **phalanx tertia** (**third, terminal, or ungual phalanx**) is the smallest of the three; it is easily recognised by the spatula-shaped surface on its distal extremity which supports the nail. The articular surface on its proximal end resembles that on the proximal end of the second phalanx, but is smaller. On the volar aspect of this end of the bone there is a rough surface for the insertion of the tendon of the flexor digitorum profundus muscle. The dorsal surface of the same extremity has attached to it the terminal portions of the tendon of the extensor digitorum communis muscle. The phalanges of the thumb resemble in the arrangement of their parts the first and third phalanges of the fingers.

The **arterial canals**, usually two in number, placed on either side of the palmar aspect and nearer the distal than the proximal end of the bone, are directed towards the finger-tips.

Ossification.—The phalanges are ossified from primary and secondary centres. From the former, which appear as early as the ninth week of

FIG. 227.—THE PHALANGES OF THE FINGERS (Volar Aspect).

FIG. 228.—RADIOGRAPHS OF FŒTAL HANDS.

1. About ten weeks. Here the ossific nuclei of the terminal phalanges and the four medial metacarpal bones are seen.
2. A little later. The centre for the metacarpal for the thumb is now present, as also the centres for the proximal row of phalanges. The centres of the medial row of phalanges have appeared in the case of the middle and ring fingers.
3. During the third month. All the primary centres for the metacarpal bones and phalanges are now developed.
4. About the fourth to fifth month.
5. About the sixth to seventh month.

fœtal life, the shaft and distal extremities are developed; whilst the latter, which begin to appear about the third year, form the proximal epiphyses which unite with the shafts

from eighteen to twenty. Dixey (*Proc. Roy. Soc.* xxx. and xxxi.) has pointed out that the primary centre in the distal phalanges commences to ossify in the distal part of the bone rather than towards the centre of the shaft. This observation has been confirmed by Lambertz, who further demonstrates the fact that ossification commences earlier in the distal phalanges than in any of the other bones of the hand. Of the other phalanges, those of the first row, beginning with that of the third finger, next ossify, subsequent to the appearance of ossific centres in the shafts of the metacarpal bones, whilst the second or middle row of the phalanges is the last to ossify about the end of the third month. Sewell has recorded a case in which the proximal phalanx had a distal as well as a proximal epiphysis.

Ossa Sesamoidea.

Two little oval nodules (sesamoid bones), which play in grooves on the volar aspect of the articular surface of the head of the first metacarpal bone, are constantly met with in the tendons and ligaments of that metacarpo-phalangeal articulation. Similar nodules, though of smaller size, are sometimes formed in the corresponding joints of the other fingers, more particularly the index and little finger; as Thilenius has pointed out (*Morph. Arbeiten*, vol. v.), these are but the persistence of cartilaginous elements which have a phylogenetic interest.

THE LOWER LIMB.

THE PELVIC GIRDLE AND THE INFERIOR EXTREMITY.

The **pelvic girdle** is formed by the articulation of the two hip bones with the sacrum dorsally, and their union with each other ventrally, at the joint called the symphysis pubis.

Os Coxæ.

The **hip bone (os coxæ)** (O.T. **innominate**) is the largest of the "flat" bones of the skeleton. It consists of three parts—the **ilium**, the **ischium**, and the **os pubis**—primarily distinct, but fused together in the process of growth to form one large irregular bone. The coalescence of these elements takes place in and around the **acetabulum**, a large circular articular hollow which is placed on the lateral side of the bone. The expanded wing-like part above this is the **ilium**; the stout V-shaped portion below and behind it constitutes the **ischium**; while the <-shaped part to the medial side, and in front and below, forms the **os pubis**. The two latter portions of the bone enclose between them a large aperture of irregular outline, called the **foramen obturatum** (**obturator foramen**), which is placed in front and below, and to the medial side of the acetabulum.

The **ilium**, almost a quadrant in form, consists of an expanded plate of bone, having a curved superior border, the **crista iliaca** (**iliac crest**). Viewed from the side, this forms a curve corresponding to the circumference of the circle of which the bone is the quadrant; viewed from above, however, it will be seen to display a double bend—convex anteriorly and laterally, and concave posteriorly and laterally. The **iliac crest** is stout and thick, and for descriptive purposes is divided into a **labium externum** (**external lip**), a **labium internum** (**internal lip**), and an **intermediate surface** (**linea intermedia**), which is broad behind, narrowest about its middle, and wider again in front. About $2\frac{1}{2}$ inches from the anterior extremity of the crest the external lip is usually markedly prominent and forms a projecting tubercle, which can readily be felt in the living. Attached to these surfaces and lips anteriorly are the muscles of the flank, whilst from them posteriorly the **latissimus dorsi**, **quadratus lumborum**, and **sacro-spinalis** muscles derive their origins. The crest ends in front in a pointed process, the **spina iliaca anterior superior** (**anterior superior iliac spine**). To this the lateral extremity of Poupert's inguinal ligament is attached, as well as the **sartorius** muscle, which also arises from the edge of bone immediately below it, whilst from the same process and from the

anterior end of the external lip of the iliac crest the tensor fasciæ latæ muscle takes origin.

The **anterior border** of the ilium stretches from the anterior superior iliac spine to the margin of the acetabulum below. Above, it is thin; but below, it forms a thick blunt process, the **spina iliaca anterior inferior** (anterior inferior iliac spine). From this the rectus femoris muscle arises, whilst the stout fibres of the

FIG. 229.—THE RIGHT HIP BONE SEEN FROM THE LATERAL SIDE.

ilio-femoral ligament of the hip-joint are attached to it immediately above the acetabular margin. Posteriorly, the crest terminates in the **spina iliaca posterior superior** (posterior superior iliac spine). Below this, the posterior border of the bone is sharp and irregularly notched, terminating in a prominent angle, the **spina iliaca posterior inferior** (posterior inferior iliac spine), in front of which the edge of the bone becomes thick and rounded, and forms a wide notch which sweeps forwards and downwards to join the mass of bone behind the acetabulum, where it becomes fused with the ischium; this is called the **incisura ischiadica major** (greater sciatic notch).

The ilium has two surfaces, medial and lateral. The *lateral surface* is divided into two parts, viz., a lower acetabular, and an upper gluteal part. The lower forms a little less than the upper two-fifths of the acetabular hollow, and is separated from the larger gluteal surface above by the upper prominent margin of the articular cavity. The *gluteal surface*, broad and expanded, is concavo-convex from behind forward. It is traversed by **three rough gluteal (O.T. curved) lines**, well seen in strongly developed bones, but often faint and indistinct in feebly marked specimens. Of these the *linea glutæa inferior* (*inferior gluteal line*) curves backwards from a point immediately above the anterior inferior spine towards the greater sciatic notch posteriorly; the bone between this and the acetabular margin is marked by a rough shallow groove, from which the reflected head of the rectus femoris muscle

FIG. 230.—LATERAL ASPECT OF THE RIGHT HIP BONE WITH THE ATTACHMENTS OF THE MUSCLES MAPPED OUT.

is for the origin of the *glutæus medius* muscle, whilst the rough surface immediately above and behind it is for some of the fibres of origin of the *glutæus maximus* muscle.

The *medial surface* of the ilium is divided into two areas which present very characteristic differences. The **posterior or sacral part**, which is rough, displays, in front, a somewhat smooth, auricular surface (*facies auricularis*) which is cartilage-coated in the recent condition, and articulates with the sacrum.

This area is said to be proportionately smaller in the female, whilst curving round in front of its anterior margin there is often a groove, for the attachment of the fibres of the anterior sacro-iliac ligaments, called the pre-auricular sulcus. According to Derry this groove is better marked in the female, and may be regarded as characteristic of that sex.

Above and behind this there is an elevated irregular area, the **tuberosity** (*tuberositas iliaca*), which is here and there deeply pitted for the attachment of the strong interosseous and posterior sacro-iliac ligaments. Above this the bone becomes confluent with the inner lip of the iliac crest, and here it affords an origin to the sacro-spinalis and multifidus muscles, and some of the fibres of the quadratus lumborum. The anterior part of the medial aspect of the bone is smooth and extensive; it

arises. The *linea glutæa anterior* (*anterior gluteal line*) commences at the crest of the ilium, about one inch and a half behind the anterior superior iliac spine, and sweeps backwards and downwards towards the upper and posterior part of the greater sciatic notch. The surface between this line and the preceding furnishes an extensive origin for the *glutæus minimus* muscle. The *linea glutæa posterior* (*posterior gluteal line*) leaves the iliac crest about two and a half inches in front of the posterior superior iliac spine, and bends downwards and slightly forwards in a direction anterior to the posterior inferior spine. The area between this and the anterior gluteal line

is subdivided by an oblique ridge, called the *ilio-pectineal line* (*linea arcuata*), which passes forwards and distally, from the most prominent point of the auricular surface towards the medial side of the ilio-pectineal eminence, which is placed just above and in front of the acetabulum and marks the fusion of the

FIG. 231.—THE RIGHT HIP BONE (Medial Aspect).

ilium with the os pubis. Above this the bone forms the shallow *iliac fossa*, from the floor of which the *iliacus* muscle arises, whilst leading from the fossa, below and in front, there is a shallow furrow, passing over the superior acetabular margin, between the anterior inferior iliac spine on the lateral side and the ilio-pectineal eminence medially, for the lodgment of the tendinous and fleshy part of the *ilio-psoas* muscle. If held up to the light the floor of the deepest part

of the iliac fossa will be seen to be formed of but a thin layer of bone. A nutrient foramen of large size is seen piercing the bone towards the posterior part of the fossa. Below and behind the ilio-pectineal line the medial surface of the ilium forms a small portion of the wall of the small pelvis; the bone here is smooth, and rounded off posteriorly into the greater sciatic notch, where it becomes confluent with the medial aspect of the ischium. This part of the bone is proportionately longer in the female than in the male, and forms with the ischium a more open angle. Just anterior to the greater sciatic notch there are usually the openings of one or two large vascular foramina. From this surface arise some of the posterior fibres of the obturator internus muscle.

The **ischium** constitutes the lower and posterior part of the hip bone. Superiorly its **body** (corpus) forms somewhat more than the inferior two-fifths of the acetabulum together with the bone supporting it behind and medially. Below this, the **superior ramus** passes downwards and posteriorly as a stout three-sided piece of bone, from the inferior extremity of which a compressed bar of bone, called the **inferior ramus**, extends forwards at an acute angle. This latter unites in front and above with the inferior ramus of the pubis, and encloses the aperture called the obturator foramen.

Superiorly, and on the lateral aspect of the ischium, the acetabular surface is separated from the bone below by a sharp and prominent margin, which is, however, deficient in front, where it corresponds to the **acetabular notch** (O.T. **cotyloid notch**) leading into the articular hollow; the floor of this notch is entirely formed by the ischium. Below the prominent acetabular margin there is a well-marked groove in which the tendon of the obturator externus lies. Beneath this the antero-lateral surface of the superior and inferior rami furnish surfaces for the attachments of the obturator externus, quadratus femoris, and adductor magnus muscles. The postero-lateral surface of the ischium forms the convex surface on the back of the acetabulum. The medial border of this is sharp and well defined, and is confluent above with the border of the ilium, which sweeps round the great sciatic notch. From this border, on a level with the lower edge of the acetabulum, there springs a pointed process, the **spina ischiadica** (**ischial spine**), to which are attached the sacro-spinous ligament and the superior gemellus muscle. Inferior to this, the postero-lateral surface narrows rapidly, its medial border just below the spine being hollowed out to form the **incisura ischiadica minor** (**lesser sciatic notch**). The lower part of this surface and the angle formed by the two rami are capped by an irregularly rough piriform mass called the **tuber ischiadicum** (**ischial tuberosity**). This is divided by an oblique ridge into two areas, the upper and lateral for the tendon of origin of the semimembranosus muscle, the lower and medial for the conjoined heads of the biceps and semitendinosus muscles. Its prominent medial lip serves for the attachment of the sacro-tuberous ligament, whilst its lateral edge furnishes an origin for the quadratus femoris muscle; in front and below, the adductor magnus muscle is attached to it.

The *medial surface* of the body and superior ramus of the ischium form in part the wall of the small pelvis. Smooth and slightly concave from before backwards, and nearly plane from above downwards, it is widest opposite the level of the ischial spine. Below this, its posterior edge is rounded and forms a groove leading to the lesser sciatic notch, along and over which the tendon of the obturator internus passes. To part of this surface the fibres of the obturator internus are attached, whilst the medial aspect of the spine supplies points of origin for the coccygeus and levator ani muscles, as well as furnishing an attachment to the "white line" of the pelvic fascia. The medial surface of the inferior ramus of the ischium is smooth, and so rounded that its inferior edge tends to be everted. To this, as well as to its margin, is attached the crus penis, together with the ischio-cavernosus, obturator internus, transversus perinei, and sphincter muscle of the membranous urethra. In the female, structures in correspondence with these are found.

The anterior part of the hip bone is formed by the **os pubis**; it is by means of the union of this bone with its fellow of the opposite side that the pelvic girdle is completed in front.

The **pubis** (**os pubis**) consists of two rami—a superior (**ramus superior ossis**

pubis) and an *inferior* (ramus inferior ossis pubis). The broad part of the bone formed by the fusion of these two rami is the *body*.

The *body* of the os pubis has two surfaces. Of these the *posterior* or *postero-superior* is smooth, and forms the anterior part of the wall of the small pelvis; hereto are attached the levator ani muscle and pubo-prostatic ligaments, and on it rests the bladder. The *anterior* or *antero-inferior* surface is rougher, and furnishes origins for the gracilis, adductor longus, adductor brevis, and some of the fibres of the obturator externus muscles. The *medial border* is provided with an elongated oval cartilage-covered surface by means of which it is united to its fellow of the opposite side, the joint being called the *facies symphyseos* (symphyseal surface) of the pubic bone. The *superior border*, thick and rounded, projects somewhat, so as to overhang the anterior surface. It is called the *crest*. Internally this forms with the medial border or symphysis the *angle*, whilst laterally it terminates in a pointed process, the *tuberculum pubicum* (pubic tubercle). From

FIG. 232.—MUSCLE ATTACHMENTS TO THE LATERAL SURFACE OF THE OS PUBIS AND ISCHIUM.

the crest arise the rectus abdominis and pyramidalis muscles, and to the tubercle is attached the medial end of the inguinal ligament. Passing upwards and laterally from the lateral side of the body towards the acetabulum, of which it forms about the anterior fifth, is the *superior ramus*. This has three surfaces: an antero-superior, an antero-inferior, and an internal or posterior. The *antero-superior* surface is triangular in form. Its apex corresponds to the pubic tubercle; its anterior inferior border to the *crista obturatoria* (obturator crest), leading from the pubic tubercle to the upper border of the acetabular notch; whilst its sharp postero-superior border trends upwards and laterally from the tubercle, and is continuous with the iliac portion of the ilio-pectineal line just medial to the ilio-pectineal eminence, forming as it passes along the superior ramus the pubic portion of that same line (*pecten ossis pubis*). On this line, just medial to the ilio-pectineal eminence, there is often a short sharp crest which marks the insertion of the psoas minor. The base of the triangle corresponds to the ilio-pectineal eminence above and the upper margin of the acetabular notch below. Slightly hollow from side to side, and convex from before backwards, this surface provides an origin for, and is in part overlain by, the pectineus muscle. The *posterior* or *postero-superior* surface of the superior ramus is smooth, concave from side to side, and slightly rounded from above downwards; by its sharp inferior curved border it completes the obturator foramen, as seen from behind. The

antero-inferior surface forms the roof of the broad *sulcus obturatorius* (obturator groove) which passes obliquely downwards and forwards between the lower margin of the antero-superior surface in front and the inferior sharp border of the medial surface behind. The **inferior ramus of the os pubis** passes downwards and laterally from the lower part of the body. Flattened and compressed, it unites with the inferior ramus of the ischium, and thus encloses the obturator foramen, whilst in correspondence with its fellow of the opposite side it completes the formation of the pubic arch. *Anteriorly* it furnishes origins for the gracilis, adductor brevis, and adductor magnus muscles, as well as some of the fibres of the obturator externus muscle. Its *medial surface* is smooth, whilst its lower border, rounded or more or less everted, has attached to it the anterior part of the crus penis and the arcuate (O.T. subpubic) ligament.

The **acetabulum** is the nearly circular hollow in which the head of the thigh bone fits. As has been already stated, it is formed by the fusion of the ilium and ischium and os pubis in the following proportions: the ilium a little less than two-fifths, the ischium somewhat more than two-fifths, the os pubis constituting the remaining one-fifth. It is so placed as to be directed downwards, laterally, and forwards, and is surrounded by a prominent margin, to which the capsule and glenoid lip of the hip-joint are attached. Opposite the obturator foramen this margin is interrupted by the *incisura acetabuli* (acetabular notch); immediately lateral to the ilio-pectineal eminence the margin is slightly hollowed, whilst occasionally there is a feeble notching of the border above and behind. These irregularities in the outline of the margin correspond to the lines of fusion of the ilium and pubis and the ilium and ischium respectively. The floor of the acetabulum is furnished with a horseshoe-shaped articular surface, which lines the circumference of the hollow, except in front, where it is interrupted by the acetabular notch. It is broad above; narrower in front and below. Within this articular surface there is a more or less circular rough area (*fossa acetabuli*) continuous in front and below with the floor of the acetabular notch. This, somewhat depressed below the surface of the articular area, lodges a quantity of fat, and provides accommodation for the intra-articular ligament of the joint. As may be seen by holding the bone up to the light, the floor of this part of the acetabulum is not usually of great thickness. The major part of the non-articular area is formed by the ischium, which also forms the floor of the acetabular notch.

The **foramen obturatum** (obturator foramen) lies in front of, below, and medial to the acetabulum. The margins of this opening, which are formed in front and above by the os pubis, and behind and below by the ischium, are sharp and thin, except above, where the under surface of the superior ramus of the pubis is channelled by the obturator groove. Below, and on either side of this groove, two tubercles can usually be seen. The one, situated on the edge of the ischium, just in front of the cotyloid notch, is named the **posterior obturator tubercle**; the other, placed on the lower border of the posterior surface of the superior ramus of the os pubis, is called the **anterior obturator tubercle**. Between these two tubercles there passes a ligamentous band, which converts the groove into a canal along which the obturator vessels and nerve pass. Elsewhere in the fresh condition the obturator membrane stretches across the opening from margin to margin. The form of the foramen varies much, being oval in some specimens, in others more nearly triangular; its relative width in the female is greater than in the male.

Nutrient foramina for the ilium are seen on the floor of the iliac fossa, just in front of the auricular surface; on the pelvic aspect of the bone, close to the greater sciatic notch; and on the gluteal surface laterally, near the centre of the anterior gluteal line. For the ischium, on its pelvic surface, and also laterally on the groove below the acetabulum. For the pubis, on the surface of the body, and deeply also from the acetabular fossa.

Connexions.—The hip bone articulates with the sacrum behind, with the femur to the lateral side and below, and with its fellow of the opposite side medially and in front. Each of its three parts comes into direct relation with the surface. Above, the iliac crest assists in forming the iliac furrow, which serves to separate the region of the flank from that of the buttock. In front, the anterior superior iliac spine forms a definite landmark; whilst behind, the posterior superior iliac spines will be found to correspond with dimples situated on either side of the median plane of the root of the back. The symphysis, the crest, and tubercle of

the pubis can all be distinguished in front, though overlain by a considerable quantity of fat, whilst the position of the tuberosities of the ischia, when uncovered by the great gluteal muscles in the flexed position of the thigh, can readily be ascertained. In the perineal region the outline of the pubic and ischial rami can easily be determined by digital examination.

Ossification commences in the ilium about the ninth week of intra-uterine life; about the fourth month a centre appears below the acetabulum for the ischium, the os pubis being developed from a centre which appears in front of the acetabulum about the fifth or sixth month. At birth the form of the ilium is well defined; the body and part of the tuberosity of the ischium are ossified, as well as the superior ramus and part of the body of the os pubis. All three parts enter into the formation of the sides of the acetabulum, and by the third year have converged to form the bottom of that hollow, being separated from each other by a tri-radiate piece of cartilage, in which, about the twelfth year, independent ossific centres make their appearance, which, may or may not become fused with the adjacent bones. In the latter case they unite to form an independent ossicle, the *os acetabuli*, which subsequently fuses with and forms the acetabular part of the os pubis. By the age of sixteen the ossification of the acetabulum is usually completed, whilst the rami of the ischium and os pubis commonly unite about the tenth year. Secondary centres, seven in number, make their appearance about the age of puberty, and are found in the following situations: one for the anterior inferior iliac spine; one for the ventral two-thirds of the iliac crest and the anterior superior iliac spine which grows backwards, one for the posterior superior iliac spine and dorsal third of the iliac crest which grows forwards—these two unite about the twentieth year; a scale-like epiphysis over the tuberosity of the ischium; a separate epiphysis for the spine of the ischium; (?) a point for the tubercle and another for the angle of the os pubis. Fusion between these and the primary centres is usually complete between the twenty-second and twenty-fifth years. Le Damany states that the proportionate depth of the acetabular cavity at the sixth month of foetal life is greater than at birth. In the third year a rapid increase in its depth again takes place correlated with the assumption of the erect position.

Parsons (*Journ. Anat. and Physiol.* vol. xxxvii. p. 315) regards the ischial epiphysis as the homologue of the hypo-ischium in reptiles, and suggests that the epiphysis over the angle of the pubis may represent the epipubic bone of marsupials.

FIG. 233.—OSSIFICATION OF THE HIP BONE.

The Pelvis.

The **pelvis** is formed by the union of the hip bones with each other in front, and with the sacrum behind. In man the dwarfed caudal vertebræ (coccygeal) are curved forwards and so encroach upon the limits of the pelvic cavity inferiorly. The pelvis is divided into two parts by the ilio-pectineal lines, which curve forwards from the upper part of the lateral parts of the sacrum behind to the roots of the tubercles of the os pubis in front. The part above is called the **pelvis major** (large pelvis), and serves by the expanded iliac fossæ to support the abdominal contents; the part below, the **pelvis minor** (small pelvis), contains the pelvic viscera, and in the female forms the bony canal through which at full term the fœtus is expelled.

The **small pelvis** is bounded in front by the symphysis pubis in the median plane, and by the body and rami of the os pubis on either side, laterally by the smooth medial surfaces of the ischia and ischial rami, together with a small part of the ilium below the iliac portion of the ilio-pectineal line. Springing from the posterior margin of the ischium are the inturned ischial spines. Behind, the broad curved

FIG. 234.—THE MALE PELVIS SEEN FROM THE FRONT.

anterior surface of the sacrum, and below it, the small and irregular coccyx, form its posterior wall. Between the sides of the sacrum behind, and the ischium and ilium in front and above, there is a wide interval, called the **greater sciatic notch**, which is, however, bridged across in the recent condition by the sacro-tuberous and sacro-spinous ligaments, which thus convert it into two foramina—the larger above

FIG. 235.—THE FEMALE PELVIS SEEN FROM THE FRONT.

the spine of the ischium, the greater sciatic foramen; the lower and smaller below the spine, called the lesser sciatic foramen.

Apertura Pelvis Superior.—The upper opening of the small pelvis is bounded in front by the symphysis pubis, with the body of the pubis on either side; laterally by the ilio-pectineal lines; and behind by the sacral promontory. The circumference of this aperture is often called the **brim of the small pelvis**; in the male it is

heart-shaped, in the female more oval. The *antero-posterior* or *conjugate diameter* is measured from the sacro-vertebral angle to the symphysis pubis; the *oblique diameter* from the sacro-iliac joint of one side to the ilio-pectineal eminence of the other; whilst the *transverse diameter* is taken across the greatest width of the pelvic aperture.

Apertura Pelvis Inferior.—The lower opening is bounded anteriorly by the *arcus pubis* (pubic arch), formed in front and above by the bodies of the ossa pubis, with the symphysis between them, and the inferior pubic rami below and on either side. These latter are continuous with the ischial rami, which pass backwards and laterally to the ischial tuberosities, which are placed on either side of this aperture. In the median plane behind, the tip of the coccyx projects forward; and in the recent condition the interval between this and the ischial tuberosities is bridged across by the sacro-tuberous ligament, the inferior edge of which necessarily assists in determining the shape of the outlet.

As the anterior wall of the cavity, formed by the symphysis pubis, measures from $1\frac{1}{2}$ to 2 inches, whilst the posterior wall, made up of the sacrum and coccyx, is from 5 to 6 inches in length, it follows that the planes of the inlet and outlet are not parallel, but placed at an angle to each other. The term *axis of the pelvis* is given to lines drawn at right angles to the centres of these planes. Thus, with the pelvis in its true position, when the figure is erect, the axis of the upper opening corresponds to a line drawn downwards and backwards from the umbilicus towards the tip of the coccyx below, whilst the axis of the lower opening is directed downwards and slightly backwards, or downwards and a little forwards, varying according to the length of the coccyx. Between these two planes the axis of the cavity, as it passes through planes of varying degrees of obliquity, describes a curve repeating fairly closely the curve of the sacrum and coccyx.

Position of the Pelvis.—The position of the pelvis in the living, when the figure is erect, may be approximately represented by placing it so that the anterior superior iliac spines and the symphysis pubis lie in the same vertical plane. Under these conditions the plane of the upper opening is oblique, and forms with a horizontal line an angle of from 50° to 60° . The position of the pelvis depends upon the length of the ilio-femoral ligaments of the hip-joint, being more oblique when these are short, as usually happens in women in whom the anterior superior iliac spines tend to lie in a plane slightly in advance of that occupied by the symphysis pubis. In cases where the ilio-femoral ligament is long a greater amount of extension of the hip-joint is permitted, and this leads to a lessening of the obliquity of the pelvis. This condition, which is more typical of men, results in the anterior superior iliac spines lying in a plane slightly posterior to the plane of the symphysis, whilst the angle formed by the plane of the inlet and the horizontal is thereby reduced. Bearing in mind the oblique position of the pelvis, it will now be seen that the front of the sacrum is directed downwards more than forwards, and that the sacral promontory is raised as much as from $3\frac{1}{2}$ to 4 inches above the upper border of the symphysis pubis, lying higher than the level of a line connecting the two anterior superior iliac spines. From the manner in which the sacrum articulates with the ilia, it will be noticed that the weight of the trunk is transmitted downwards through the thickest and strongest part of the bone (see Architecture, Appendix A) to the upper part of the acetabula, where these rest on the heads of the femora.

Sexual Differences.—The female pelvis is lighter in its construction than that of the male; its surfaces are smoother, and the indications of muscular attachments less marked. Its height is less and the splay of its walls not so pronounced as in the male, so that the female pelvis has been well described as a short segment of a long cone as contrasted with the male pelvis, which is a long segment of a short cone. The cavity of the small pelvis in the female is more roomy, and the ischial spines not so much inturned. The pubic arch is wide and rounded, and will usually admit a right-angled set-square being placed within, so that the summit touches the inferior surface of the symphysis pubis, whilst the sides lie in contact with the ischial rami. In the male the arch is narrow and angular, forming an angle of from 65° to 70° . The greater sciatic notch in the female is wide and shallow. The distance from the posterior edge of the body of the ischium to the posterior inferior iliac spine is longer, measuring on an average 50 mm. (2 inches) in the female, as contrasted with 40 mm. ($1\frac{5}{8}$ inches) in the male. The angle formed by the ischial and iliac borders is more contracted and acute in the male as compared with the

female, in whom it is wider and more open. In the female the acetabulum is proportionately smaller than in the male.

The upper opening in the female is large and oval or reniform, as compared with the cribbed and heart-shaped aperture in the male. The sacro-vertebral angle is more pronounced in the female, and the obliquity of the upper opening greater. The sacrum is shorter and wider. The posterior superior iliac spines lie wider apart; the pubic crests are longer; and the pubic tubercles are separated by a greater interval than in man. The outlet is larger; the tuberosities of the ischia are farther apart; and the coccyx does not project forward so much. The curve of the sacrum is liable to very great individual variation. As a rule the curve is more uniform in the male, whilst in the female it tends to be flatter above and more accentuated below. There is a greater proportionate width between the acetabular hollows in the female than in the male. Of much importance from the standpoint of the obstetrician are the various diameters of the small pelvis. In regard to this it is worthy of note that the plane of "greatest pelvic expansion" extends from the union between the second and third sacral vertebræ behind, to the middle of the symphysis pubis in front, its lateral boundaries on either side corresponding with the mid-point of the medial surface of the acetabulum; whilst the plane of "least pelvic diameter" lies somewhat lower, and is defined by lines passing through the sacro-coccygeal articulation, the ischial spines, and the lower third of the symphysis pubis (Norris). Subjoined is a table showing the principal average measurements in the two sexes :—

PELVIS MAJOR.

	Males.	Females.
Maximum distance between the iliac crests .	11½ in., or 282 mm.	10¾ in., or 273 mm.
Distance between the anterior superior iliac spines	9½ in., or 240 mm.	9¾ in., or 250 mm.
Distance between the last lumbar spine and the front of the symphysis pubis	7 in., or 176 mm.	7⅞ in., or 180 mm.

PELVIS MINOR.

	MALES.		FEMALES.			
	Upper Opening.	Lower Opening.	Upper Opening.	Cavity.		Lower Opening.
				Greatest.	Least.	
Antero-posterior (conjugate) diameter	4 in., or 101 mm.	3¾ in., or 95 mm.	4⅜ in., or 110 mm.	5 in., or 127 mm.	4⅝ in., or 110 mm.	4½ in., or 115 mm.
Oblique diameter .	4¾ in., or 120 mm.	3½ in., or 88 mm.	5 in., or 125 mm.	...	...	4½ in., or 115 mm.
Transverse diameter .	5 in., or 127 mm.	3½ in., or 88 mm.	5¼ in., or 135 mm.	4⅞ in., or 125 mm.	4⅜ in., or 110 mm.	4⅝ in., or 110 mm.

Growth of the Pelvis.—From the close association of the pelvic girdle with the lower limb we find that its growth takes place concurrently with the development of that member. At birth the lower limbs measure but a fourth of the entire body length; consequently at that time the pelvis, as compared with the head and trunk, is relatively small. At this period of life the bladder in both sexes is in greater part an abdominal organ, whilst in the female the uterus has not yet sunk into the small pelvic cavity, and the ovaries and uterine tubes rest in the iliac fossæ. The sacro-vertebral angle, though readily recognised, is as yet but faintly marked. Coincident with the remarkable growth of the lower limbs and the assumption of the erect position when the child begins to walk, striking changes take place in the form and size of the pelvis. These consist in a greater expansion of the iliac bones necessarily associated with the growth of the muscles which control the movements of the hip, together with a marked increase in the sacro-vertebral angle due to the development of a forward lumbar curve; at the same time, the weight of the trunk being thrown on the sacrum causes the elements of that bone to sink to a lower level between the hip bones. The cavity of the small pelvis increases in size proportionally, and the viscera afore-mentioned now begin to sink down and have assumed a position within the pelvis by the fifth or sixth year. The extension of the thighs in the upright position necessarily brings about a more pronounced pelvic obliquity, whilst the stoutness and thickness of the ilium over the upper part of the acetabulum is much increased to withstand the pressure to which it is obviously subjected. Coincident with this is the gradual development

of the iliac portion of the ilio-pectineal line, which serves in the adult to separate sharply the large from the small pelvis. This part of the bone is remarkably strong, as will be shown (see Architecture, Appendix A), and serves to transmit the body weight from the sacrum to the thigh bone. The sexual differences of the pelvis, so far as they refer to the general configuration of this part of the skeleton, are as pronounced at the third or fourth month of foetal life as they are in the adult. (Fehling, *Ztschr. f. Geburtsh. u. Gynaek.* Bd. ix. and x.; A. Thomson, *Journ. Anat. and Physiol.* vol. xxxiii. p. 359.) The rougher appearance of the male type is correlated with the more powerful muscular development.

The Femur.

The femur or thigh bone is remarkable for its length, being the longest

FIG. 237.—ANTERIOR ASPECT OF PROXIMAL PORTION OF THE RIGHT FEMUR WITH ATTACHMENTS OF MUSCLES MAPPED OUT.

bone in the body. Proximally the femora are separated by the width of the pelvis. Distally they articulate with the tibiae and patellae. In the military position of attention, with the knees close together, the shafts of the thigh bones occupy an oblique position.

For descriptive purposes the bone is divided into a **proximal extremity**, comprising the head, neck, and two trochanters; a **shaft**; and a **distal extremity**, forming the expansions known as the condyles.

The caput femoris (head) is the hemispherical articular surface which fits into the acetabulum. Its pole is directed upwards,

medially, and slightly forwards. A little below the summit, and usually somewhat

FIG. 236.—THE RIGHT FEMUR SEEN FROM THE FRONT.

behind it, is a hollow oval pit (*fovea capitis femoris*) for the attachment of the *ligamentum teres*. Piercing the floor of this depression are seen several foramina

FIG. 238.—THE RIGHT FEMUR SEEN FROM BEHIND.

through which vessels pass to supply the head of the bone; the proximal epiphysis thus having a double blood supply, viz., from the neck distally, and through the medium of the *ligamentum teres* proximally. The circumference of the head forms a lip with a wavy outline, more prominent proximally and dorsally than in front. The head is supported by a stout compressed bar of bone, the *collum femoris* (neck), which forms with the proximal end of the shaft an angle of about 125 degrees, and is directed proximally, medially, and a little forwards. Its vertical width exceeds its antero-posterior thickness. Constricted about its middle, it expands medially to support the head, whilst laterally, where it joins the shaft, its vertical diameter is much increased. Anteriorly it is clearly defined from the shaft by a rough ridge which commences above on a prominence, sometimes called the *tubercle* of the femur, and passes obliquely downwards and medially. This constitutes the upper part of the *linea intertrochanterica* (intertrochanteric line), and serves for the attachment of the ilio-femoral ligament of the hip-joint. Posteriorly where the neck unites with the shaft, there is a full rounded ridge passing from the trochanter major proximally to the trochanter minor distally; this is the *crista intertrochan-*

terica (intertrochanteric crest). A little proximal to the middle of this ridge there is usually a fulness which serves to indicate the proximal limit of attachment of the *quadratus femoris* muscle, and is called the *tubercle for the quadratus*. Laterally the

neck is embedded in the medial surface of the **trochanter major**, by which, at its proximal and dorsal part, it is to some extent overhung. Here is situated the **trochanteric fossa**, into which the tendon of the obturator externus is inserted. Passing nearly horizontally across the back of the neck there is a faint groove leading into this depression; in this the tendon of the obturator externus muscle lies. Distally the neck becomes confluent with the **trochanter minor** behind, and is continuous with the medial surface of the shaft in front. The neck is pierced by many vascular canals, most numerous at the proximal and dorsal part. Some are directed proximally towards the head, whilst others pass in the direction of the trochanter major.

The **trochanter major** (greater trochanter) is a large quadrangular process which caps the proximal and lateral part of the shaft, and overhangs the root of the neck above and behind. Its *lateral surface*, of rounded irregular form, slopes proximally and medially, and is separated from the lateral surface of the shaft distally by a more or less horizontal ridge. Crossing it obliquely from the posterior superior to the anterior inferior angle is a rough line which serves for the insertion of the

FIG. 239.—DORSAL ASPECT OF THE PROXIMAL PORTION OF THE RIGHT FEMUR WITH THE ATTACHMENTS OF MUSCLES MAPPED OUT.

FIG. 240.—DORSAL VIEW OF THE PROXIMAL END OF THE RIGHT FEMUR.

glutæus medius muscle; proximally and distally to this the surface of the bone is smoother and is overlain by bursæ. The *ventral surface*, somewhat oblong in shape, and inclined obliquely from below upwards and medially, is elevated from the general aspect of the shaft below, from which it is separated in front by an oblique line leading upwards and medially to the tubercle at the proximal end of the superior part of the intertrochanteric line. This surface serves for the insertion of the glutæus minimus. The *proximal border* is curved and elevated; into it are inserted the tendons of the obturator internus and gemelli muscles medially and in front, and the piriformis muscle proximally and dorsally. The *dorsal border* is thick and rounded, and forms the upper part of the intertrochanteric crest. The angle formed by the proximal and dorsal borders is sharp and pointed, and forms the tip of the trochanter overhanging the trochanteric fossa, which lies immediately distal and medial to its medial surface.

The **lesser trochanter (trochanter minor)** is an elevated pyramidal process situated at the dorsal side of the medial and proximal part of the shaft, where that becomes continuous with the distal and dorsal part of the neck. Confluent above with the intertrochanteric crest, it gradually fades away into the dorsal aspect of the shaft below. The combined tendon of the ilio-psoas is inserted into this process and into the bone immediately below it.

The **shaft (corpus femoris)**, which is characterised by its great length, is cylindrical in form. As viewed from the front, it is straight or but slightly curved; as seen in profile, it is bent forwards, the curve being most pronounced in its proximal part. The shaft is thinnest at some little distance proximal to its middle; distal to this it gradually increases in width to support the condyles; its antero-posterior diameter, however, is not much increased distally. Its surfaces are generally smooth and rounded, except behind, where, running longitudinally along the centre of its curved dorsal aspect, there is a rough-lipped ridge, the **linea aspera**. Most salient towards the middle of the shaft, the linea aspera consists of a **medial lip** and a **lateral lip**, with a narrow intervening rough surface. Proximally, about 2 to $2\frac{1}{2}$ inches from the trochanter minor, the linea aspera is formed by the convergence of three lines. Of these the lateral is a rough, somewhat elevated, ridge, which commences proximally, on the back of the shaft, lateral to and on a level with the trochanter minor, and becomes continuous distally with the lateral lip of the linea aspera. This serves for the bony insertion of the gluteus maximus, and is occasionally developed into an outstanding process called the **trochanter tertius**. The medial lip of the linea aspera is confluent proximally with a line which winds round the shaft upwards and forwards in front of the trochanter minor to become continuous with the rough ridge which serves to define the neck from the shaft anteriorly (see p. 240). The whole constitutes what is known as the **spiral line**, and extends from the anterior part of the trochanter major proximally to the linea aspera distally. Intermediate in position between the spiral line in front and medially, and the gluteal ridge laterally, there is a third line, the **pectineal line**, which passes distally from the trochanter minor and fades away into the surface between the two lips of the linea aspera. Into this the pectineus muscle is inserted. About the junction of the middle with the distal third of the shaft the two lips of the linea aspera separate from one another, each passing in the direction of the epicondyle of the corresponding side. The lines so formed are called the medial and lateral epicondylar lines, respectively, and enclose between them a smooth triangular area corresponding to the back of the distal third of the shaft; this, called the **planum popliteum (popliteal surface)**, forms the floor of the proximal part of the popliteal fossa. The continuity of the proximal part of the medial epicondylar line is but faintly marked, being interrupted by a wide and faint groove along which the popliteal artery passes to enter the fossa of that name. Distally, where the line ends on the proximal and medial surface of the medial epicondyle, there is a little spur of bone called the **adductor tubercle**, to which the tendon of the adductor magnus is attached, and behind which the medial head of the gastrocnemius muscle takes origin.

The **linea aspera** affords extensive linear attachments to many of the muscles of the thigh. The vastus medialis arises from the spiral line proximally and the medial lip of the linea aspera distally. This muscle overlies but does not take origin from the medial aspect of the shaft. The adductor longus is inserted into the medial lip about the middle third of the length of the shaft. The adductor magnus is inserted into the intermediate part of the line, extending to the level of the trochanter minor, where it lies medial to the insertion of the gluteus maximus. Distally, its insertion passes on to the medial epicondylar ridge, reaching as far as the adductor tubercle. The adductor brevis muscle is inserted into the linea aspera proximally, between the pectineus and adductor longus muscles medially and the adductor magnus laterally. Distal to the insertion of the gluteus maximus the short head of the biceps arises from the lateral lip as well as from the lateral epicondylar line; in front these also serve for the origin of the vastus lateralis muscle. There is frequently a small tubercle which marks the distal attachment of the lateral intermuscular septum on the lateral condylar line, about two inches from the condyle. This is known as the lateral epicondyle. Immediately proximal to this there is often a groove for a large muscular artery which pierces the septum at this point (Frazer).

The canals for the nutrient arteries of the shaft, which have a proximal direction, are usually two in number, and are placed on or near the linea aspera—the proximal one about the level of the junction of the middle and proximal third of the bone, the distal some three or four inches distal

to this—usually on the medial side of the shaft, immediately in front of the medial lip of the *linea aspera*.

The anterior and lateral aspects of the shaft are covered by, and furnish surfaces for, the origins of the vastus lateralis and vastus intermedius. The medial aspect is covered by the vastus medialis.

The **distal extremity** of the femur comprises the two **condyles** and **epicondyles**. The condyles are two recurved processes of bone, each provided with an articular surface, and separated behind by a deep **intercondylic notch**. United in front, where their combined articular surfaces form an area on which the patella rests, the two condyles differ from each other in the following respects: If the shaft of the bone be held vertically, the **medial condyle** is seen to reach a more distal level than the **lateral**; but, as the femur lies obliquely in the thigh, the condyles are so placed that their distal surfaces lie in the same horizontal plane. Viewed on their distal aspect, the medial condyle is seen to be the narrower and shorter of the two. The lateral condyle is broader, and advances farther forward and to a more proximal level on the anterior surface of the shaft. The **intercondyloid fossa** reaches forwards as far as a transverse line drawn through the centre of the lateral condyle. Its sides are formed by the medial and lateral surfaces of the

FIG. 241.—POSTERIOR ASPECT OF DISTAL PORTION OF THE RIGHT FEMUR WITH ATTACHMENTS OF MUSCLES MAPPED OUT.

lateral and medial condyles respectively, the latter being more deeply excavated, and displaying an oval surface near its distal and anterior part for the attachment of the posterior cruciate ligament of the knee-joint. On the posterior and proximal part of the medial surface of the lateral condyle there is a corresponding surface for the attachment of the anterior cruciate ligament. The floor of the notch, which is pierced by numerous vascular canals, slopes proximally and dorsally towards the popliteal surface on the back of the shaft, from which it is separated by a slight ridge (**linea intercondyloidea**) to which the posterior part of the capsule of the knee-joint is attached.

Epicondyles.—The cutaneous aspect of each condyle (*i.e.* the lateral surface of the lateral condyle and the medial surface of the medial condyle) presents an elevated rough surface called the **epicondyle**, the **medial (epicondylus medialis)** projecting more prominently from the line of the shaft; capped proximally by the adductor tubercle, it affords attachment near its most prominent point to the fibres of the tibial collateral ligament of the knee-joint. The **epicondylus lateralis (lateral epicondyle)**, less pronounced and lying more in line with the lateral surface of the shaft, is channelled behind by a curved groove, the distal rounded lip of which serves to separate it from the distal articular surface. This groove ends in front in a pit which is placed just distal to the most salient point of the tuberosity; hereto is attached the tendon of the popliteus muscle, which overlies the distal lip of the groove, which is often indented for it in the extended position of the joint, but slips into and occupies the groove when the joint is flexed. Dorsal to the most prominent part of the lateral epicondyle, and just proximal to the pit for the attachment of the popliteus, the fibular collateral ligament of the knee-joint is attached, whilst proximal to that there is a circumscribed area for the origin of the tendinous part of the lateral head of the gastrocnemius muscle.

FIG. 242.—DISTAL END OF THE RIGHT FEMUR (Lateral Side).

The articular surface on the distal extremity is divisible into three parts—that which corresponds to the distal surface of the shaft and is formed by the coalescence of the two condyles in front; and those which overlie the distal and posterior aspects of each of those processes. The former is separated from the latter by two shallow oblique grooves which traverse the articular surface from before backwards, on either side, in the direction of the anterior part of the intercondyloid fossa. These furrows are the impressions in which fit the anterior parts of the medial and lateral menisci of the knee-joint, respectively, when the knee-joint is extended. The anterior articular area or *facies patellaris* (patellar surface) is adapted for articulation with the patella. Convex proximo-distally, it displays a broad and shallow central groove, bounded on either side by two slightly convex surfaces. Of the two sides, the lateral is the wider and more prominent, and rises on the front of the bone to a more proximal level than the medial, thus tending to prevent lateral dislocation of the patella. The condylar or tibial surfaces are convex from side to side, and convex from before backwards. Sweeping round the distal surface and posterior extremities of the condyles, they describe a spiral curve more open in front than behind. The medial condylar articular surface is narrower

than the lateral, and when its distal aspect is viewed it is seen to describe a curve around a vertical axis. Along the lateral edge of this, and in front, where it bounds the intercondyloid fossa, is a semilunar articular area, best seen when the bone is coated with cartilage. This articulates with the medial edge of the patella in extreme flexion of the joint. The articular surface of the lateral con-

FIG. 243.—DISTAL ASPECT OF DISTAL END OF THE RIGHT FEMUR.

dyle is inclined obliquely from before backwards and slightly laterally. The surfaces of the condyles proximal to the articular area posteriorly are continuous with the popliteal surface of the shaft. The bone from which the medial head of the muscle springs is often elevated in the form of a tubercle placed on the distal part of the popliteal surface of the shaft, just proximal to the medial condyle.

The proportionate length of the femur to the body height is as 1 is to 3.53–3.92.

Arterial Foramina.—Numerous vascular canals are seen in the region of the neck, at the bottom of the trochanteric fossa, in the fossa for the ligamentum teres, on the intertrochanteric crest, and on the lateral surface of the greater trochanter. The nutrient arteries for the shaft pierce the bone in a proximal direction on or near the linea aspera. Both back and front of the distal end of the shaft display the openings of numerous vascular canals, and the floor of the intercondyloid fossa is also similarly pierced.

Connexions.—The femur articulates with the hip bone proximally and the tibia and patella distally. The lateral surface of the greater trochanter determines the point of greatest hip width in the male, being covered only by the skin and superficial fascia and the aponeurotic insertion of the *glutæus maximus*. In the erect position the tip of the trochanter corresponds to the level of the centre of the hip-joint. When the thigh is flexed the trochanter major sinks under cover of the anterior fibres of the *glutæus maximus*. In women the hip width is usually greatest at some little distance distal to the trochanter, due to the accumulation of fat in this region. The shaft of the bone is surrounded on all sides by muscles. Its forward curve, however, is accountable to some extent for the fulness of the front of the thigh. *The exposed surfaces of the condyles determine to a large extent the form of the knee.* In flexion the articular edges can easily be recognised on either side of and distal to the patella.

Sexual Differences.—According to Dwight, the head of the femur in the female is proportionately smaller than that of the male.

Ossification.—The shaft begins to ossify early in the second month of foetal life, and at birth displays enlargements at both ends, which are capped with cartilage. If at birth the distal cartilaginous end be sliced away, a small ossific nucleus for the distal epiphysis will usually be seen. This, as a rule, makes its appearance towards the latter end of the ninth

month of foetal life, and is of service from a medico-legal standpoint in determining the age of the foetus. According to Hartman, it is absent in about 12 per cent of children at term, and may appear as early as the eighth month of foetal life in about 7 per cent. The proximal extremity, entirely cartilaginous at birth, comprises the head, neck, and trochanter major. A centre appears for the head during the early part of the first year. It is worthy of note that this epiphysis has a double blood-supply—one through the neck, the other through the ligamentum teres. That for the trochanter major begins to ossify about the second or third year, whilst the neck is developed as a proximal extension of the shaft, which is, however, not confined to the neck alone, but forms the distal circumference of the articular head, as may be seen in bones up to the age of twelve or sixteen; after that, the separate epiphysis of the head begins to overlap it so as to cover it entirely when fusion is complete at the age of eighteen or twenty.

FIG. 244.—OSSIFICATION OF THE FEMUR.

The epiphysis of the greater trochanter unites with the shaft and neck about eighteen or nineteen, whilst the epiphysis for the trochanter minor, which usually makes its appearance about the twelfth or thirteenth year, is usually completely fused with the shaft about the age of eighteen. The epiphysis for the distal end, although the first to ossify, is not completely united to the shaft until from about the twentieth to the twenty-second year. It is worthy of note that the line of fusion of the shaft and distal epiphysis passes through the adductor tubercle, a point which can easily be determined in the living. The distal end is the so-called "growing end of the bone."

The Patella.

The **patella**, the largest of the sesamoid bones, overlies the front of the knee-joint in the tendon of the quadriceps extensor. Of compressed form and somewhat triangular shape, its distal angle forms a peak, called the **apex patellæ**, whilst its proximal edge, or base (**basis patellæ**), broad, thick, and sloping forwards and a little distally, is divided into two areas by a transverse line or groove; the anterior area so defined serves for the attachment of the common tendon of the quadriceps extensor muscle, whilst the posterior, of compressed triangular shape, is covered by synovial membrane. The *medial* and *lateral borders*, of curved outline, receive the insertions of the vastus medialis and lateralis muscles, respectively, the attachment of the vastus medialis being more extensive than that of the vastus lateralis. The *anterior surface* of the bone, slightly convex in both diameters, has a fibrous appearance, due to its longitudinal striation, and is pierced here and there by the openings of vascular canals. Oftentimes at the superior lateral angle there is a well-defined area for the tendinous insertion of the vastus lateralis. The *posterior* or *articular surface* is divided into two unequal parts (of which the lateral is the wider) by a vertical elevation which glides in the furrow of the trochlear surface of the femur, and in extreme flexion passes to occupy the intercondyloid fossa. The lateral of the two femoral surfaces is slightly concave in both its diameters; the medial, though slightly concave proximo-distally, is

usually plane, or somewhat convex transversely. Occasionally, in the macerated bone, indications of a third vertical area are to be noted along the medial edge of the posterior aspect. This defines the part of the articular surface which rests on

the lateral border of the medial condyle in extreme flexion. In the recent condition, when the femoral surface is coated with cartilage, a more complex arrangement of facets may be in some cases displayed (as indicated in Fig. 244). Lamont (*Journal of Anat. and Physiol.*, 1910, vol. xlv. p. 149) has shown that these areas undergo considerable variation in

FIG. 245.—THE RIGHT PATELLA.

A. Anterior Surface.

B. Posterior Surface.

their arrangement in races who habitually adopt the squatting posture.

Distal to the femoral articular area the posterior surface of the apex is rough and irregular; the greater part of this is covered by synovial membrane, the ligamentum patellæ being attached to its summit and margins, reaching some little distance round the borders on to the anterior aspect of this part of the bone.

Ossification.—The patella is laid down in cartilage about the third month of foetal life. At birth it is cartilaginous, and the tendon of the quadriceps is continuous with the ligamentum patellæ over its anterior surface, and can easily be dissected off. About the third year an ossific centre appears in it and spreads more particularly over its deeper surface. Two centres, vertically disposed, have also been described. Ossification is usually completed by the age of puberty.

The Tibia.

The **tibia** is the medial bone of the leg. It is much stouter and stronger than its neighbour the fibula, with which it is united proximally and distally. By its proximal expanded extremity it supports the condyles of the femur, while distally it shares in the formation of the ankle-joint, articulating with the proximal surface and medial side of the talus.

The proximal extremity comprises the medial and lateral condyles (O.T. tuberosities), the intercondyloid eminence (O.T. spine), and the tuberosity (O.T. tubercle). Each con-

FIG. 246.—THE PROXIMAL SURFACE OF THE PROXIMAL EXTREMITY OF THE RIGHT TIBIA.

dyle is provided on its proximal aspect with an articular surface (facies articularis superior), which supports the corresponding femoral condyle, as well as the interposed meniscus. Of these two condylic surfaces the medial is the larger. Of oval shape, its long axis is placed antero-posteriorly; slightly concave from before backwards and from side to side, its circumference rises in the form of a sharp and well-defined edge. The lateral condylic surface is smaller and rounder. Slightly concave from side to side, and gently convex from before backwards, its circumfer-

ence is well defined in front, but is rounded off behind, thus markedly increasing the convexity of its posterior part. Between the two condylic surfaces the bone is raised in the centre to form the **intercondyloid eminence** which consists of two **intercondyloid tubercles** separated by an oblique groove, in the anterior part of which lies the anterior cruciate ligament. The medial tubercle (**tuberculum intercondyloideum mediale**), the higher, is prolonged backwards and laterally by an oblique ridge to which part of the posterior cornu of the lateral meniscus is attached. The lateral tubercle (**tuberculum intercondyloideum laterale**) is more pointed and not so elevated. In front and behind the intercondyloid eminence the articular areas are separated by two irregular V-shaped surfaces, the **intercondyloid fossæ**. The **anterior intercondyloid fossa**, the larger and wider, furnishes areas for the attachment of the menisci on either side, and for the anterior cruciate ligament immediately in front of the intercondyloid eminence. The floor of this space is pierced by many nutrient foramina. The **posterior intercondyloid fossa** is concave from side to side, and slopes downwards and backwards. The lateral meniscus is attached near its apex to a surface which rises on to the back of the intercondyloid eminence; the medial meniscus is fixed to a groove which runs along its medial edge, and the posterior cruciate ligament derives an attachment from the smooth posterior rounded surface.

The **lateral condyle** is the smaller of the two. It overhangs the shaft to a greater extent than the medial, though this is obscured in the living by its articulation with the fibula. The facet for the fibula, often small and indistinct, is placed postero-laterally on the distal surface of its most projecting part. Antero-laterally the imprint caused by the attachment of the trachis iliotibialis (O.T. ilio-tibial band) is often quite distinct. Curving distally and forwards from the fibular facet there is often a definite ridge for the attachment of the expansion of the biceps tendon;

FIG. 247.—THE RIGHT TIBIA AND FIBULA AS SEEN FROM THE FRONT.

The anterior part of the medial surface of the fibula is coloured blue. The posterior part of the medial surface of the fibula is coloured red. The lateral or peroneal surface of the fibula is left uncoloured.

distal to this the areas for the origins of the peronæus longus and extensor digitorum longus are often crisply defined. The circumference of the **medial condyle** is grooved postero-medially for the insertion of the tendon of the semi-membranosus.

In front of the condyles, and about an inch distal to the level of the condylic surfaces, there is an oval elevation called the **tuberosity of the tibia**. The proximal half of this is smooth and covered by a bursa, while the distal part is rough and serves for the attachment of the ligamentum patellæ.

Considered in its entirety, the proximal extremity of the tibia is broader transversely than antero-posteriorly, and is inclined backwards so as to overhang the shaft posteriorly.

The *corpus tibiæ* (shaft) is irregularly three-sided, possessing a **medial**, a **lateral**, and a **posterior surface**, separated by an **anterior crest**, a **medial margin**, and a **lateral or interosseous crest**. It is narrowest about the junction of its middle and distal thirds, and expands proximally and distally to support the extremities. Running along the front of the bone there is a gently-curved, prominent margin, the **crista anterior**, confluent proximally with the tuberosity, but fading away distally

on the anterior surface of the distal third of the bone, where it may be traced in the direction of the anterior border of the medial malleolus. This is the **anterior crest** or **shin**, which is subcutaneous throughout its entire length. To the medial side of this is a smooth, slightly convex surface, which reaches the medial tuberosity proximally, and distally becomes continuous with the medial surface of the medial malleolus. This is the **medial** or **subcutaneous surface** of the shaft, which is covered only by skin and superficial fascia, except in its proximal fourth, where

FIG. 248.—ANTERIOR ASPECT OF THE PROXIMAL PORTIONS OF THE BONES OF THE RIGHT LEG WITH ATTACHMENTS OF MUSCLES MAPPED OUT.

the tendons of the sartorius, gracilis, and semitendinosus muscles overlie it, as they pass towards their insertions. This surface is limited posteriorly by the **medial margin**, which passes from the medial and distal surface of the medial condyle proximally to the posterior border of the medial malleolus distally. This margin is rounded and indefinite proximally and distally, being usually best marked about its middle third. To the lateral side of the anterior crest is the lateral surface of the bone; it is limited behind by a straight vertical ridge, the **crista interossea** (interosseous crest), to which the interosseous membrane, which occupies the interval between the tibia and the fibula, is attached. This ridge commences near the middle of the lateral and distal surface of the lateral condyle, and terminates about two inches from the distal extremity by dividing into two lines, which separate and enclose between them the surface for articulation with the distal end of the fibula, and the area of attachment of the interosseous ligament, which here unites the two bones. In its proximal two-thirds the lateral surface provides an extensive origin for the tibialis anterior. Distally, where the anterior crest is no longer well defined, the lateral surface turns forward on to the front of the shaft, and is limited by the anterior margin of the distal articular surface. Over this the tendon of the tibialis anterior, and the combined fleshy and tendinous parts of the extensor hallucis proprius and extensor digitorum communis muscles pass obliquely distally. The **posterior surface** of the shaft lies between the interosseous crest laterally and the medial margin on the medial side. Its contours are liable to considerable variation according to the degree of lateral compression of the bone. It is usually full

and rounded proximally, and flat distally. Proximally it is crossed by the *linea poplitea* (*popliteal line*), which runs distally and medially, from the fibular facet to the medial border on a level with the junction of the middle with the proximal third of the shaft. To this line the deep transverse fascia is attached, whilst distal to it, as well as from the medial border of the bone distally, the soleus muscle takes origin. Into the bulk of the triangular area proximal to it the popliteus muscle is inserted. Arising from the middle of the popliteal line there is a vertical ridge, which passes distally and divides the posterior aspect of the shaft into two surfaces—a lateral for the tibial origin of the *tibialis posterior* muscle, and a medial for the *flexor digitorum longus* muscle. The distal third of this surface of the shaft is free from muscular attachments, but is overlain by the tendons of the above muscles, together with that of the *flexor hallucis longus*. A large nutrient canal, having a distal direction, opens on the posterior surface of the shaft a little distal to the popliteal line and just lateral to the vertical ridge which springs from it.

The distal extremity of the tibia displays an expanded quadrangular form. It is furnished with a saddle-shaped articular surface on its distal surface (*facies articularis inferior*), which is concave from before backwards and slightly convex from side to side. This rests upon the proximal articular surface of the body of the talus, and is bounded in front and behind by well-defined borders. The anterior border is the rounder and thicker, and is oftentimes channelled by a groove for the attachment of the anterior ligament of the joint; further, it is occasionally provided with a pressure facet caused by the locking of the bone against the neck of the talus in extreme flexion. Laterally the edge of the articular area corresponds to the base of the triangle formed by the splitting of the interosseous ridge into two parts. Where these two lines join it, both in front and behind, the bone is elevated into the form of tubercles, in the hollow between which (*incisura fibularis*) the distal end of the fibula is lodged, being held in position by powerful ligaments. The cartilage-covered surface occasionally extends for some little distance proximal to the base of the triangle. Medially there is a process projecting distally, and called the *medial malleolus*, the medial aspect of which is subcutaneous and forms the projection of the medial ankle. Its lateral surface is furnished with a piriform facet (*facies articularis malleolaris*), confluent with the cartilage-covered area on the distal extremity of the shaft; this articulates with a corresponding area on the medial surface of the body of the talus. Distally the malleolus is pointed in front, but notched behind for the attachment of the tibial collateral ligament of the ankle. Running obliquely along the posterior surface of the malleolus there is a broad groove (*sulcus malleolaris*) in which the tendons of the *tibialis posterior* and *flexor digitorum longus* muscles are lodged; whilst a little to the fibular side of this, and running distally over the posterior surface of the distal extremity of the bone, there is another groove, often faintly marked, for the lodgment of the tendon of the *flexor hallucis longus* muscle.

The proportionate length of the tibia to the body height is as 1 is to 4·32–4·80.

Arterial Foramina.—Nutrient canals are seen piercing the proximal extremity of the bone around its circumference and proximal to the tuberosity. The floors of the intercondyloid fossæ are also similarly pierced, and there is usually a canal of large size opening on the summit of the intercondyloid eminence. Two or three foramina of fair size are seen running proximally into the substance of the bone a little distal to and to the medial side of the tuberosity, while the principal vessel for the shaft passes distally into the bone on its posterior surface, about the level of the junction of the proximal and middle thirds. The medial surface of the medial malleolus, as well as the anterior and posterior borders of the distal extremity, are likewise pitted by the orifices of small vascular channels.

Connexions.—Proximally the tibia supports the condyles of the femur, and is connected in front with the patella by means of the patellar ligament. Articulating laterally with the fibula proximally and distally, it is united to that bone throughout nearly its entire length by the interosseous membrane. The crest and medial surface can be readily examined, as they are subcutaneous, except proximally, where the medial surface is overlain by the thin tendinous aponeuroses of the muscles passing over the medial side of the knee. The form of the distal part of the knee in front is determined by the condyles on either side crossed centrally by the *ligamentum patellæ*. Distally the medial malleolus forms the projection of the medial ankle, which is wider, not so low, less pointed, and placed in advance of the projection of the lateral ankle. The front and

back of the distal end of the bone are crossed by tendons, which mask to a certain extent its form.

Ossification.—The shaft begins to ossify early in the second month of intra-uterine life. At birth it is well formed, and capped proximally and distally by pieces of cartilage,

FIG. 249.—OSSIFICATION OF THE TIBIA.

The Fibula.

The **fibula** is a slender bone with two enlarged ends. It lies to the lateral side of the tibia, with which it is firmly united by ligaments, and nearly equals that bone in length.

The first difficulty which the student has to overcome is to determine which is the proximal and which the distal extremity of the bone. This can easily be done by recognising the fact that there is a deep pit on the medial aspect of the distal extremity immediately behind the triangular articular surface. Holding the bone vertically with the distal extremity downwards and so turned that the triangular articular area lies in front of the notch already spoken of, the subcutaneous non-articular aspect of the distal extremity will point to the side to which the bone belongs.

The **proximal extremity** or head of the fibula (*capitulum fibulæ*), of irregular rounded form, is bevelled on its medial surface so as to adapt it to the form of the distal surface of the lateral condyle of the tibia. At the border, where this surface becomes confluent with the lateral aspect of the head, there is a pointed upstanding eminence called the *apex capituli fibulæ* (*apex of the head*); to this the short fibular collateral ligament is attached, as well as a piece of the tendon of the biceps, which is inserted into its anterior part. Immediately to the medial side of this, and occupying the summit of the medial sloping surface, there is an articular area (*facies articularis capituli*), of variable size and more or less triangular shape. This serves for articulation with the lateral condyle of the tibia. The long fibular collateral ligament, together with the remainder of the tendon of the biceps muscle which surrounds it, is attached to the lateral and proximal side of the head in front of the apex capituli. In front and behind the head there are usually prominent tubercles. The anterior of these is associated with the origin of the peronæus longus muscle; the posterior, whilst furnishing an origin for the upper fibres of the soleus, serves to deepen the groove, behind the proximal tibio-fibular articulation, in which the tendon and fleshy part of the popliteus muscle play. The constricted portion of the shaft distal to the head

is often referred to as the **neck**; around the lateral side of this the common peroneal nerve winds.

SHAFT.

The **shaft** of the fibula (*corpus fibulae*) presents many varieties of shape and form, being ridged and channelled in such a way as greatly to increase the difficulties of the student in recognising the various surfaces described. The most important point is first to determine the position of the interosseous ridge. Holding the bone in the position which it normally occupies in the leg, it

FIG. 250.—THE RIGHT TIBIA AND FIBULA SEEN FROM BEHIND.

The Posterior surface of the fibula is coloured red; the lateral surface is left uncoloured.

will be noticed that the lateral surface of the distal extremity is limited in

FIG. 251.—POSTERIOR ASPECT OF THE BONES OF THE LEG WITH ATTACHMENTS OF MUSCLES MAPPED OUT.

FIG. 252.—RIGHT FIBULA AS SEEN FROM THE MEDIAL SIDE.

The anterior part of the medial surface is coloured blue; the posterior part of the medial surface is coloured red.

front and behind by two lines, which converge and enclose between them a triangular subcutaneous area which lies immediately proximal to the lateral malleolus. From the summit of the triangle so formed a well-defined ridge may be traced along the front of the shaft to reach the anterior aspect of the head. This is the **anterior crest**, and must not be mistaken for the **interosseous crest**, which is now easy to find, for the next ridge which lies just medial to the anterior crest, or towards the tibial side on the anterior aspect of the bone, is the line to which the interosseous membrane is attached. As a rule these two lines are separated by a considerable interval in the distal half of the bone, but tend to run much closer together proximally; indeed it is not uncommon to find that they coalesce to form a single crest. *Let it therefore be clear that the interosseous line is that which lies just medial to the ridge which springs from the malleolar subcutaneous triangular surface, notwithstanding the differences in width of the surface which separates the lines, or their occasional coalescence above.*

The position of the anterior crest enables us at once to separate the **medial surface** of the bone from its **lateral surface**. In addition, there is the **posterior surface**.

Starting then at the interosseous crest, and passing forwards, the *anterior* part of the **medial surface** is the first met with; this, as has been said, may be either of considerable width or almost linear. From this arises the *extensor digitorum communis*, together with the *peronæus tertius* and the *extensor hallucis longus* muscles.

The **anterior crest** serves for the attachment of the intermuscular septum, which separates the foregoing group of muscles from that which lies along the lateral side of the shaft, viz., the *peronæus longus* and *brevis* muscles. The surface from which these arise is limited behind by the **lateral crest**, which is usually sharp and well defined distally, where it is continuous with the bone immediately proximal to the pit on the medial surface of the distal extremity, whilst it tends to be less distinct and more rounded proximally, where it runs into the base of the apex capituli. In its proximal third or fourth this crest is often rough and tubercular where it serves for the origin of the soleus. The **lateral** or **peroneal surface** is somewhat twisted, being directed rather forwards proximally, but tending to turn backwards distally, where it becomes continuous with the groove which courses along the back of the lateral malleolus and which lodges the tendons of the *peronæus longus* and *brevis* muscles. The remainder of the shaft is included between the lateral crest behind and the interosseous crest in front and medially. Here arise the several muscles whose action in part is to extend the ankle. This surface is cut up by a curved ridge often the most prominent and outstanding on the bone, and hence frequently mistaken by the student for the interosseous ridge; it serves to define the area for the origin of the *tibialis posterior*, and arises distally

from the posterior border of the interosseous crest at the junction of the middle and distal thirds of the shaft, curves a little backwards, and passing proximally ends at the medial side of the posterior surface of the head. This is called the **medial crest**; and the surface so mapped off between it and the interosseous crest is the *posterior* part of the **medial surface**. The crest itself serves for the attachment of the aponeurosis which covers the *tibialis posterior* muscle. The remainder of the posterior aspect of the shaft, which, proximally, is directed backwards, is so twisted that distally it is directed medially. It lies between the medial and lateral crests, and is known as the **posterior surface**. From this, in its proximal part, the soleus muscle arises; whilst more distally, the flexor hallucis longus muscle derives an extensive origin. Both of these muscles, together with the *tibialis posterior*, act as extensors of the ankle. On this aspect of the bone, at or near the middle of the shaft, and just behind the prominent medial crest, is the opening of the nutrient canal, which has a distal direction.

The distal extremity of the fibula, or lateral malleolus, is of pyramidal form. Its medial surface is furnished with a triangular articular area (*facies articularis malleoli*), plane from before backwards, and slightly convex proximodistally, which articulates with a corresponding surface on the lateral side of the body of the talus. Behind this there is a deep pit, to which the posterior talo-fibular ligament is attached. Proximal to the articular facet there is a rough triangular area, from the summit of which the interosseous crest arises; to this are attached the strong fibres of the distal interosseous ligament which binds together the opposed surfaces of the tibia and fibula. The lateral surface of the distal extremity forms the elevation of the lateral malleolus which determines the shape of the projection of the lateral ankle. Rounded from side to side and proximodistally, it terminates in a pointed process, which reaches a more distal level than the corresponding process of the tibia, from which it also differs in being narrower and more pointed and being placed in a plane nearer the heel. Proximally, this surface, which is subcutaneous, is continuous with the triangular subcutaneous area so clearly defined by the convergence of the lines which unite to form the anterior crest. The anterior border and tip of the lateral malleolus furnish attachments to the anterior talo-fibular and calcaneo-fibular ligaments. The posterior surface of the lateral malleolus, broad proximally, where it is confluent with the lateral or peroneal surface, is reduced in width distally by the presence of the pit which lies to its medial side. This aspect of the bone is grooved (*sulcus malleolaris*) by the tendons of the *peronæus longus* and *brevis* muscles, which curve round the posterior and distal aspects of the malleolus.

The proportionate length of the fibula to the body height is as 1 is to 4·37-4·82.

Arterial Foramina.—Numerous minute vascular canals are seen piercing the lateral surface of the head, and one or two of larger size are seen on the medial surface immediately anterior to the proximal articular facet. The canal for the nutrient artery of the shaft, which has a distal direction, is situated on the posterior surface of the bone about its middle. The lateral surface of the lateral malleolus displays the openings of many small canals, and one or two larger openings are to be noted at the bottom of the pit behind the distal articular surface.

Connexions.—The head and lateral malleolus, and part of the shaft immediately proximal to the latter, are subcutaneous. The remainder of the shaft is covered on all sides by the muscles which surround it. Proximally the bone plays no part in the formation of the knee-joint, but distally it assists materially in strengthening the ankle-joint by its union with the tibia and its articulation with the talus. In position the bone is not parallel to the axis of the tibia, but oblique to it, its proximal extremity lying posterior and lateral to a vertical line passing through the lateral malleolus.

Ossification.—The shaft begins to ossify about the middle of the second month of foetal life. At the end of the third month there is but little difference in size between it and the tibia, and at birth the fibula is much larger in proportion to the size of the tibia than in the adult. Its extremities are cartilaginous, the distal extremity not being as long as the medial malleolar cartilage of the tibia. It is in this, however, that an ossific centre first appears about the end of the second year, which increases rapidly in size, and unites with the shaft in about nineteen years. The centre for the proximal epiphysis begins to ossify about the third or fourth year, and union with the shaft is

not complete until a period somewhat later than that for the distal epiphysis. The mode of ossification of the distal extremity is an exception to the general rule that epiphyses which are the first to ossify are the last to unite with the shaft. This may possibly be accounted for by the fact that the distal end is functionally more important than the rudimentary proximal end, since in man alone, of all vertebrates, does the lateral malleolus reach beyond the level of the medial malleolus. Its early union with the shaft is doubtless required to ensure the stability of the ankle-joint necessitated by the assumption of the erect position.

FIG. 253.—OSSIFICATION OF FIBULA.

The bones of the foot, twenty-six in number, are arranged in three groups: the tarsal, seven in number; the metatarsal, five in number; the phalanges, fourteen in number.

Comparing the foot with the hand, the student will be struck with the great proportionate size of the tarsus as compared with the carpus, and the reduction in size of the bones of the toes as compared with the fingers. The size of the metatarsal segment more nearly equals that of the metacarpus.

BONES OF THE FOOT.

The Tarsus.

The **tarsus** consists of seven bones (*ossa tarsi*)—the talus or astragalus, calcaneus, navicular or scaphoid, three cuneiforms, and the cuboid. Of irregular form and varying size, they may be described as roughly cubical, presenting for examination dorsal and plantar surfaces, as well as anterior or distal, posterior or proximal, medial, and lateral aspects.

The Talus.

The **talus** (O.T. *astragalus*) is the bone through which the body weight is transmitted from the leg to the foot. Proximally the tibia rests upon it, whilst on either side it articulates with the medial and lateral malleolar processes of the tibia and fibula respectively; distally it overlies the calcaneus, and anteriorly it articulates with the navicular. For descriptive purposes the bone is divisible into three parts—the **corpus tali** (body) blended in front with the **collum tali** (neck), which supports the **caput tali** (head).

The proximal surface of the body is provided with a saddle-shaped articular surface (*trochlea tali*), broader in front than behind, for articulation with the distal surface of the tibia. The medial edge of the trochlea is straight; whilst the lateral border, which is sharp in front and more rounded behind, is curved medially posteriorly, where it is bevelled to form a narrow, elongated, triangular facet, which is in contact with the transverse or distal tibio-fibular ligament during flexion of the ankle. (Fawcett, *Ed. Med. Journ.*, 1895.) Over the lateral border the cartilage-covered surface is continuous laterally with an extensive area of the form of a quadrant. This is concave from above downwards, and articulates with the medial surface of the lateral malleolus. The distal angle of this area is prominent and somewhat everted, and sometimes referred to as the **processus lateralis tali** (lateral

process). The medial aspect of the body has a comma-shaped facet, confluent with the superior articular surface, over the medial edge of the trochlea; this articulates with the lateral surface of the medial malleolus. Distal to this facet

FIG. 254.—DORSAL SURFACE OF THE BONES OF THE RIGHT FOOT.

the bone is rough and pitted by numerous small openings, and just below the tail of the comma there is a circular impression for the attachment of the deep fibres of the deltoid ligament (talo-tibial fibres). On the distal surface of the body there is a deep concave facet, called the posterior calcanean facet (*facies calcanea articularis posterior*), which is of more or less oval or oblong form and is

placed obliquely from behind forwards and laterally; this rests upon a corresponding surface on the dorsal aspect of the calcaneus. In front of this, and crossing the bone from the medial side laterally and forwards, is a deep furrow (*sulcus tali*),

FIG. 255.—PLANTAR SURFACE OF THE BONES OF THE RIGHT FOOT.

the floor of which is pierced by numerous large canals. It serves for the attachment of the strong interosseous ligament which unites the talus with the calcaneus, and separates the facet already described from a smaller oval articular area having a slightly convex surface, which lies immediately in front of it. This is called the middle calcanean facet (*facies articularis calcanea media*), and articulates with

the dorsal surface of the sustentaculum tali of the calcaneus. Posteriorly the body is provided with two tubercles, separated by a groove; the lateral of these (*processus posterior tali*) is usually the larger, and is occasionally a separate ossicle (*os trigonum*). To it is attached the posterior talo-fibular ligament of the ankle-joint. The groove, which winds obliquely from above downwards and medially over the posterior surface of the bone, lodges the tendon of the flexor hallucis longus muscle.

The head, of oval form, is directed forwards and medially. Its anterior surface

FIG. 256.—MUSCLE-ATTACHMENTS TO LEFT TARSUS AND METATARSUS (Plantar Aspect).

is convex from side to side and from above downwards, and articulates with the navicular bone (*facies articularis navicularis*). Inferiorly this surface is confluent with the middle calcanean facet, but in well-marked specimens, or when the bones are articulated, it will be seen that a small area in front of, and lateral to, the middle calcanean facet rests upon an articular surface on the dorsal surface of the anterior portion of the calcaneus, and is called the anterior calcanean facet (*facies articularis calcanea anterior*). On the medial and distal surface of the head there is a cartilage-covered surface which does not articulate with any bone, but rests on the dorso-lateral surface of the plantar calcaneo-navicular ligament, and is supported on the medial side by the tendon of the tibialis posterior muscle. (Fawcett, *Ed. Med. Journ.*, 1895, p. 987.)

The neck, best seen on dorsal surface, passes from the front of the body and

of the medial malleolar facet, and laterally forms a wide groove, which becomes continuous on the plantar surface with the lateral end of the interosseous groove.

The Calcaneus.

The **calcaneus** is the largest of the tarsal bones. It supports the talus on its dorsal surface and articulates with the cuboid anteriorly. On the plantar aspect and behind, its posterior extremity, or tuberosity (**tuber calcanei**), forms the heel, on which so large a proportion of the body weight rests. The long axis of the bone inclines forwards and a little laterally.

The **dorsal surface** of the calcaneus is divisible into two parts—a posterior non-articular part and an anterior articular portion. The length of the former varies according to the projection of the heel; rounded from side to side, it is slightly concave from before backwards. In front of this there is a convex articular area of variable shape (**facies articularis posterior**), sometimes nearly circular, at other times oval and occasionally almost triangular. This is directed upwards and forwards, and articulates with the posterior calcanean facet on the plantar surface of the talus. Anterior to this facet the bone is deeply excavated, forming a fossa from

FIG. 259.—THE RIGHT CALCANEUS. A. Seen from above; B. Seen from below.

which a **groove (sulcus calcanei)** leads backwards and medially around the antero-medial border of the articular surface. When the calcaneus is placed in contact with the talus, this groove coincides with the sulcus on the plantar surface of the talus, and so forms a **canal or tunnel (sinus tarsi)** in which the strong interosseous ligament which unites the two bones is lodged. To the front and medial side of this groove there is an elongated articular facet directed obliquely from behind forwards and laterally, and concave in the direction of its long axis. This is frequently divided into two smaller oval areas by an intermediate non-articular surface. Of these facets the posterior (**facies articularis media**) articulates with the middle calcanean facet on the plantar surface of the talus, whilst the anterior (**facies articularis anterior**) supports the plantar surface of the head of the talus (**facies articularis calcanei anterior**). The lateral side of the anterior extremity of the dorsal surface of the bone is rough, and to this is attached the origin of the short extensor muscle of the toes.

The **plantar surface** of the bone is slightly concave from before backwards, and convex from side to side. The plantar aspect of the **tuberosity** is provided with two tubercles, a **medial (processus medialis tuberis calcanei)** and a **lateral (processus lateralis tuberis calcanei)**, of which the former is the larger. From this the short flexor of the toes and the abductor hallucis muscle arise, whilst from both tubercles

spring the fibres of origin of the abductor digiti quinti muscle. On the anterior part of the plantar surface there is an elevated elongated tubercle, which terminates somewhat abruptly just behind the anterior border of this aspect of the bone, giving rise at times to a notch. From the former spring the fibres of the long plantar ligament, whilst the latter serves for the attachment of the deeper fibres of the plantar calcaneo-cuboid ligament. The two heads of origin of the quadratus plantæ muscle arise from the bone on either side of the long plantar ligament.

The **medial surface** of the calcaneus is crossed obliquely, from above downwards and forwards, by a broad groove of considerable depth; along this pass many of the structures which enter the sole of the foot from the back of the leg. The

groove is overhung in front and above by a projecting bracket-like process, called the **sustentaculum tali**. The plantar surface of the sustentaculum is channelled by a groove, in which is lodged the tendon of the flexor hallucis longus muscle; whilst its medial border, to which is attached a part of the deltoid ligament (tibio-calcanean fibres) of the ankle, is overlain by the tendon of the flexor digitorum longus. To the anterior border of the sustentaculum is attached the plantar calcaneo-navicular ligament, and placed on its dorsal surface is the articular facet already alluded to (*facies articularis media*). Posteriorly the medial surface of the bone is limited inferiorly by the projection of the medial process of the tuber calcanei, and above by the medial lipped edge of the tuberosity.

The **lateral surface**, broad behind and narrower in front, is of flattened form. Springing from it, just below the lateral end of the sinus tarsi, is the **trochlear process**, often indistinctly marked. To this the fibres of the inferior retinaculum of the peroneal tendons are attached; whilst in grooves, above and below it, pass the

tendons of the peronæus brevis and longus muscles respectively. To the upper and posterior part of this surface are attached the fibres of the calcaneo-fibular ligament of the ankle.

The **anterior extremity** is furnished with a saddle-shaped surface on its anterior aspect for articulation with the cuboid. This facet is concave from above downwards, and slightly convex from side to side; its edges are sharply defined, except medially, and serve for the attachment of ligaments.

The **posterior extremity**, called the **tuber calcanei** (tuberosity), forms the projection of the heel. Of oval form and rounded surface, it rests upon the two processes or tubercles inferiorly and is divisible into three areas. Of these the highest is smooth and crescentic, and is covered by a bursa; the intermediate is also fairly smooth, and is defined inferiorly by an irregular line, sometimes a definite ridge,

FIG. 260.—THE RIGHT CALCANEUS. C. Seen from the lateral side; D. Seen from the medial side.

the edges of which are striated. Into this surface the *tendo calcaneus* is inserted. The lowest surface is rough and striated, and is confluent below with the medial and lateral processes; this is overlain by the dense layer of tissue which forms the pad of the heel.

Os Naviculare Pedis.

The **navicular bone** (O.T. *scaphoid*), of compressed piriform shape, is placed on the medial side of the foot, between the head of the *talus* posteriorly and the three cuneiform bones anteriorly. The bone derives its name from the oval or boat-shaped hollow on its **proximal surface**, which rests upon the head of the *talus*. Its **distal aspect** is furnished with a semilunar articular area, which is subdivided by two faint ridges into three wedge-shaped facets for articulation, medio-laterally, with the first, second, and third cuneiform bones. The **dorsal surface** of the bone, convex from side to side, is rough for the attachment of the ligaments on the dorsal aspect of the foot. On its **plantar aspect** the bone is irregularly concave; projecting downwards and backwards from its lateral side there is often a prominent spur of bone, the **plantar process**, to which is attached the

FIG. 261.—THE RIGHT NAVICULAR BONE.

A. Seen from behind. B. Seen from the front.

plantar calcaneo-navicular ligament. The **lateral surface** is narrow from before backwards, and rounded from above downwards. In 70 per cent of cases (Manners Smith) it is provided with a facet which rests upon a corresponding area on the cuboid. Behind this in rare instances there is a facet for the calcaneus. The **medial surface** of the bone projects beyond the general line of the medial border of the foot, so as to form a thick rounded **tuberosity** (*tuberositas oss. navicularis*), the position of which can be easily determined in the living. To the medial and under surface of this process an extensive portion of the tendon of the *tibialis posterior* muscle is inserted.

The Cuneiform Bones.

The **cuneiform bones**, three in number, are placed between the navicular proximally and the bases of the first, second, and third metatarsal bones distally, for which reason they are now named the **first**, **second**, and **third** cuneiforms (O.T. *internal*, *middle*, and *external*). More or less wedge-shaped, as their name implies, the first is the largest, whilst the second is the smallest of the group. Combined, they form a compact mass, the proximal surface of which, fairly regular in outline, rests on the distal surface of the navicular; whilst distally they form a base of support for the three medial metatarsals, the outline of which is irregular, owing to the base of the second metatarsal bone being recessed between the first and third cuneiforms, as it articulates with the distal extremity of the shorter second cuneiform.

The **first cuneiform bone**, the largest of the three, lies on the medial border of the foot between the base of the metatarsal bone of the great toe distally, and the medial part of the distal surface of the navicular proximally. In form the bone is less characteristically wedge-shaped than its fellows of the same name and differs from them in this respect, that whilst the second and third cuneiforms are so disposed that the bases of their wedges are directed upwards towards the dorsum of the foot, the first cuneiform is so placed that its base is

directed towards the plantar aspect; further, the vertical diameter of the bone is not the same throughout, but is much increased at its anterior or distal end. The

FIG. 262.—DISTAL SURFACES OF THE THREE CUNEIFORM BONES OF THE RIGHT FOOT.

base of the second metatarsal bone. Running along the proximal and dorsal edges of this area is an Γ -shaped articular surface, the distal and dorsal part of which is for the base of the second metatarsal bone, the remainder articulating with the medial side of the second cuneiform. The non-articular part of this aspect of the bone is rough for the attachment of the strong interosseous ligaments which bind it to the second cuneiform and second metatarsal bones, respectively. The proximal end of the

FIG. 263.—THE RIGHT FIRST CUNEIFORM (Medial Side).

FIG. 264.—THE RIGHT FIRST CUNEIFORM (Lateral Side).

FIG. 265.—THE RIGHT SECOND CUNEIFORM (Medial Side).

FIG. 266.—THE RIGHT SECOND CUNEIFORM (Lateral Side).

bone is provided with a piriform facet which fits on the medial articular area of the navicular. Here the wedge-shaped form of the bone is best displayed. Distally the vertical diameter of the bone is much increased, and the facet for the

base of the metatarsal bone of the great toe is consequently much larger than that for the navicular. This metatarsal facet is usually of semilunar form, but not infrequently is more reniform in shape, and may in some cases display complete separation into two oval portions.

The second cuneiform is of a typical wedge shape, the base of the wedge being directed towards the dorsum of the foot; shorter than the others, it lies between them, articulating with the base of the second metatarsal in front, and the

middle facet on the distal surface of the navicular behind. Its dorsal surface, which corresponds to the base of the wedge, conforms to the roundness of the instep, and is slightly convex from side to side, affording attachments for the dorsal ligaments. Its plantar aspect is narrow and rough, forming the edge of the wedge; with this the plantar ligaments are connected. The medial surface, quadrilateral in outline, is furnished with an Γ -shaped articular area along its proximal and dorsal borders in correspondence with the similar area on the lateral side of the first cuneiform. The rest of this aspect is rough for ligaments.

The **lateral side** displays a facet arranged along its proximal border, and usually somewhat constricted in the middle; this is for the third cuneiform. Distal to this the bone is rough for the interosseous ligaments, which bind the two bones together. The proximal end is provided with a triangular facet slightly concave from above downwards; this rests on the central articular surface on the anterior aspect of the navicular. In front the bone articulates by means of a wedge-shaped facet with the base of the metatarsal bone of the second toe.

The **third cuneiform**, intermediate in size between the first and second, is also of a fairly typical wedge shape; though its antero-posterior axis is not straight but bent, so that the distal end of the bone turns slightly medially. Its **dorsal surface**, which corresponds to the base of the wedge, is slightly convex from

FIG. 267.—RIGHT THIRD CUNEIFORM (Medial Side).

FIG. 268.—RIGHT THIRD CUNEIFORM (Lateral Side).

side to side, and provides attachments for the dorsal ligaments. Its **inferior or plantar aspect** forms a rough blunt edge, and serves for the attachment of the plantar ligaments. Its **medial side**, of quadrilateral form, displays two narrow articular strips, placed along its distal and proximal borders respectively, each somewhat constricted in the middle. The distal articulates with the lateral side of the base of the second metatarsal bone, the proximal with the lateral side of the second cuneiform. The rough non-articular surface, which separates the two elongated facets, serves for the attachment of ligaments. The **lateral aspect** of the bone is characterised by a large circular or oval facet, placed near its proximal border, for articulation with the cuboid; in front of this the distal border is lipped above by a small semi-oval facet for articulation with the medial side of the base of the fourth metatarsal. The rest of the bone around and between these facets is rough for ligaments. **Proximally** the bone is furnished with a blunt, wedge-shaped facet for articulation with the corresponding area on the distal surface of the navicular. Below this the surface is narrow and rough for the attachment of ligaments. The **distal end** of the bone articulates with the base of the third metatarsal by a surface of triangular shape.

Os Cuboideum.

The **cuboid** lies on the lateral side of the foot, about its middle, articulating with the calcaneus proximally and the fourth and fifth metatarsal bones distally. Its **dorsal surface**, plane in an antero-posterior direction, is slightly rounded from side to side, and provides attachment for ligaments. Its **plantar aspect** is traversed obliquely from the lateral side medially and forwards by a thick and prominent ridge, the lateral extremity of which, at the point where it is confluent with the lateral surface, forms a prominent **tubercle** (*tuberositas oss. cuboidei*), the anterior and lateral surface of which is smooth and faceted to allow of the play of a sesamoid bone which is frequently developed in the tendon of the peronæus longus muscle. Distal to this ridge there is a groove (*sulcus peronæi*) in which the tendon of the peronæus longus muscle is lodged as it passes across the under surface of the bone. Proximal to the ridge the bone is rough, and serves for the attachment of the plantar calcaneo-cuboid ligament, the superficial fibres of which pass forwards and are attached to the summit of the ridge. The **lateral aspect** of the bone is short and rounded, and is formed by the confluence of the dorsal and plantar surfaces: it is more or less notched by the peroneal groove which turns round its plantar edge. The **medial surface** of the bone is the most extensive; it is easily recognisable on account of the presence of a rounded or oval facet situated near

its middle and close to its dorsal border. This is for articulation with the lateral side of the third cuneiform; proximal and distal to this the surface is rough for ligaments. Not infrequently, proximal to the facet for the third cuneiform, there is

FIG. 269.—THE RIGHT CUBOID BONE.

A. Lateral Side.

B. Medial Side.

Anat. Soc.," *Journ. Anat. and Physiol.* vol. xxvi. p. 18.) The **distal surface** is oval or conical in outline; sloping obliquely from the medial side laterally and backwards, it is divided about its middle by a slight vertical ridge into two parts, the medial of which articulates with the base of the fourth metatarsal bone, the lateral with that of the fifth. The **proximal surface**, also articular, has a semilunar outline, the convex margin of which corresponds to the dorsal roundness of the bone. The inferior lateral angle corresponds to the tubercle on the lateral border of the bone, whilst the inferior medial angle forms a pointed projection which is sometimes called the *calcanean process*. This surface articulates with the calcaneus by means of a saddle-shaped facet, which is convex from side to side, and concave from dorsal to plantar margins.

The **tarsus as a whole** may be conveniently described as arranged in two

FIG. 270.—RADIOGRAPHS OF THE FETAL FOOT.

1. About fifth month. No ossification in the tarsus visible.
2. About sixth month. Appearance of a nucleus for the calcaneus.
3. About seventh month. Nucleus for calcaneus well developed.
- 4 and 5. About eighth month. Centres for talus and calcaneus now seen.
6. About birth. Centres for the talus and calcaneus are well developed, there is also a considerable centre for the cuboid, and the appearance of a centre for the third cuneiform is now displayed.

columns; the medial, corresponding to the medial border of the foot, comprising the talus, navicular, and three cuneiforms, and forming a base for the support of the three medial metatarsal bones and their phalanges. The lateral column, formed by the calcaneus and cuboid, supports the fourth and fifth metatarsal bones together with their phalanges. The dorsal surface of the anterior portion of the

tarsus determines the side-to-side roundness of the instep, whilst its plantar surface forms arches in both a transverse and longitudinal direction, in which the softer tissues of the sole are lodged, and so protected from injury.

Ossification.—Unlike the carpus, the tarsus is at birth partially ossified. At this period there is a well-marked osseous nucleus within the body and neck of the talus, and the calcaneus is extensively ossified. In the latter the deposition of earthy matter appears as early as the sixth month of foetal life, whilst in the talus the ossific centre makes its appearance in the later weeks of gestation. Shortly before or after birth the

FIG. 271.—RADIOGRAPH OF THE HAND AT BIRTH.

It will be noticed that whilst the primary centres for the metacarpus and phalanges are well ossified, the carpus is still entirely cartilaginous.

FIG. 272.—RADIOGRAPH OF THE FOOT AT BIRTH.

The centres of ossification for the calcaneus and talus are well developed, the nucleus for the cuboid is quite distinct, and in this instance the third cuneiform is already commencing to ossify.

cuboid begins to ossify, succeeded early in the first year by the third cuneiform, followed in order by the second cuneiform, first cuneiform, and navicular. The ossific centre of the latter appears at the third year or somewhat later. An epiphysis, which forms a cap over the extremity of the tuberosity of the calcaneus, appears from the seventh to the ninth year, and fusion is completed between the ages of sixteen and twenty.

To emphasize the different conditions which obtain in the wrist and ankle, at, and for some time after birth, drawings of radiographs of both are given.

The Metatarsus.

The **metatarsal bones**, five in number, in their general configuration resemble the metacarpal bones. They are, however, slightly longer, their bases are proportionately larger, their shafts more slender and laterally compressed, and their heads proportionately smaller. They are named numerically the first, second, third, fourth, and fifth metatarsal bones, in order from the tibial to the fibular side. The first can be readily recognised on account of its stoutness; it is also the shortest of the series. The second is the longest of the five, and the fifth can easily be distinguished by the projecting tubercle at its base.

FIG. 273.—THE FIRST METATARSAL BONE OF THE RIGHT FOOT (Plantar Aspect).

The **first metatarsal** or metatarsal bone of the great toe, the shortest of the series, is remarkable for its stoutness. Its **proximal end** or **base**, where the bone is provided with a reniform facet for articulation with the first cuneiform, is wider from the dorsal to the plantar aspect than from side to side. The concavity of the kidney-shaped articular area is directed to the fibular side. As a rule the lateral aspects of the base are non-articular, though occasionally on its lateral side there is a “pressure” facet for the base of the second metatarsal bone. The plantar basal angle projects proximally and laterally, and forms a prominent tubercle which is pitted for the insertion of the tendon of the peronæus longus muscle, whilst its tibial margin is lipped by a surface for the attachment of part of the tendon of the tibialis anterior. The **shaft**, short, thick, and prismatic on section, tapers rapidly towards the head, the distal and plantar surfaces of which are articular. The former is convex in both directions, and supports the proximal or first phalanx. It is confluent with the plantar articular surface, which is divided by a median ridge into two shallow grooves, of which the tibial is the wider. In these grooves are lodged the two sesamoid bones of the metatarsophalangeal joint. On either side of the head, the bone is pitted for the strong collateral ligaments of the joint.

The **second metatarsal**, the longest of the series, has a **base** of wedge-shaped

FIG. 274.—VIEW OF THE BASES AND SHAFTS OF THE SECOND, THIRD, AND FOURTH METATARSAL BONES OF THE RIGHT FOOT.

form, the proximal aspect of which articulates with the second cuneiform. On its tibial aspect, near its dorsal edge there is a small circular facet for the first

cuneiform; distal to this and near the plantar surface there is sometimes a tubercle with a "pressure" facet on it, where the bone comes in contact with the base of the first metatarsal. On the fibular side of the base there is one, more usually two small facets, each divided into two parts, a proximal for articulation with the third cuneiform, and a distal for the base of the third metatarsal. The shafts of this and the three succeeding bones are slender and laterally compressed. The heads are small and narrow, and display a pronounced side-to-side and vertical convexity.

The **third metatarsal bone** also possesses a base of wedge-shaped form, the proximal surface of which articulates with the third cuneiform. On its tibial side it is provided with one, more usually two, small facets, for articulation with the base of the second metatarsal. Laterally the base has a larger facet for articulation with the base of the fourth metatarsal, more or less conical in outline, and having its plantar edge sharply defined by a narrow groove which underlies it.

The **fourth metatarsal** has a base more cubical in shape. It articulates with the cuboid, whilst medially an elongated oval facet, divided by a slight vertical ridge, provides surfaces for articulation with the third metatarsal distally and the lateral side of the first cuneiform proximally. On the lateral side there is a demi-oval facet, bearing a slightly saddle-shaped surface, for articulation with the tibial side of the base of the fifth metatarsal.

Its proximal aspect

The **fifth metatarsal** can be readily recognised by the peculiar shape of its base, from the lateral side of which there projects proximally and laterally a prominent **tuberosity** (*tuberositas oss. metacarpi quinti*). To the proximal extremity of this is attached the tendon of the *peronæus brevis* muscle. Into its dorsal surface the tendon of the *peronæus tertius* is inserted, whilst its plantar surface provides an origin for the *flexor digiti quinti brevis* muscle. The tibial surface of the base is provided with a demi-oval, slightly concave facet, for the lateral side of the base of the fourth metatarsal, whilst proximally it articulates with the cuboid by means of a semicircular facet.

FIG. 275.—FIFTH RIGHT METATARSAL BONE (Dorsal Aspect).

Vascular Foramina.—The canals for the nutrient vessels open, as a rule, on the plantar aspects of the middle of the shafts. Those of the lateral metatarsals are directed towards the bases of the bones, whilst that for the metatarsal of the great toe passes towards its head.

Ossification.—In correspondence with the mode of ossification which obtains in the metacarpus, the primary centres for the metatarsus appear as early as the third month of foetal life. In the case of the second, third, fourth, and fifth, these centres furnish the bases and shafts of the bones, the heads being developed from secondary centres which appear from two to four years after birth, fusion with the shaft being usually completed about the eighteenth year. In striking contrast to this is the mode of ossification of the first metatarsal. From its primary centre the head and shaft is developed; the secondary centre appears at its base about the second or third year, and fuses with the shaft about eighteen. In this respect, therefore, the metatarsal bone of the great toe resembles in its mode of development the phalanges. Mayet, however (*Bull. Soc. Anat. Paris*, 1895), describes the occurrence of two ossific centres in the proximal epiphysis. These fuse early, and he considers that the one represents the metatarsal element, whilst the other may be regarded as phalangeal in its origin.

Phalanges Digitorum Pedis.

The **phalanges** of the toes differ from those of the fingers in the striking reduction of their size, and in the case of the bones of the first row, in the lateral compression of their shafts. Each toe is provided normally with three phalanges, except the great toe, which has only two. In their general

configuration and in the arrangement of their articular facets they resemble the phalanges of the fingers, though owing to the reduction in their size, the shafts, particularly those of the second row, are often so compressed longitudinally as to reduce the bone to a mere nodule. The proximal end of each of the bones of the first row is proportionately large, and is provided with a simple hollow in which the head of the metatarsal bone rests; the distal ends are furnished with condyloid surfaces. The proximal extremities of the second row are each provided with two small concavities, separated by a slight ridge for articulation with the condyles of the first row. The joint between the second and third row displays the same arrangement—the third, or ungual phalanx, being easily distinguished by the spatula-shaped surface at its extremity, on which the bed of the nail is supported.

FIG. 276.—THE PHALANGES OF THE TOES (Plantar Aspect).

The phalanges of the great toe, two in number, differ from the others in their size and length. Into the base of the first phalanx are inserted the short muscles of the great toe, whilst the second phalanx receives on its plantar aspect the insertion of the flexor hallucis longus muscle, the tendon of the extensor hallucis longus being inserted into the dorsal aspect.

Ossification.—Each phalanx is developed from two centres—one primary for the shaft and distal extremity, the other for the epiphysis on the proximal end. The primary centres for the ungual phalanges are the first to appear, commencing to ossify from the eleventh to the twelfth week of foetal life. The centre for the ungual phalanx of the great toe makes its appearance before that of its corresponding metatarsal bone. The primary centres for the phalanges of the first row appear from the fourteenth to the sixteenth week. The primary centres for the middle phalanges of the second and

FIG. 277.

- A. About the end of the third month. The primary centres of all the metatarsals are shown as well as the centres for the phalanges of the great toe and the terminal phalanx of the third toe.
- B.¹ A little later. The centres for the terminal phalanges of the four medial toes are seen, as well as the centres for the first phalanges of the great and second toe.
- C. About the fourth month. The centres for all the terminal phalanges as well as those of the first row are well ossified.
- D. About the fifth month. In this the centre for the second phalanx of the second toe has already made its appearance.

¹ This specimen displays the occurrence of anomalous centres within the tarsus the significance of which is not apparent. The appearance is not due to any defect in the plate, but recurred in repeated radiographs.

third toes begin to ossify about the sixth month, those for the fourth and fifth toes not till later—the shaft of the middle phalanx of the fourth toe being frequently cartilaginous at birth, the normal condition in the case of the fifth toe (Lambert). The proximal epiphyses do not begin to ossify until about the fourth year, and are usually fused with the diaphyses about the age of sixteen or eighteen. Union between the shafts and epiphyses of the first row precedes that of the second and third rows.

Ossa Sesamoidea.

As in the hand, small independent nodules of bone, called **sesamoid bones**, are met with in the ligaments and tendons of the foot. The most constant of these are found in connexion with the metatarso-phalangeal articulation of the great toe, where they lie in grooves on the plantar surface of the head of the metatarsal bone in connexion with the tendons of the short muscles of the great toe. Small osseous nodules occupying a corresponding position are occasionally met with in the other toes, and instances have been recorded of like ossicles occurring on the plantar aspect of the interphalangeal joint of the great toe.

An osseous nodule is not infrequently met with in the tendon of the peronæus longus as it turns round the lateral border of the foot to lie in the groove on the under surface of the cuboid.

APPENDIX A.

ARCHITECTURE OF THE BONES OF THE SKELETON.

The Vertebrae.—The vertebrae are formed of spongy bone confined within a thin and dense envelope. In the bodies the arrangement of the spongy tissue, which is traversed by venous channels, is such as to display a vertical striation with lamellae arranged horizontally. The lateral, superior, and inferior walls are very thin—that directed to the vertebral canal being usually thicker and denser than the others. In the roots of the vertebral arches and roots of the transverse processes the spongy tissue is much more open. The outer envelope is much thicker where it bounds the vertebral canal, and where it forms the bottom of the superior and inferior intervertebral notches. In the laminæ the spongy tissue is confined between two compact layers, of which that directed to the vertebral canal is the thicker. In the spinous processes the upper edge is always the more compact.

The Sternum consists of large-celled spongy bone, which is highly vascular, and is contained between two layers of thin compact tissue.

The Ribs.—Each rib consists of a curved and compressed bar of bone, the interior of which consists of highly vascular spongy tissue with an external envelope of compact bone. The inner table is much the stronger, attaining its maximum thickness opposite the angle—in front and behind which it becomes gradually reduced. The outer table, much thinner, is stoutest opposite the angle; on the posterior surface of the tubercle and neck it forms but a thin layer. The compact layers forming the upper and lower borders are not so thick as those forming the inner and outer surfaces. The spongy tissue, loose and open in the shaft, is most compact in the region of the head and towards the anterior extremity.

The Frontal Bone.—The frontal bone is composed, like the other bones of the cranial vault, of two layers of compact tissue, enclosing between them a layer of spongy cancellous texture—the diploë. In certain definite situations, owing to the absorption of this intermediate layer, the bone is hollow, forming the **frontal air-sinuses**. The position and extent of these is to some extent indicated by the degree of projection of the superciliary ridges, though this must not be taken as an absolutely reliable guide, for cases are recorded where the ridges were low and the sinuses large, and *vice versa*. Of much surgical importance, these air-spaces only attain their full development after the age of puberty, being of larger size in the male than in the female, a circumstance which accounts for the more vertical appearance of the forehead in woman as contrasted with man. Usually two in number, they are placed one on either side of the median plane, and communicate by means of the infundibulum with the nasal cavity of the same side. It is exceptional to find the sinuses of opposite sides in communication with each other, as they are generally separated by a complete partition which, however, is occasionally much deflected to one or other side. Logan Turner ("On the Illumination of the Air Sinuses of the Skull, with some Observations upon the Surgical Anatomy of the Frontal Sinus," *Edin. Med. Journ.*, May 1898) gives the average dimensions of these sinuses as follows:—Height, 31 mm., *i.e.* from the fronto-nasal aperture upwards; breadth, 30 mm., *i.e.* from the septum horizontally in a lateral direction; depth, 17 mm., from the anterior wall at the level of fronto-nasal suture backwards along the orbital roof. Exceptionally large sinuses are sometimes met with extending backwards over the orbit so as to form a double roof to that space. There is a specimen in the Oxford collection in which the sinus is so large, and extends so far back, that the optic nerve is transmitted through it in a bony tube. Another point of some practical importance is that the sinuses are hardly ever symmetrical. It is rare to meet with cases of their complete absence, although sometimes the sinus on one or other side may be wanting.

The zygomatic process, from the arrangement of its surfaces and the density of its structure, is particularly well adapted to resist the pressure to which it is subjected when the jaws are firmly closed.

The Parietal Bone.—Thin towards its lower part, where it enters into the formation of the temporal fossa, it is thickest along the superior border and in the neighbourhood of the posterior superior angle.

The Occipital Bone.—The squamous part displays thickenings in the position of the various ridge and crests, the stoutest part corresponding to the internal and external occipital protuberances,

though it should be noted that the two protuberances do not necessarily coincide, the internal being, as a rule, placed at a higher level than the external. If the bone be held up to the light it will be at once apparent that it is much thinner where it forms the floor of the inferior fossæ than in the upper part. The basilar portion consists of a spongy core surrounded by a more compact outer envelope, thickest on its lower surface. In the condyles the spongy tissue is arranged radially to their convex articular surfaces, the hypoglossal canal being surrounded by particularly dense and compact bone, which assists in strengthening this naturally weak part of the bone.

The Temporal Bone.—The temporal bone is remarkable for the hardness and density of its petrous part, wherein is lodged the osseous labyrinth, which contains the delicate organs associated with the senses of hearing and equilibration. The middle ear or tympanum is a cavity which contains the small auditory ossicles, and is separated from the external acoustic meatus by the membrana tympani. *In front* it communicates with the pharynx by the auditory tube; *behind*, it opens into the tympanic antrum and mastoid air-cells by the aditus ad antrum. *Superiorly*, it is separated from the middle cranial fossa by a thin plate of bone called the tegmen tympani. *Inferiorly*, its floor is formed in part by the roof of the jugular fossa and the carotid canal. *Medially*, it is related to the structures which form the inner ear, notably the cochlea and vestibule, in front of which it is separated by a thin plate of bone from the carotid canal. Owing to the disposition of the internal and external acoustic meatus the weakest part of the bone corresponds to a line connecting these two channels, the only parts intervening being the cochlea and tympanum. It is usually in this position that fracture of the bone occurs. Curving over the cavity of the tympanum is the canalis facialis, the thin walls of which are occasionally deficient. These details, together with an account of the tympanic ossicles, will be further dealt with in the section devoted to the Organs of Sense.

The Sphenoid Bone.—In the adult the body of the bone is hollow and encloses the sphenoidal air-sinuses, usually two in number, separated by a septum. The arrangement and extent of these air-sinuses vary; sometimes they are multilocular, at other times simple, while occasionally they extend backwards into the basi-occipital and laterally and downwards into the roots of the great wings and pterygoid processes. Cases are on record in which in the adult the body of the bone was not pneumatic.

The Lacrimal Bone.—The bone consists of a thin papery translucent lamina, somewhat strengthened by the addition of the vertical crest.

The Vomer.—The bone is composed of two compact layers fused below, but separated above by the groove for the lodgment of the rostrum of the sphenoid behind, and the septal cartilage in front. The lamellæ are also separated from each other by a canal which runs horizontally from behind forwards in the substance of the bone, and which transmits the nutrient vessel of the bone.

The Nasal Bone.—Formed of dense and compact bone; the strength of the nasal bones is increased by their mode of union and the formation of a median crest posteriorly.

The Maxilla.—The disposition of the maxillary sinus within the body of the bone has been already referred to. In union with its fellow, the vaulted arrangement of the hard palate is well displayed, and the arched outline of the alveolar processes is obvious. It is in these latter processes around the sockets for the reception of the teeth that the spongy tissue of the bone is seen; elsewhere its walls are formed by thin and dense bone.

The Zygomatic Bone.—In structure the bone is compact, with little spongy tissue. Together with the zygomatic process of the temporal bone it forms the buttress which supports the maxilla and the lateral wall of the orbit. Additional strength is imparted to the bone by the angular mode of union of its orbital and facial parts.

The Mandible.—The mandible is remarkable for the density and thickness of its medial and lateral walls. Where these coalesce below at the base of the body, the bone is particularly stout. Superiorly, where they form the walls of the alveoli, they gradually thin, being thicker, however, on the medial than the lateral side, except in the region of the last molar tooth, where the medial wall is the thinner. The spongy substance is open-meshed below, finer and more condensed where it surrounds the alveoli. The mandibular canal is large and has no very definite wall; it is prolonged beyond the mental foramen to reach the incisor teeth. From it numerous channels pass upwards to the sockets of the teeth, and it communicates freely with the surrounding spongy tissue. Above the canal the substance of the bone is broken up by the alveoli for the reception of the roots of the teeth. In the substance of the condyle the spongy tissue is more compact, with a general striation vertical to the articular surface.

The mental protuberance is an essentially human characteristic; by some it is associated with the development of speech in man, others regard it as due to the reduction in the size of the teeth.

The Clavicle.—The shaft consists of an outer layer of compact bone, thickest towards the centre, but gradually thinning towards the extremities, the investing envelope of which consists merely of a thin shell. Within the shaft the spongy tissue displays a longitudinal striation, which internally assumes a more cellular appearance. At the acromial end the general arrangement of the fibres resembles the appearance of the sides of a Gothic arch. The curves of the bone impart an elasticity to it, which is of much service in reducing the effects of the shocks to which it is so frequently subjected.

The Scapula.—For so light and thin a bone, the scapula possesses a remarkable rigidity. This is owing to the arrangement of its parts. Stout and thick where it supports the glenoid cavity

and coracoid process, the rest of the bone is thin, except along the axillary margin; but strength is imparted to the body by the manner in which the spine is fused at right angles to its dorsal surface.

The Humerus.—The shaft consists of a layer of compact bone surrounding a long medullary canal. The outer shell, thickest in the distal third of the bone, gradually thins until it reaches the proximal epiphysial line, where it forms a layer no thicker than stout paper. Distally the external shell is thicker and stouter than it is proximally, until it reaches the epicondyles, distal to which the articular surfaces are formed of a layer of compact spongy bone. The proximal end of the medullary canal is surrounded by loose spongy tissue, the fibres of which arch inwards from the inner surface of the compact outer layer, whilst at the distal end the spongy tissue which springs from the outer shell sweeps distally in a radiating fashion on either side of the olecranon fossa towards the epicondyles. Proximal to the olecranon fossa there is a number of laminae of dense bone which arch across from one side to the other, the convexity of the arches being directed distally. The proximal epiphysis, formed of spongy bone, is united to the shaft by a wavy line, concave laterally and convex medially, leading from the base of the greater tuberosity on the lateral side to the distal articular edge on the medial side. The mass above this includes the head and two tuberosities. The spongy tissue of the head is fine, and is arranged generally in lines radial to its surface; that of the greater tuberosity is more open, and often displays large spaces towards its interior, which in old bones communicate freely with the medullary cavity of the shaft. The general direction of the fibres is parallel to the lateral surface of the tuberosity. The distal articular end is formed of fine spongy tissue, more compact towards the surface, and arranged in lines more or less at right angles to its articular planes. In the adult the principal nutrient canal, viz., that which opens on the surface near the insertion of the coraco-brachialis, traverses the outer compact wall of the shaft obliquely distally for a distance of two and a quarter inches before it opens into the medullary cavity.

The Ulna.—The weakest parts of the bone are the constricted portion of the semilunar notch, and the shaft in its distal third, the bone being most liable to fracture at these points. On section the medullary cavity is seen to extend proximally as high as the base of the coronoid process; distally it reaches the proximal end of the distal fifth of the bone. The walls of the shaft, which are formed of dense bone, are much thicker on the dorsal surface than on the volar. Proximally they are continuous with the volar surface of the coronoid process and the dorsal surface of the olecranon, where they are composed of layers of looser texture, which, however, gradually become thinner as the points of these processes are reached. Distally they gradually taper until the head and styloid process are reached, round which they form a thin shell, considerably thickened, however, in the region of the groove for the extensor carpi ulnaris muscle. The bulk of the proximal extremity is formed of loose spongy bone, arranged in a series of arcades, stretching from the interior to the dorsal wall over the proximal end of the medullary canal. Proximal to the constricted part of the semilunar notch the bone displays a different structure; here it is formed of spongy bone, of closer texture, arranged generally in lines radiating from the articular surface. At the point of constriction of the semilunar notch the layer immediately subjacent is much denser and more compact.

The distal fifth of the bone is formed of loose spongy bone, the fibres of which have a general longitudinal arrangement; towards its extremity the meshes become smaller.

The Radius.—The neck is the narrowest part of the bone; here fracture may occur, though not commonly. The point at which the bone is usually broken is about one inch proximal to the distal extremity. This is accounted for by the fact that the radius supports the hand at the radio-carpal articulation, and the shocks to which the latter is subjected, as in endeavouring to save oneself from falling, are naturally transmitted to the radius. On section, the medullary canal is seen to extend to the neck; distally, it reaches to the level of the distal fifth of the bone. Its walls are thick as compared with the diameters of the bone, particularly along the interosseous border, thus imparting rigidity to the curve of the shaft; these walls thin out proximally and distally. Proximally, the surface of the tuberosity is formed of a thin shell of bone, which, however, thickens again where it passes on to the neck. The proximal extremity is formed of spongy bone arranged in the form of arcades, reaching distal to the level of the tuberosity medially, but not extending distal to the level of the neck laterally. Beneath the caputular articular surface there is a dense layer, thickest in the centre, and thinning towards the circumference; this is overlain by a very thin layer of less compact bone.

The distal fifth of the shaft and distal extremity are formed of loose spongy bone arranged more or less longitudinally. Immediately subjacent to the carpal articular surface the tissue is more compact, and displays a striation parallel to the articular plane. The nutrient canal of the shaft pierces the volar wall of the proximal part of the medullary cavity obliquely running proximally for the space of half an inch.

The Carpus.—The bones are formed of fairly compact spongy tissue, surrounded by a thin shell of denser bone. They are very vascular, and their non-articular surfaces are pierced by many foramina.

The Metacarpus.—Similar in arrangement to that of long bones generally, though it may be noted that the compact walls of the shaft are thicker in proportion to the length of the bone than in the other long bones of the upper extremity.

The Phalanges.—Each phalanx has a medullary cavity, the walls of the shaft being formed of dense compact bone, especially thick along the dorsal aspect. The extremities are made up of spongy bone within a thin dense shell.

The Hip Bone.—As a flat bone the os coxae consists of spongy tissue between two compact external layers. These latter vary much in thickness, being exceptionally stout along the ilio-pectineal line and the floor of the iliac fossa immediately above it. The gluteal aspect of the ilium is also formed by a layer of considerable thickness. The spongy tissue is loose and cellular in the thick part of the ilium and in the body of the ischium; absent where the floor of the iliac fossa is formed by the coalescence of the thin dense confining layers; fine grained and more compact in the tuberosity of the ischium, the iliac crest, and the floor of the acetabulum, in which latter situation it is striated by fibres which are directed radially to the surface of that hollow, these again being crossed at right angles by others which are arranged circumferentially. This spongy tissue forms a more compact layer over the surface of the upper and posterior portion of the acetabular articular area. The bottom of the floor of the acetabulum varies in thickness; in most cases it is thin, and in exceptional instances the bone is here deficient. The same condition has been met with in the iliac

FIG. 278.—DISSECTION SHOWING THE CALCAR FEMORALE.

A slice of bone has been removed from the posterior aspect of the proximal part of the shaft of the femur, passing through the trochanter major superiorly and the trochanter minor inferiorly and to the medial side. The loose spongy tissue has been scraped away, leaving the more compact tissue with the dense core forming the calcar femorale. By a similar dissection from the front the anterior surface of the calcar may be exposed.

FIG. 279.—SECTION THROUGH HEAD AND NECK OF FEMUR TO SHOW CALCAR FEMORALE.

it reaches the head. From this aspect of the neck there spring a series of oblique lamellæ which pass proximally and upwards, spreading in fan-shaped manner into the under surface of the head. These are intersected above by lamellæ which arch medially from the lateral side of the

fossa, where absorption of the thin bony plate has taken place.

The Femur.—The shaft has a medullary cavity which reaches the root of the lesser trochanter proximally. Distally it extends to within $3\frac{1}{2}$ inches of the distal articular surface. In the proximal half the outer compact wall is very thick, but distal to the middle of the shaft it gradually thins until it reaches the condyles, over which it passes as a thin, hardly definable external layer. Proximally, it is especially thick along the line of the linea aspera, and here the large nutrient canal may be seen passing obliquely towards the proximal end in the substance of the dense bone for the space of two inches. In the proximal end of the shaft the osseous lamellæ springing from the sides of the medullary cavity arch inwards towards the centre, intersecting each other in a manner comparable to the tracery of a Gothic window. The lower wall of the neck is thick distally, near the trochanter minor, but thins rapidly before

shaft distal to the greater trochanter, as well as from the under surface of the thin but compact outer shell of the upper surface of the neck, the whole forming a bracket-like arrangement which assists materially in adding to the strength of the neck. Further support is afforded by the addition of a vertical layer of more compact bone within the spongy tissue of the neck. Distally, as may be seen in Fig. 278, this is continuous with the dense posterior wall of the shaft below; whilst proximally it sweeps up beneath the lesser trochanter, from which it is separated by a quantity of loose spongy tissue, to fuse proximally with the posterior dense wall of the neck above and medial to the intertrochanteric crest. It may be regarded as a continuation proximally of the posterior wall of the shaft beneath the trochanteric epiphysis. When studied in section (see Fig. 279), the central dense core of this partition exhibits a spur-like appearance: hence the name **calcar femorale** applied to it. It is of surgical importance in cases of fracture of the neck of the femur. (R. Thompson, *Journ. Anat. and Physiol.*, vol. xlii. p. 60.) From it, stout lamellæ having a vertical direction arise. The spongy tissue of the head and greater trochanter is finely reticulated, that of the distal part of the neck and proximal part of the shaft being more open in its texture. Passing vertically through this tissue there is a vascular canal, the orifice of which opens externally on the floor of the trochanteric fossa.

The spongy tissue of the distal part of the shaft is more delicate and uniform in its arrangement, displaying a more or less parallel striation in a longitudinal direction. Subjacent to the articular surface the tissue is rendered more compact by the addition of lamellæ disposed in curves in harmony with the external aspect of the bone.

The Patella.—The bone consists of a thick dense layer anteriorly, which thins towards the edges on either side and distally; above, it corresponds to the area of insertion of the quadriceps. The femoral articular surface is composed of a layer of compact bone, thickest in correspondence with the vertical elevation. Sandwiched between these two layers is a varying thickness of spongy tissue of fairly close grain, the striation of which on cross section runs in parallel lines from back to front; on vertical section the tissue appears to be arranged in lines passing radially from the deep surface of the femoral area to the more extensive anterior dense plate.

The Tibia.—The shaft of the bone is remarkable for the thickness and density of the osseous tissue which underlies the anterior crest. The posterior wall is stout, but the medial and lateral walls are thinner. The several walls are thickest opposite the middle of the shaft, and thin out proximally and distally where the shaft unites with the epiphyses. The medullary canal, narrow and circular in the middle of the bone, increases in all its diameters proximally and distally, and reaches to within $2\frac{1}{2}$ to 3 inches of either extremity. Proximally the arrangement of the lamellæ of the spongy tissue resembles a series of arches springing from the dense outer walls. These form a platform on which the proximal epiphysis rests, the spongy tissue of which displays a more or less vertical striation. This is much more compact under the condylic surfaces, the superficial aspect of which is formed by a thin layer of dense bone. The intercondyloid eminence and the tuberosity are also formed of compact tissue, whilst the circumference of the condyles is covered by a thinner and less dense wall. In the distal end of the shaft the spongy tissue, of a loose and cellular character, is arranged in vertical fibres, blending with the closer tissue of the distal epiphysis, the articular surface of which is covered by a thin but dense layer.

In the adult bone the nutrient canal for the shaft is embedded in the dense posterior wall for the space of two inches.

The Fibula.—A medullary canal runs throughout the length of the shaft, reaching the neck proximally, and extending to a point about $2\frac{1}{2}$ inches from the distal extremity of the lateral malleolus. The lateral wall of the shaft is usually considerably thicker than the medial. The head is formed of loose spongy bone, enclosed within a very thin dense envelope. The spongy tissue of the distal extremity is more compact, and acquires considerable density on the surfaces underlying the articular area and the pit behind it. The canal for the nutrient artery of the shaft opens into the medullary cavity about an inch distal to its external aperture.

The Bones of the Foot.—A longitudinal section through the articulated bones of the foot reveals the fact that the spongy structure of each individual bone is determined by the stress to which it is habitually subjected. In this connexion it is necessary to refer to the arched arrangement of the bones of the foot, a subject which is also treated in the section which deals with the Joints. The summit of the arch is formed by the talus, on which rests the tibia. Subjected as the talus is to a crushing strain, it is obvious that this load must be distributed throughout the arch, of which the calcaneus is the posterior pillar, whilst the heads of the metatarsal bones constitute the anterior pillar. It is found, consequently, that the lamellæ of the spongy tissue of the talus are arranged in two directions, which intercross and terminate below the proximal articular surface. Of these fibres, some sweep backwards and downwards towards the posterior calcanean facet, beyond which they are carried in the substance of the calcaneus in a curved and wavy manner in the direction of the heel, where they terminate; whilst others, curving downwards and forwards from the trochlea of the talus, pass through the neck to reach the articular surface of the head, through which in like manner they may be regarded as passing onwards through the several bones which constitute the anterior part of the arch, thus accounting for the longitudinal striation as displayed in the structure of the navicular, cuneiform, and metatarsal bones. In the calcaneus, in addition to the foregoing arrangement, another set of curving fibres sweep from back to front of the bone beneath the more compact tissue which forms its under shell. These are obviously of advantage to prevent the spread of the bone when subjected to the crushing strain. In the sustentaculum tali a bracket-like

arrangement of fibres is evident, and the plantar surface of the neck of the talus is further strengthened by lamellæ arranged vertically.

In the separate bones the investing envelope is thin, though under the articular surfaces there is a greater density, due to the accession of lamellæ lying parallel to the articular planes. The stoutest bony tissue in the talus is met with in the region of the plantar surface of the neck, whilst in the calcaneus the greatest density occurs along the floor of the sinus tarsi.

The Metatarsus.—In structure and the arrangement of their lamellæ the metatarsal bones agree with the metacarpus.

The Phalanges.—In their general structure they resemble the bones of the fingers.

APPENDIX B.

VARIATIONS IN THE SKELETON.

Cervical Vertebrae.—Szawlowski records the presence of an independent rib element in the transverse process of the fourth cervical vertebra. (*Anat. Anz. Jena*, vol. xx. p. 306.)

Atlas.—The foramen transversarium is often deficient in front. Imperfect ossification occasionally leads to the anterior arch, and more frequently the posterior arch, being incomplete. The superior articular surfaces are occasionally partially or completely divided into anterior and posterior portions. In some instances the extremity of the transverse process has two tubercles. The transverse process may, in rare cases, articulate with a projecting process (paroccipital) from the under surface of the jugular process of the occipital bone (see p. 278). An upward extension from the medial part of the anterior arch, due probably to an ossification of the anterior occipito-atlantal ligament, may articulate with the anterior surface of the summit of the dens of the epistropheus. Allen has noticed the articulation of the superior border of the posterior arch with the posterior border of the foramen magnum. Cases of partial or complete fusion of the atlas with the occipital bone are not uncommon (see p. 278).

Epistropheus.—In some instances the summit of the dens articulates with a prominent tubercle on the anterior border of the foramen magnum (third occipital condyle, see p. 278). Bennett (*Trans. Path. Soc. Dublin*, vol. vii.) records a case in which the dens was double, due to the persistence of the primitive condition in which it is developed from two centres. Occasionally the dens fails to be united with the body of the epistropheus, forming an *os odontoidum* comparable to that met with in the crocodilia. (Giacomini, Romiti, and Turner.) The foramen transversarium is not infrequently incomplete, owing to the imperfect ossification of the posterior root of the transverse process. Elliot Smith has recorded a case in which there was fusion between the atlas and epistropheus without any evidence of disease.

Seventh Cervical Vertebra.—The foramen transversarium may be absent on one or other side.

Thoracic Vertebrae.—Barclay Smith (*Journ. Anat. and Physiol.* Lond. 1902, p. 372) records five cases in which the superior articular processes of the twelfth thoracic vertebra displayed thoracic and lumbar characteristics on opposite sides. Duckworth (*Journ. of Anat. and Physiol.* vol. xlv. p. 65) has described a first thoracic vertebra, in which a bony process, arising from the front of the root of the transverse process, curves forwards and medially so as almost to enclose a foramen like that of the cervical vertebrae. The ventral surface of this process articulates with the neck of the first rib.

Lumbar Vertebrae.—The mamillary and accessory processes are sometimes unduly developed. The vertebral arch of the fifth lumbar vertebra is occasionally interrupted on either side by a synchondrosis which runs between the upper and lower articular processes. In macerated specimens the two parts of the bone are thus separate and independent. The anterior includes the body, together with the roots of the vertebral arches and the transverse and superior articular processes; the posterior comprises the inferior articular processes, the laminae, and the spine. (Turner, *Challenger Reports*, vol. xvi.) Fawcett has seen the same condition in the fourth lumbar vertebra. Szawlowski and Dwight record instances of the occurrence of a foramen in the transverse process of the Vth lumbar vertebra (*Anat. Anz. Jena*, vol. xx.), and Ramsay Smith describes a case in which the right transverse process of the IVth lumbar vertebra of an Australian sprang from the side of the body in front of the root of the vertebral arch, being unconnected either with the arch or articular process.

Sacrum.—The number of sacral segments may be increased to six or reduced to four (see p. 276). Transition forms are occasionally met with in which the first sacral segment displays on one side purely sacral characters, *i.e.* it articulates with the hip bone, whilst on the opposite side it may present all the features of a lumbar vertebra. Through deficiency in the development of the laminae, the sacral canal may be exposed throughout its entire length, or to a greater extent than is normally the case. (Paterson, *Roy. Dublin Soc. Scientific Trans.* vol. v. Series II.) Szawlowski and Barclay Smith record the occurrence of a foramen in the lateral part of the Ist sacral vertebra. (*Journ. of Anat. and Physiol.* Lond. vol. xxxvi. p. 372.)

Vertebral Column as a Whole.—Increase in the number of vertebral segments is usually

due to differences in the number of the coccygeal vertebræ; these may vary from four—which may be regarded as the normal number—to six. The number of presacral or movable vertebræ is normally 24 (7 C, 12 Th, and 5 L); in which case the 25th vertebra forms the first sacral segment (vertebra fulcralis of Welcker). The number of presacral vertebræ may be increased by the intercalation of a segment either in the thoracic or lumbar region without any alteration in the number of the sacral or coccygeal elements: thus we may have 7 C, 13 Th, and 5 L, or 7 C, 12 Th, and 6 L, or it may be reduced by the disappearance of a vertebral segment—thus, 7 C, 12 Th, and 4 L. Such an arrangement presupposes developmental errors either of excess or default in the segmentation of the column. On the other hand, the total number of vertebral segments remaining the same (24 or 25), we may have variations in the number of those assigned to different regions due to the addition of a vertebral segment to one, and its consequent subtraction from another region. Thus, in the 24 presacral vertebræ, in cases of the occurrence of cervical ribs the formula is rearranged thus—6 C, 13 Th, and 5 L, or, in the case of a thirteenth rib being present, the formula would be 7 C, 13 Th, 4 L, as happens normally in the gorilla and chimpanzee. Similarly, the number of the presacral vertebræ (24) may be increased by the withdrawal of a segment from the sacral region—7 C, 12 Th, 6 L, and 4 S—or diminished by an increase in the number of the sacral vertebræ, as in the formula 7 C, 12 Th, 4 L, and 6 S. Increase in the number of sacral segments may be due to fusion with a lumbar vertebra, or by the addition of a coccygeal element: the latter is more frequently the case. This variability in the constitution of the sacrum is necessarily correlated with a shifting backwards and forwards of the pelvic girdle along the vertebral column. Rosenberg considers that the 26th, 27th, and 28th vertebræ are the primitive sacral segments, and that the sacral characters of the 25th vertebræ (the first sacral segment in the normal adult column) are only secondarily acquired. He thus supposes that during development there is a forward shifting of the sacrum and pelvic girdle, with a consequent reduction in the length of the presacral portion of the column. This view is opposed by Paterson (*Roy. Dublin Soc. Scientific Trans.* vol. v. Ser. II.), who found that ossification took place in the alæ of the 25th vertebra (first adult sacral segment) before it made its appearance in the alæ of the 26th vertebra. He thus assumes that the alæ of the 25th vertebra may be regarded as the main and primary attachment with the ilium. His conclusions, based on a large number of observations, are at variance with Rosenberg's views, for, according to his opinion, liberation of the first sacral segment is more common than assimilation with the fifth lumbar vertebra, and assimilation of the first coccygeal vertebra with the sacrum is more common than liberation of the fifth sacral, thus leading to the inference that the sacrum tends to shift backwards more often than forwards. Dwight (*Anat. Anz. Jena*, vol. xxviii. p. 33), after a study of this question, whilst admitting that some of these variations may be reversible, denies that there is any evidence that they are progressive, and further states that after the occurrence of the original error in development, there is a tendency for the vertebral column to assume as nearly as possible its normal disposition and proportions.

Sternum.—The sternum is liable to considerable individual variations affecting its length and direction. The majority of bones are asymmetrical, displaying irregularities in the levels of the clavicular facets. The higher costal facets may be closer together on one, usually the right side, than the other, whilst the synchondrosis sternalis is often oblique, sloping somewhat to the right. According to Birmingham, these are the result of the strain thrown on the shoulder by pressure either directly applied or through the pull of a weight carried in the hand.

Sometimes the sternum articulates with eight rib cartilages. This may happen on one or both sides, but when unilateral, much more frequently on the right side—a condition by some associated with right-handedness. It is, however, more probably a persistence of the primitive condition of the cartilaginous sternum, in which each half is connected with the anterior extremities of the first eight costal arches. In some rare cases only six pairs of ribs articulate by means of their costal cartilages with the sternum. Recently Lickley has brought forward evidence to show that the seventh rib is undergoing regressive changes. (*Anat. Anz.* vol. xxiv. p. 326.)

Occasionally the presternum supports the first three ribs; in other words, the manubrium has absorbed the highest segment of the body. Keith has pointed out that this is the condition most commonly met with in the gibbon, and regards its occurrence in man as a reversion to the simian type. As far as is at present known, its occurrence seems more common in the lower races. Through errors of development the sternum may be fissured throughout, due to failure of fusion of the cartilaginous hemisterna. The two ossified halves are usually widely separated above, but united together below by an arthrodial joint. The heart and pericardium are thus uncovered by the bone. Occasionally this condition is associated with ectopia cordis, under which circumstances life is rendered impossible. Through defects in ossification the body of the sternum may be pierced by a hole, usually in its lower part, or through failure of fusion of the lateral centres one or more of the segments of the body may be divided longitudinally.

Sometimes small ossicles are found in the ligaments of the sterno-clavicular articulation. These are the so-called episternal bones, the morphological significance of which, however, has not yet been satisfactorily determined. They are by some regarded as the homologues of the interclavicle or episternal bone of monotremata, whilst by others they are considered to represent persistent and detached portions of the pre-coracoids.

Ribs.—The number of ribs may be increased or diminished. Increase may occur by the addition of a cervical rib due to the independent development of the costal element in the transverse process of the seventh cervical vertebra. This may happen on one or both sides. The range of development of these cervical ribs varies; they may unite in front with the sternum, or they may

be fused anteriorly with the cartilage of the first rib, or the cervical rib may be free. It may in some instances be represented mainly by a ligamentous band, or its vertebral and sternal ends may be alone developed, the intermediate part being fibrous. At times the vertebral end only may be formed, and may be fused with the first rib, thus leading to the formation of a bicipital rib such as occurs in many cetaceans. (For a detailed account of this anomaly see Wingate Todd's paper in the *Journ. of Anat. and Physiol.* vol. xvi. pp. 244-258.) Increase in the number of ribs may also be due to the ossification of the costal element which is normally present in the embryo in connexion with the first lumbar vertebra. (Rosenberg, *Morph. Jahrb.* i.) Reduction in the number of ribs is less common. The twelfth rib rarely aborts; in some cases the first rib is rudimentary. Cases of congenital absence of some of the ribs have been recorded by Hutchinson, Murray, and Ludeke. Fusion of adjacent ribs may occur. (Lane, *Guy's Hosp. Reports*, 1883.) In this way, too, the occurrence of a bicipital rib is explained. This anomaly occurs most usually in connexion with the first rib, which either fuses with a cervical rib above or with the second rib below.

Variations in form may be in great part due to the occupation of the individual and the constricting influence of corsets. Independently of these influences, the ventral part of the shaft is sometimes cleft so as to appear double; at other times the cleft may be incomplete so as to form a perforation. Occasionally adjacent ribs are united towards their posterior part by processes having an intermediate ossicle between (Meckel), thus recalling the condition normally met with in birds; more usually, however, the bony projections are not in contact.

The number of true or vertebro-sternal ribs may be reduced to six, or increased to eight (*vide ante*, p. 276). Dwight (*Journ. of Anat. and Physiol.* vol. xlv. p. 438) describes a series of cases in which the interval between the transverse process of the first thoracic vertebra and the neck of the first rib is bridged across or converted into a linear cleft by a dorsal extension from the neck of the rib.

Costal Cartilages.—Occasionally a costal cartilage is unduly broad, and may be pierced by a foramen. The number of costal cartilages connected with the sternum may be reduced to six or increased to eight (see p. 276). In advanced life there is a tendency towards ossification in the layers underlying the perichondrium, more particularly in the case of the first rib cartilage, in which it may be regarded as a more or less normal occurrence.

Frontal Bone.—The variation most frequently met with is a persistence of the suture which unites the two halves of the bone in the infantile condition: skulls displaying this peculiarity are termed **metopic**. The researches of various observers—Broca, Ranke, Gruber, Manouvrier, Anoutchine, and Papillault (*Rev. mens. de l'école d'Anthropol. de Paris*, année 6, n. 3,—point to the more frequent occurrence of this metopic suture in the higher than in the lower races of man; and Calmette asserts its greater frequency in the brachycephalic than the dolichocephalic type. Separate ossicles (*ossa suturarum*) may occur in the region of the anterior fontanelle. The fusion of these with one or other half of the frontal explains how the metopic suture is not always in line with the sagittal suture (Stieda, *Anat. Anz.* 1897, p. 227); they occasionally persist, however, and form by their coalescence a bregmatic bone. (G. Zoja, *Bull. Scientifico*, xvii. p. 76, Pavia.) Turner (*Challenger Reports*, part xxix.) records an instance of direct articulation of the frontal with the frontal process of the maxilla in a Bush skull, and other examples of the same anomaly, which obtains normally in the skulls of the chimpanzee and gorilla, have been observed. (*Journ. Anat. and Physiol.* vol. xxiv. p. 349.)

There is sometimes a small arterial groove just medial to the supra-orbital notch or foramen, and occasionally the latter is double, the lateral aperture piercing the orbital margin wide of its middle point. Frequently the bone corresponding to the floor of the lacrimal fossa displays a cribriform appearance.

Schwalbe (1901) records the presence of small independent ossicles (supra-nasal bones) in the anterior part of the metopic suture. The same anatomist has also directed attention (*Zeit. f. Morph. und Anthr.* vol. iii. p. 93) to the existence of the metopic fontanelle, first described by Gerdy, and the occurrence of metopic ossicles (*ossa interfrontalia*) and canals.

Parietal.—A number of cases have been recorded in which the parietal is divided into an upper and lower part by an antero-posterior suture parallel to the sagittal suture. Coraini (*Atti d. XI. Congr. Med. Internaz. Roma*, 1894, vol. v.) records a case in which the parietal was incompletely divided into an anterior and posterior part by a vertical suture. A tripartite condition of the bone has also been observed (Frassetto). The parietal foramina vary greatly in size, and to some extent in position. They are sometimes absent on one or other side, or both. They correspond in position to the sagittal fontanelle. Sometimes the ossification of this fontanelle is incomplete and a small transverse fissure remains. The parietal foramen represents the patent lateral extremity of this fissure after its edges have coalesced. Occasionally in the region of the anterior fontanelle an ossicle of variable size may be met with. This is the so-called pre-interparietal bone. According to its fusion with adjacent bones it may disturb the direction of the sagittal suture.

Occipital.—The *torus occipitalis transversus* is the term applied to an occasional elevation of the bone which includes the external occipital protuberance and extends laterally along the superior curved line. Occasionally an emissary vein pierces the bone opposite the occipital protuberance. In about 15 per cent of cases the hypoglossal canal is double. Much rarer three or even four foramina may be met with. The most striking of the many variations to which this bone is subject is the separation of the upper part of the squamous part of the occipital to form an independent bone—the interparietal bone, called also, from the frequency

of its occurrence in Peruvian skulls, the *os Inca*. By a reference to the account of the ossification of the bone, the occurrence of this anomaly is explained developmentally. In place of forming a single bone the interparietal is occasionally met with in two symmetrical halves, and instances have been recorded of its occurrence in three or even four pieces. In the latter cases the two anterior parts form the pre-interparietals. Not uncommonly the internal occipital crest is split and furrowed close to the foramen magnum for the lodgment of the vermiform lobe of the cerebellum, and is hence called the *vermiform fossa*. Instances are recorded of the presence of a separate epiphysis between the basi-occipital and the sphenoid, the *os basioticum* (Albrecht) or the *os pre-basi-occipitale*. An oval pit, the fovea bursæ or pharyngeal fossa, is sometimes seen in front of the tuberculum pharyngeum. This marks the site of the bursa pharyngea. Occasionally the basilar part is pierced by a small venous canal. The articular surface of the condyles is sometimes divided into an anterior and posterior part. The so-called **third occipital condyle** is an outstanding process rising from the anterior border of the foramen magnum, the extremity of which articulates with the dens of the epistropheus. Guerri has recorded a case, in which in a foetal skull, there were two projecting tubercles in the position of the third occipital condyle, independent of the basi-occipital portions of the condyles. (*Anat. Anz.* vol. xix. p. 42.) This appears to confirm the view of Macalister that there are two different structures included under this name—one a medial ossification in the sheath of the notochord, and the second, a lateral, usually paired process, caused by the deficiency of the medial part of the hypochordal element of the hindmost occipital vertebra, with thickenings of the lateral parts of the arch. Springing from the under surface of the extremity of the jugular process, a rough or smooth elevated surface, or else a projecting process, the extremity of which may articulate with the transverse process of the atlas, is sometimes met with. This is the paroccipital or *paramastoid process*. The size and shape of the foramen magnum varies much in different individuals and races, as also the disposition of its plane. Elliot Smith has called attention to the asymmetry of the cerebral fossæ, which is correlated with asymmetry of the caudal poles of the cerebral hemispheres. Numerous instances of fusion of the atlas with the occipital bone have been recorded. Many are, no doubt, pathological in their origin; others are associated with errors in development. Interesting anomalies are those in which there is evidence of the intercalation of a new vertebral element between the atlas and occipital, constituting what is termed a **pro-atlas**.

Temporal Bone.—The occurrence of a deficiency in the floor of the external acoustic meatus is not uncommon in the adult. It is met with commonly in the child till about the age of five, and is due to incomplete ossification of the tympanic plate. The line of the petro-squamosal suture is occasionally grooved for the lodgment of a sinus (petro-squamosal); sometimes the posterior end of this is continuous with a canal which pierces the superior border of the bone and opens into the transverse sinus. Anteriorly the groove may pass into a canal which pierces the root of the zygoma and appears externally above the lateral extremity of the petro-tympanic fissure. These are the remains of channels through which the blood passed in the foetal condition (see *ante*). Kazzander has recorded a case in which the squamous part of the temporal was pneumatic, the sinus reaching as high as the parietal and the squamoso-sphenoidal suture. Symington has described a case in which the squamous part was distinct and separate from the rest of the temporal bone in an adult; whilst Hyrtl has observed the division of the squamous part of the temporal into two by a transverse suture. The zygomatic process has been observed separated from the rest of the bone by a suture close to its root (Adacni). P. P. Laidlaw (*Journ. Anat. and Physiol.* vol. xxxvii. p. 364) describes a temporal bone in which there was absence of the internal acoustic meatus and of the stylo-mastoid foramen. The jugular fossa also was absent, and there was partial absence of the groove for the transverse sinus associated with the presence of a large mastoid foramen. An instance of a rudimentary condition of the carotid canal is also referred to in the same volume by G. H. K. Macalister.

G. Caribbe (*Anat. Anz.* vol. xx. p. 81) notes the occurrence in idiots and imbeciles of a more pronounced form of post-glenoid tubercle, and associates it with regressive changes in the development of the temporal bone.

Sphenoid.—Through imperfect ossification the foramen spinosum and foramen ovale are sometimes incomplete posteriorly. Le Double (*Bull. et mém. de la Soc. d'Anth. de Paris*, 5^e sér. vol. iii. p. 550) records a case in which the foramen rotundum and the superior orbital fissure were united so as to form a single cleft.

Through deficiency of its lateral wall, the optic foramen, in rare instances, communicates with the superior orbital fissure. Duplication of the optic foramen is also recorded as a rare occurrence, the artery passing through one canal, the nerve through the other. Persistence of the cranio-pharyngeal canal is also occasionally met with. Owing to the ossification of fibrous bands which frequently connect the several bony points, anomalous foramina are frequently met with. Of such are the carotico-clinoid formed by the union of the anterior and middle clinoid processes, the pterygo-spinous foramen enclosed by the ossification of the ligament connecting the angular spine with the lateral pterygoid lamina, and the porus crotaphitico-buccinatorius similarly developed by the ossification of ligament immediately below and lateral to the inferior aperture of the foramen ovale.

Ethmoid.—The size of the lamina papyracea is liable to considerable variations. In the lower races it tends to be narrower from above downwards than in the higher, in this respect resembling the condition met with in the anthropoids. The lamina papyracea may fail to articulate with the lacrimal owing to the union of the frontal with the frontal process of the maxilla

in front of it. (Orbito-maxillary-frontal suture. A. Thomson, *Journ. Anat. and Physiol.* vol. xxiv. p. 349.) Division of the lamina papyracea by a vertical suture into an anterior and posterior part has been frequently recorded. The number of the conchæ may be increased from two to four, or may be reduced to one. (Report of Committee of Collect. Invest., *Journ. Anat. and Physiol.* vol. xxviii. p. 74.)

Maxillæ.—Not infrequently there is a suture running vertically through the bar of bone which separates the infra-orbital foramen from the infra-orbital margin. Through imperfections in ossification, the infra-orbital canal may form an open groove along the floor of the orbit.

Duckworth records four instances of a spinous process projecting inwards into the apertura piriformis from the lower part of the nasal notch. A case has been described (Fischel) in which there was complete absence of the premaxillæ, together with the incisor teeth.

A not uncommon anomaly is the occurrence of a rounded elongated ridge extending along the interpalatal or intermaxillary sutures on the under surface of the hard palate. This is called the *torus palatinus*, and is of interest because its presence has given rise to the assumption that it was due to a pathological growth. (See Stieda, *Virchow's Festschrift*, vol. i. p. 147.)

The sulcus lacrimalis may be constricted towards its centre.

A part of the antrum may be constricted off anteriorly and, owing to its relation to the nasolacrimal duct, is for this reason called the recessus lacrimalis.

Underwood (*Journ. Anat. and Physiol.* vol. xlv. p. 339) records the occurrence of all but complete septa dividing the antral cavity.

Zygomatic Bone.—Cases of division of the zygomatic bone by a horizontal suture have been recorded, as well as instances of its separation into two parts by a vertical suture. Owing to the supposed more frequent occurrence of this divided condition in Asiatics the zygomatic has been named the *os Japonicum*. Barclay Smith ("Proc. Anat. Soc." *Journ. Anat. and Physiol.*, April 1898, p. 40) describes a case in which the zygomatic bone was divided into two parts, an upper and lower, by a backward extension of the maxilla, which articulated with the zygomatic process of the temporal, thus forming a temporo-maxillary arch. Varieties of a like kind have also been described by Gruber and others. Cases have been noted where, owing to deficiency in the development of the zygomatic, the continuity of the zygomatic arch has been incomplete.

Nasal Bones.—The size and configuration of the nasal bones vary greatly in different races, being, as a rule, large and prominent in the white races, and flat and reduced in size, as well as depressed, in the Mongolian and Negro stock. Complete absence of the nasal bones has been recorded, and their division into two or more parts has also been noted. Obliteration of the internasal suture is unusual; it is stated to occur more frequently in negroes, and is the recognised condition in adult apes.

Duckworth has recorded a case (*Journ. Anat. and Physiol.* vol. xxxvi. p. 257) of undue extension downwards of the nasal bone, which may be perhaps accounted for on the supposition that the lower part is a persistent portion of the premaxilla.

Lacrimal.—The lacrimal is occasionally absent. In some cases it is divided into two parts; in others replaced by a number of smaller ossicles. In rare instances the hamulus may extend forwards to reach the orbital margin, and so bear a share in the formation of the face, as in lemurs (Gegenbauer). In other instances the hamulus is much reduced in size. Occasionally the lacrimal is separated from the lamina papyracea of the ethmoid by a down-growth from the frontal, which articulates with the frontal process of the maxilla, as is the normal disposition in the gorilla and chimpanzee. (Turner, *Challenger Reports*, "Zoology," vol. x. Part IV. Plate I.; and A. Thomson, *Journ. Anat. and Physiol.*, London, vol. xxiv. p. 349.)

Inferior Concha.—A case in which the inferior conchæ were absent has been recorded by Hyrtl.

Vomer.—Owing to imperfect ossification there may be a deficiency in the bone, filled up during life by cartilage. The separation of the two lamellæ along the anterior border varies considerably, and instances are recorded where they were separated by a considerable cavity within the substance of the bone. Instances of an extension forwards of the sphenoidal air sinus into and separating the laminae of the bone have also been described. The sphenovomerine canal is a minute opening behind the rostrum of the sphenoid, and between it and the alæ of the vomer, by which the nutrient artery enters the bone.

Palate Bones.—The occurrence of a torus palatinus may be noted (see Variations of Maxilla).

Mandible.—Considerable differences are met with in the height of the coronoid process: usually its summit reaches the same level as the condyle, or slightly above it; occasionally, however, it rises to a much higher level; in other cases it is much reduced. These differences naturally react on the form of the mandibular notch. The projection of the mental protuberance is also liable to vary. Occasionally the mental foramen is double, and sometimes the mylo-hyoid groove is for a short distance converted into a canal. There is often a marked eversion of the angle of the mandible, which Dieulafoy homologises with the angular apophysis met with in lemurs and carnivora.

Clavicle.—The clavicles of women are more slender, less curved, and shorter than those of men. In the latter the bone is so inclined that its acromial end lies slightly higher or on the same level with the sternal end. In women the bone usually slopes a little downward and laterally. The more pronounced curves of some bones are probably associated with a more powerful development of the pectoral and deltoid muscles, a circumstance which also affords an explanation of the differences usually seen between the right and left bones, the habitual use of the right

upper limb reacting on the form of the bone of that side. The influence of muscular action, however, does not wholly account for the production of the curves of the bone, since the bone has been shown to display its characteristic features in cases where there has been defective development or absence of the upper limb (Reynault). Partial or complete absence of the clavicle has been recorded. W. S. Taylor exhibited an interesting case of this kind at the Clinical Society of London, October 25, 1901. Sometimes there is a small canal through the anterior border of the bone near its middle for the transmission of one of the supra-clavicular nerves.

Scapula.—The most common variation met with is a separated acromion. In these cases there has been failure in the ossific union between the spine and acromion, the junction between the two being effected by a layer of cartilage or by an articulation possessing a joint cavity. The condition is usually symmetrical on both sides, though instances are recorded where this arrangement is unilateral. Very much rarer is the condition in which the coracoid process is separable from the rest of the bone. The size and form of the scapular notch differs. In certain cases the superior border of the bone describes a uniform curve reaching the base of the coracoid without any indication of a notch. In some scapulæ, more particularly in those of very old people, the floor of the subscapular fossa is deficient owing to the absorption of the thin bone, the periosteal layers alone filling up the gap.

At birth the vertical length of the bone is less in proportion to its width than in the adult.

Humerus.—As has been stated in the description of the bone, the olecranon and coronoid fossæ may communicate with each other in the macerated bone. The resulting supra-trochlear foramen is most commonly met with in the lower races of man, as well as in the anthropoid apes, and in some other mammals. The occurrence of a hook-like spine, called the *epicondylar process*, which projects in front of the medial epicondylar ridge, is not uncommon. Its extremity is connected with the medial epicondyle by means of a fibrous band, underneath which the median nerve, accompanied by the brachial artery, or one of its large branches, may pass, or in some instances, the nerve alone, or the artery unaccompanied by the nerve. This arrangement is the homologue in a rudimentary form of a canal present in many animals, notably in the carnivora and marsupials. In addition to the broad radial groove already described, and which is no doubt produced by the twisting or torsion of the shaft, there is occasionally a distinct narrow groove posterior to it, which marks precisely the course of the radial nerve as it turns round the lateral side of the shaft of the bone.

Ulna.—Cases of partial or complete absence of the ulna through congenital defect have been recorded. Rosenmüller has described a case in which the olecranon was separated from the proximal end of the bone, resembling thus in some respects the patella. In powerfully developed bones there is a tendency to the formation of a sharp projecting crest corresponding to the insertion of the triceps.

Radius.—Cases of congenital absence of the radius are recorded; in these the thumb is not infrequently wanting as well.

Carpus.—Increase in the number of the carpal elements is occasionally met with, and these have been ascribed to division of the navicular, os lunatum, os triquetrum, capitate, lesser multangular, and os hamatum. Of these the most interesting is the *os centrale*, first described by Rosenberg, and subsequently investigated by Henke, Leboucq, and others. This is met with almost invariably as an independent cartilaginous element during the earlier months of foetal life, and occasionally becomes developed into a distinct ossicle placed on the back of the carpus between the navicular and capitate bones and the lesser multangular. Its significance depends on the fact that it is an important component of the carpus in most mammals, and is met with normally in the orang and most monkeys. Ordinarily in man, as was pointed out by Leboucq, it becomes fused with the navicular, where its presence is often indicated by a small tubercle, a condition which obtains in the chimpanzee, the gorilla, and the gibbons. Dwight has described a case in which there was an *os subcapitulum* in both hands. The ossicle lay between the base of the middle metacarpal bone and the capitate bone, with the lesser multangular to its radial side. (*Anat. Anz.* vol. xxiv.) Further addition to the number of the carpal elements may be due to the separation of the styloid process of the third metacarpal bone and its persistence as a separate ossicle.

Reduction in the number of the carpus has been met with, but this is probably due to pathological causes. Morestin (*Bull. Soc. Anat. de Paris*, tome 71, p. 651), who has investigated the subject, finds that ankylosis occurs most frequently between the bases of the second and third metacarpal bones and the carpus, seldom or never between the carpus and the first metacarpal, or between the pisiform and os triquetrum. Instances of complete fusion of the os lunatum and triquetral bones, without any apparent pathological change, have been recorded in Europeans, Negroes, and an Australian.

Metacarpal Bones.—As previously stated above, the styloid apophysis of the third metacarpal bone appears as a separate ossicle in about 1·8 per cent of cases examined. ("Fourth Annual Report of the Committee of Collect. Invest. Anat. Soc. Gt. Brit. and Ireland," *Journ. Anat. and Physiol.* vol. xxviii. p. 64.) In place of being united to the third metacarpal, the styloid apophysis may be fused with either the capitate bone or the lesser multangular, under which conditions the base of the third metacarpal bone is without this characteristic process.

Phalanges.—Several instances have been recorded of cases in which there were three phalanges in the thumb. Bifurcation of the terminal phalanx has occasionally been met with, and examples of suppression of a phalangeal segment or its absorption by another phalanx have also been described. (Hasselwander, *Zeits. für Morph. u. Anthr.* vol. vi. 1903.)

Hip Bone.—Some of the anomalies met with in the hip bone are due to ossification of the ligaments connected with it; in other cases they depend on errors of development. Failure of union between the pubic and ischial rami has also been recorded. Cases have occurred where the obturator groove has been bridged across by bone, and one case is noted of absence of the acetabular notch on the acetabular margin. In rare cases the os acetabuli (see Ossification) remains as a separate bone. Derry (*Journ. Anat. and Physiol.* vol. xlv. p. 202) has drawn attention to the occurrence of a small accessory articular facet, situated on the rough non-articular area immediately behind the auricular surface of the ilium, which articulates with a depressed facet on the posterior surface of the sacrum to the lateral side of the first posterior sacral foramen, in the neighbourhood of the transverse process of the second sacral segment. This he homologises with the normal articulation between the ilium and sacral transverse processes found in many lower animals.

Femur.—Absence of the fovea on the head of the femur for the attachment of the ligamentum teres has been recorded. This corresponds with the condition met with in the orang. Not infrequently there is an extension of the articular surface of the head on to the fore and upper aspect of the neck; this is a "pressure facet" caused by the contact of the iliac portion of the acetabular margin with the neck of the bone, when the limb is maintained for long periods in the flexed position, as in tailors, and also in those races who habitually squat (Lane, *Journ. Anat. and Physiol.* vol. xxii. p. 606).

The occurrence of a *trochanter tertius* has been already referred to. Its presence is not confined to individuals of powerful physique, but may occur in those of slender build, so far suggesting that it is not to be regarded merely as an indication of excessive muscular development. The observations of Dixon (*Journ. Anat. and Physiol.* vol. xxx. p. 502), who noted the occurrence of a separate epiphysis in three cases in connexion with it, seem to point to its possessing some morphological significance. Occasionally the gluteal tuberosity may be replaced by a hollow, the *fossa hypotrochanterica*, or in some cases the two may co-exist.

The angle of the neck is more open in the child than in the adult, and tends to be less when the femoral length is short and the pelvic width great—conditions which particularly appertain to the female. There is no evidence to show that after growth is completed any alteration takes place in the angle with advancing years (Humphry).

The curvature of the shaft may undergo considerable variations, and the appearance of the posterior surface of the bone may be modified by an absence of the *linea aspera*, a condition resembling that seen in apes; or by an unusual elevation of the bone which supports the ridge (*fémur à pilastre*), produced, as Manouvrier has suggested, by the excessive development of the muscles here attached.

Under the term "*platymerie*," Manouvrier describes an antero-posterior compression of the proximal part of the shaft, frequently met with in the femora of prehistoric races.

Patella.—Cases of congenital absence of the patella have been recorded.

F. C. Kempson (*Journ. Anat. and Physiol.* vol. xxxvi.) has recently drawn attention to the condition described as emargination of the patella. In specimens displaying this appearance the margin of the bones is concave from a point about half an inch to the lateral side of the middle line, to a point half-way down the lateral margin of the bone; here there is usually a pointed spine directed proximally and laterally. The condition appears to be associated with the insertion of the tendon of the vastus lateralis. G. Joachimstal (*Archiv u. Atlas der normalen und pathologischen Anatomie in typischen Röntgenbildern*, Bd. 8) figures a case in which on both sides the patella was double in an adult, the distal and much the smaller portion was embedded in the ligamentum patellæ.

Tibia.—The tibia is often unduly laterally compressed, leading to an increase in its antero-posterior diameter as compared with its transverse width. This condition is more commonly met with in the bones of prehistoric and savage races than in modern Europeans. Attention was first directed to this particular form by Busk, who named the condition *platyknesia*. The general appearance of such tibiæ resembles that seen in the apes, and depends on an exceptional development of the tibialis posterior muscle, though, as Manouvrier has pointed out, in apes this is associated with the direct action of the muscle on the foot, as in climbing, whereas in man, as a consequence of the bipedal mode of progression, the muscle is employed in an inverse sense, viz., by steadying the tibia on the foot, and thus providing a fixed base on which the femur can move. This explanation, however, is disputed by Derry (*Journ. Anat. and Phys.* vol. xli. p. 123). Such platyknesmic tibiæ are occasionally met with in the more highly civilised races, and are, according to Manouvrier, associated with habits of great activity among the inhabitants of rough and mountainous districts.

Another interesting condition is one in which the proximal extremity is more strongly recurved than is usual. This retroversion of the head of the tibia was at one time supposed to represent an intermediate condition in which the knee could not be fully extended so as to bring the axis of the leg in line with the thigh; but such opinion has now been upset by the researches of Manouvrier, who claims that it is the outcome of a habit not uncommon amongst peasants and countrymen, viz., that of walking habitually with the knees slightly bent.

Habitual posture also leaves its impress on the form of the tibia, and in races in which the use of the chair is unknown, the extreme degree of flexion of the knee and ankle necessitated by the adoption of the squatting position as an attitude of habitual rest is associated with an increase in the convexity of the lateral condylic surface, and the appearance, not infrequently, of a pressure facet on the anterior border of the distal extremity, which rests in that position on the neck of the talus. Cases of congenital absence of the tibia have been frequently described, amongst the most recent being those recorded by Clutton, Joachimsthal, Bland-Sutton, and Waitz.

Fibula.—The fibula may be ridged and grooved in a remarkable manner, as is the case in many bones of prehistoric races. This is probably associated with a greater or perhaps more active development of the muscles attached to it.

The proximal articular facet varies much in size. Bennett (*Dublin Journ. Med. Sc.*, Aug. 1891) records a case in which it was double, and also notes the occurrence of specimens in which it was absent and in which the head of the bone did not reach the lateral condyle of the tibia.

Many instances of partial or complete absence of the bone have been published. (Lefèvre, *Contribution à l'étude de l'absence congénitale du péroné*, Lille, 1895.)

Talus.—The anterior is sometimes separated from the middle calcanean facet by a non-articular furrow. The posterior process, often largely developed, is occasionally (2·6 per cent) a separate ossicle forming what is known as the *os trigonum* (Bardeleben); or it may be united to the body of the talus by a distinct synchondrosis. A smooth articular surface may occasionally be found on the *medial* side of the proximal surface of the neck. This is a pressure facet dependent on the frequent use of the ankle-joint in a condition of extreme flexion, and is caused by the opposition of the bone against the anterior edge of the distal end of the tibia.

The form of the bone at birth differs from that of the adult in that the medial splay of the neck on the body is more pronounced, forming on an average an angle of 35° as compared with a mean of 12° in the adult; moreover, the articular surface for the medial malleolus extends forwards along the *medial* side of the neck, and to some extent overruns its superior surface. This is doubtless a consequence of the inverted position of the foot maintained by the fœtus during intra-uterine life. In these respects the fetal bone conforms to the anthropoid type.

For a detailed study of the varieties of this bone, see R. B. S. Sewell. (*Journ. Anat. and Physiol.* vol. xxxviii.)

Calcaneus.—The trochlear process is occasionally unduly prominent, constituting the sub-malleolar apophysis of Hyrtl, and cases are recorded of the calcaneus articulating with the navicular. (Morestin, H., *Bull. de la Soc. Anat. de Paris*, 1894, 5^e sér. t. 8, n. 24, p. 798; and Petrini, *Atti del XI. Congr. Med. Internaz. Roma*, 1894, vol. ii., "Anat." p. 71.) Pfitzner (*Morphologische Arbeiten*, vol. vi. p. 245) also records the separation of the sustentaculum tali to form an *os sustentaculi*. (See also P. P. Laidlaw, *Journ. Anat. and Physiol.* vol. xxxviii. p. 133.)

Navicular.—According to Manners Smith this bone displays more variety of form than any other of the tarsal bones. He accounts for this both on morphological and mechanical grounds. He regards the tuberosity as probably of threefold origin, an apophysial, an epiphysal, and a sesamoid element, the latter being the so-called sesamoid bone in the tendon of the tibialis posterior. Cases are recorded where the tuberosity has formed an independent ossicle.

Cuneiform Bones.—Numerous cases of division of the first cuneiform bone into dorsal and plantar parts have been recorded; the frequent division of its metatarsal articular facet is no doubt correlated with this anomalous condition. T. Dwight has described (*Anat. Anz.* vol. xx. p. 465) in two instances the occurrence of an *os intercuneiforme*. The ossicle so named lies on the dorsum of the foot at the proximal end of the line of articulation between the first and second cuneiform bones.

Cuboid.—Blandin has recorded a case of division of the cuboid. Occasionally there is a facet on the lateral surface of the bone for articulation with the tuberosity of the fifth metatarsal (Manners Smith).

Tarsus as a Whole.—Increase in the number of the tarsal elements may be due to the occurrence of division of either the first cuneiform or the cuboid bone, or to the occasional presence of an *os trigonum*. Cases of separation of the tuberosity of the navicular bone have been recorded, and instances of supernumerary ossicles between the first cuneiform and second metatarsal bone have been noted. Stieda mentions the occurrence of a small ossicle in connexion with the articular surface on the anterior and upper part of the calcaneus, and Pfitzner notes the occurrence of an *os sustentaculi*. For further information on the variations of the skeleton of the foot, see Pfitzner. (*Morphologische Arbeiten*, vol. vi. p. 245.)

The possibility of an injury having been the cause of the occurrence of some of these so-called supernumerary ossicles must not be overlooked. The use of the Röntgen rays has proved that accidents of this kind are much more frequent than was at first supposed.

The reduction in the number of the tarsus is due to the osseous union of adjacent bones. In many instances this is undoubtedly pathological, but cases have been noticed (Leboucq) of fusion of the cartilaginous elements of the calcaneus and talus, and the calcaneus and navicular in fœtuses of the third month.

Metatarsal Bones.—Several instances of separation of the tuberosity of the fifth metatarsal (*os Vesaleanum*) have been recorded, whilst numerous examples of an *os intermetatarsum* between the bases of the first and second metatarsal bones have been recorded by Gruber and others. The tubercle on the base of the first metatarsal for the attachment of the peronæus longus tendon is occasionally met with as a separate ossicle. An epiphysis over the spot where the tuberosity of the fifth metatarsal rests on the ground has been described. (Kirchner, *Archiv klin. Chir.* B 80.)

Phalanges.—It is not uncommon to meet with fusion of the second and third phalanges, particularly in the fifth, less frequently in the fourth, and occasionally in the second and third toes. The union of the phalangeal elements has been observed in the fœtus as well as the adult (Pfitzner). The proportionate length of the phalanges varies much; in some cases the ungual phalanges are of fair size, the bones of the second row being mere nodules, whilst in other instances the reduction in size of the terminal phalanges is most marked.

APPENDIX C.

SERIAL HOMOLOGIES OF THE VERTEBRÆ.

It is a self-evident fact that the vertebral column consists of a number of segments or vertebræ all possessing some characters in common. These vertebræ or segments undergo modifications

according to the region they occupy and the functions they are called upon to serve, so that their correspondence and identity is thereby obscured. There is no difficulty in recognising the homology of the bodies and vertebral arches throughout the column. According to some anatomists the vertebral arch is the more primitive element in the formation of a vertebra, whilst others hold that the bodies are the foundation of the column. Be that as it may we find that in the higher vertebrates, at least, the bodies are the parts which most persist. They are, however, subject to modifications dependent on their fusion with one another. This occurs in the cervical part of the column where the body of the first cervical or atlas has for functional reasons become fused with the body of the second or epistropheus to form the dens of that segment. For similar reasons, and in association with the union of the girdle of the hind-limb with the column, the bodies of the vertebræ which correspond to the sacral segment become fused together to form a solid mass. In the terminal portion of the caudal region the bodies alone represent the vertebral segments.

As regards the vertebral arch, this in man becomes deficient in the lower sacral region, and absent altogether in the lower coccygeal segments. The spinous processes are absent in the case of the first cervical, lower sacral, and all the coccygeal vertebræ, and display characteristic differences in the cervical, thoracic, and lumbar regions, which have been already described. The articular processes (zygapophyses) are secondary developments, and display great diversity of form, determined by their functional requirements. It is noteworthy that, in the case of the upper

FIG. 280.—DIAGRAM TO ILLUSTRATE THE HOMOLOGOUS PARTS OF THE VERTEBRÆ.

The bodies are coloured purple ; the vertebral arch and its processes, red ; the costal elements, blue. A, from above. B, from the side.

two cervical vertebræ, they are so disposed as to lie in front of the foramina of exit of the upper two spinal nerves, and by this arrangement the weight of the head is transmitted to the solid column formed by the vertebral bodies, and not on to the series of vertebral arches. It is in regard to the homology of the transverse processes, so called, that most difficulty arises. In the

thoracic region they can best be studied in their simplest form ; here the ribs—which Gegenbauer regards as a differentiation from the inferior or hæmal arches, in opposition to the view advanced by others that they are a secondary development from the fibrous intermuscular septa—articulate with the transverse processes and bodies of the thoracic vertebræ through the agency of the tubercular (diapophyses) and caputular (parapophyses) processes respectively, the latter being placed, strictly speaking, on the vertebral arch behind the line of the neuro-central synchondrosis.

An interval is thus left between the neck of the rib and the front of the transverse process ; this forms an arterial passage which corresponds to the foramen transversarium in the transverse processes of the cervical vertebræ, the anterior bar of which is homologous with the head and tubercle of the thoracic rib, whilst the posterior part lies in series with the thoracic transverse process. These homologies are further emphasised by the fact that in the case of the seventh cervical vertebra the anterior limb of the so-called transverse process is developed from an independent ossific centre, which occasionally persists in an independent form as a cervical rib.

In the lumbar region the lateral or transverse process is serially homologous with the thoracic ribs, though here, owing to the coalescence of the contiguous parts, there is no arterial channel between the rib element and the true transverse process, which is represented by the 'accessory processes (anapophyses), placed posteriorly at the root of the so-called transverse process of human anatomy. Support is given to this view by the presence of a distinct costal element in connexion with the transverse process of the first lumbar vertebra, which accounts for the occasional formation of a supernumerary rib in this region. The cases of foramina in the transverse processes of the lumbar vertebræ (see p. 275) are also noteworthy as supporting this view.

In the sacrum the lateral part of the bone is made up of combined transverse and costal elements, with only very exceptionally an intervening arterial channel. In the case of the upper three sacral segments the costal elements are largely developed and assist in supporting the ilia, and they are called the true sacral vertebræ ; whilst the lower sacral segments, which are not in contact with the ilia, are referred to as the pseudo-sacral vertebræ.

The anterior arch of the atlas vertebra is, according to Frobiep, developed from a hypochondral strip of cartilage (hypochondral sponse).

APPENDIX D.

MEASUREMENTS AND INDICES EMPLOYED IN PHYSICAL ANTHROPOLOGY.

(1) Craniometry.

The various groups of mankind display in their physical attributes certain features which are more or less characteristic of the stock to which they belong. Craniology deals with these differences so far as they affect the skull. The method whereby these differences are recorded involves the accurate measurement of the skull in most of its details. Such procedure is included under the term craniometry. Here only the outlines of the subject are briefly referred to ; for such as desire fuller information on the subject, the works of Broca, Topinard, Flower, and Turner may be consulted.

The races of man display great variations in regard to the size of the skull. Apart altogether from individual differences and the proportion of head-size to body-height, it may be generally assumed that the size of the skull in the more highly civilised races is much in excess of that displayed in lower types. The size of the head is intimately correlated with the development of the brain. By measuring the capacity of that part of the skull occupied by the encephalon, we are enabled to form some estimate of the size of the brain. The cranial capacity is determined by filling the cranial cavity with some suitable material and then taking the cubage of its contents. Various methods are employed, each of which has its advantage. The use of fluids, which of course would be the most accurate, is rendered impracticable, without special precautions, owing to the fact that the macerated skull is pierced by so many foramina. As a matter of practice, it is found that leaden shot, glass beads, or seeds of various sorts are the most serviceable. The results obtained display a considerable range of variation. For purposes of classification and comparison, skulls are grouped according to their cranial capacity into the following varieties :—

Microcephalic skulls are those with a capacity below 1350 c.c., and include such well-known races as Andamanese, Veddahs, Australians, Bushmen, Tasmanians, etc.

Mesocephalic skulls range from 1350 c.c. to 1450 c.c., and embrace examples of the following varieties : American Indians, Chinese, some African Negroes.

Megacephalic skulls are those with a capacity over 1450 c.c., and are most commonly met with in the more highly civilised races : Mixed Europeans, Japanese, etc.

Apart from its size, the form of the cranium has been regarded as an important factor in the classification of skulls ; though whether these differences in shape have not been unduly emphasised in the past is open to question.

The relation of the breadth to the length of the skull is expressed by means of the **cephalic index** which records the proportion of the maximum breadth to the maximum length of the skull, assuming the latter equal 100, or—

$$\frac{\text{Max. breadth} \times 100}{\text{Max. length}} = \text{Cephalic index.}$$

The results are classified into three groups:—

1. **Dolichocephalic**, with an index below 75 : Australians, Kaffirs, Zulus, Eskimo, Fijians.
2. **Mesaticephalic**, ranging from 75 to 80 : Europeans (mixed), Chinese, Polynesians (mixed).
3. **Brachycephalic**, with an index over 80 : Malays, Burmese, American Indians, Andamanese.

In order to provide for uniformity in the results of different observers, some system is necessary by which the various points from which the measurements are taken must correspond. Whilst there is much difference in the value of the measurements insisted on by individual anatomists, all agree in endeavouring to select such points on the skull as may be readily determined, and which have a fairly fixed anatomical position. The more important of these "fixed points" are included in the subjoined table:—

FIG. 281.

Nasion.—The middle of the naso-frontal suture.

Glabella.—A point midway between the two superciliary ridges.

Ophryon.—The central point of the narrowest transverse diameter of the forehead, measured from one temporal line to the other.

Inion.—The external occipital protuberance.

Maximum Occipital Point.—The point on the squamous part of the occipital in the sagittal plane most distant from the glabella.

Opisthion.—The middle of the posterior margin of the foramen magnum.

Basion.—The middle of the anterior margin of the foramen magnum.

Bregma.—The point of junction of the coronal and sagittal sutures.

Rhinion.—The most prominent point at which the nasal bones touch one another.

Alveolar Point or Prosthion.—The centre of the anterior margin of the upper alveolar margin.

Subnasal Point.—The middle of the inferior border of the piriform (anterior nasal) aperture at the centre of the anterior nasal spine.

Akanthion.—The most prominent point on the nasal spine.

Vertex.—The summit of the cranial vault.

Obelion.—A point over the sagittal suture, on a line with the parietal foramina.

Lambda.—The meeting-point of the sagittal and lambdoid sutures.

Pterion.—The region of the antero-lateral fontanelle where the angles of the frontal, parietal, squamous part of the temporal, and great wing of sphenoid lie in relation to one another. As a rule, the sutures are arranged like the letter H, the parietal and great wing of sphenoid separating the frontal from the squamous temporal. In other cases the form of the suture is like an X; whilst in a third variety the frontal and squamous part of the temporal articulate with each other, thus separating the great wing from the parietal.

Asterion is the region of the postero-lateral fontanelle where the lambdoid, parieto-mastoid, and occipito-mastoid sutures meet.

Stephanion.—The point where the coronal suture crosses the temporal line.

Dacryon.—The point where the vertical lacrimo-maxillary suture meets the fronto-nasal suture at the inner angle of the orbit.

Jugal Point.—Corresponds to the angle between the vertical border and the margin of the temporal process of the zygomatic bone.

Supra-auricular Point.—A point immediately above the middle of the orifice of the external acoustic meatus close to the edge of the posterior root of the zygoma.

Gonion.—The outer side of the angle of the mandible.

Pogonion.—The most prominent point of the chin as represented on the mandible.

The measurements of the length of the skull may be taken between a variety of points—the nasion, glabella, or ophryon in front, and the inion or maximum occipital point behind. Or the maximum length alone may be taken without reference to any fixed points. In all cases it is better to state precisely where the measurement is taken. The maximum breadth of the head is very variable as regards its position; it is advisable to note whether it occurs above or below the parieto-squamosal suture. The inter-relation of these measurements as expressed by the cephalic index has been already referred to. The width of the head may also be measured from one asterion to the other, **biasterionic width**, or by taking the **bistephanic diameter**.

The height of the cranium is usually ascertained by measuring the distance from the basion to the bregma. The relation of the height to the length may be expressed by the **height or vertical index**, thus—

$$\frac{\text{Height} \times 100}{\text{Length}} = \text{Vertical index.}$$

Skulls are classified in accordance with the relations of length and height as follows:—

Tapeinocephalic index below 72.

Metricocephalic index between 72 and 77.

Akrocephalic index above 77 (Turner).

or

Chamæcephalic index up to 70.

Orthocephalic index from 70·1 to 75.

Hypsicephalic index 75·1 and upwards
(Kollmann, Ranke, and Virchow).

The **horizontal circumference** of the cranium, which ranges from 450 mm. to 550 mm., is measured around a plane cutting the glabella or ophryon anteriorly, and the maximum occipital point posteriorly. The **longitudinal arc** is measured from the nasion in front to the opisthion behind; if to this be added the basi-nasal length and the distance between the basion and the opisthion, we have a record of the vertico-median circumference of the cranium. This may further be divided by measuring the lengths of the frontal, parietal, and occipital portions of the superior longitudinal arc. In this way the relative proportions of these bones may be expressed.

The measurements of the skeleton of the face are more complex, but, on the whole, of greater value than the measurements of the cranium. It is in the face that the characteristic features of race are best observed, and it is here that osseous structure most accurately records the form and proportions of the living.

The form of the face varies, like that of the cranium, in the relative proportions of its length and breadth. Generally speaking, a dolichocephalic cranium is associated with a long face, whilst the brachycephalic type of head is correlated with a rounder and shorter face. This rule, however, is not universal, and there are many exceptions to it.

The determination of the facial index varies according to whether the measurements are made with or without the mandible in position. In the former case the length is measured from the ophryon or nasion above to the mental tubercle below, and compared with the maximum bizygomatic width. This is referred to as the **total facial index**, and is obtained by the formula—

$$\frac{\text{Ophryo-mental length} \times 100}{\text{Bizygomatic width}} = \text{Total facial index.}$$

More usually, however, owing to the loss of the mandible, the proportions of the face are expressed by the **superior facial index**. This is determined by comparing the ophryo-alveolar or naso-alveolar length with the bizygomatic width, thus—

$$\frac{\text{Ophryo-alveolar length} \times 100}{\text{Bizygomatic width}} = \text{Superior facial index.}$$

The terms **dolichofacial** or **leptoprosope** and **brachyfacial** or **chamæprosope** have been employed to express the differences thus recorded.

Uniformity in these measurements, however, is far from complete since many anthropologists compare the width with the length=100.

The proportion of the face-width to the width of the calvaria is roughly expressed by the use of the terms **cryptozygous** and **phænozygous** as applied to the skull. In the former case the zygomatic arches are concealed, when the skull is viewed from above, by the overhanging and projection of the sides of the cranial box; in the latter instance, owing to the narrowness of the calvaria, the zygomatic arches are clearly visible.

The projection of the face, so characteristic of certain races (Negroes for example), may be estimated on the living by measuring the angle formed by two straight lines, the one passing from the middle of the external acoustic meatus to the lower margin of the septum of the nose; the other drawn from the most prominent part of the forehead above to touch the incisor teeth below. The angle formed by the intersection of these two lines is called the **facial angle** (Camper), and ranges from 62° to 85°. The smaller angle is characteristic of a muzzle-like

projection of the lower part of the face. The larger angle is the concomitant of a more vertical profile. The degree of projection of the maxilla in the macerated cranium is most commonly expressed by employing the **gnathic** or **alveolar index** of Flower. This records the relative proportions of the basi-alveolar and basi-nasal lengths, the latter being regarded as=100, thus—

$$\frac{\text{Basi-alveolar length} \times 100}{\text{Basi-nasal length}} = \text{Gnathic index.}$$

The results are conveniently grouped into three classes :—

Orthognathous, index below 98 : including mixed Europeans, ancient Egyptians, etc.

Mesognathous, index from 98 to 103 : Chinese, Japanese, Eskimo, Polynesians (mixed).

Prognathous, index above 103 : Tasmanians, Australians, Melanesians, various African Negroes.

Unfortunately, however, little reliance can be placed on the results obtained by this method, since it takes no account of the proportion of the third or facial side of the gnathic triangle. For a further discussion of this matter see Thomson and MacIver, *Races of the Thebaid* (Oxford : Clarendon Press, 1905).

The form of the piriform aperture in the macerated skull is of much value from an ethnic standpoint, as it is so intimately associated with the shape of the nose in the living. The greatest width of the aperture is compared with the nasal height (measured from the nasion to the lower border of the aperture) and the **nasal index** is thus determined :—

$$\frac{\text{Nasal width} \times 100}{\text{Nasal height}} = \text{Nasal index.}$$

Skulls are—

Leptorhine, with a nasal index below 48 : as in mixed Europeans, ancient Egyptians, American Indians, etc.

Mesorhine, with an index ranging from 48 to 53 : as in Chinese, Japanese, Malays, etc.

Platyrrhine, with an index above 53 : as in Australians, Negroes, Kaffirs, Zulus, etc.

The form of the orbit varies considerably in different races, but is of much less value from the standpoint of classification. The **orbital index** expresses the proportion of the orbital height to the orbital width, and is obtained by the following formula :—

$$\frac{\text{Orbital height} \times 100}{\text{Orbital width}} = \text{Orbital index.}$$

The orbital height is the distance between the upper and lower margins of the orbit at the middle ; whilst the orbital width is measured from a point where the ridge which forms the posterior boundary of the lacrimal groove meets the fronto-lacrimal suture (Flower), or from the dacryon (Broca) to the most distant point from these on the anterior edge of the lateral border of the orbit.

The form of the orbital aperture is referred to as—

Megaseme, if the index be over 89 ;

Mesoseme, if the index be between 89 and 84 ;

Microseme, if the index be below 84.

The variations met with in the form of the palate and dentary arcade may be expressed by the **palato-maxillary index** of Flower. The length is measured from the alveolar point to a line drawn across the posterior borders of the maxilla, whilst the width is taken between the outer borders of the alveolar arch immediately above the middle of the second molar tooth. To obtain the index, the following formula is employed :—

$$\frac{\text{Palato-maxillary width} \times 100}{\text{Palato-maxillary length}} = \text{Palato-maxillary index.}$$

For purposes of classification Turner has introduced the following terms :—

Dolichuranic, index below 110.

Mesuranic, index between 110 and 115.

Brachyuranic, index above 115.

As is elsewhere stated the size of the teeth has an important influence on the architecture of the skull. Considered from a racial standpoint, the relative size of the teeth to the length of the cranio-facial axis has been found by Flower to be a character of much value. The dental length is taken by measuring the distance between the anterior surface of the first premolar and the posterior surface of the third molar of the upper jaw.

To obtain the **dental index** the following formula is used :—

$$\frac{\text{Dental length} \times 100}{\text{Basi-nasal length}} = \text{Dental index.}$$

Following the convenient method of division adopted with other indices, the dental indices may be divided into three series, called respectively—

Microdont, index below 42 : including the so-called Caucasian or white races.

Mesodont, index between 42 and 44 : including the Mongolian or yellow races.

Megadont, index above 44 : comprising the black races, including the Australians.

Many complicated instruments have been devised to take the various measurements required, but for all practical purposes the calipers designed by Flower or the *compas glissière* of Broca are sufficient.

As an aid to calculating the indices, the tables published in the *Osteological Catalogue of the Royal College of Surgeons of England*, Part I., Man; *Index-Tabellen zum anthropometrischen Gebrauche*, C. M. Furst, Jena, 1902; or the index calculator invented by Waterston will be found of much service in saving time.

(2) Indices and Measurements of other Parts of the Skeleton.

In addition to the indices employed to express the proportions of the cranial measurements, there are others similarly made use of to convey an idea of the proportions of different parts of the skeleton. Of these the following may be mentioned as those in most common use :—

Scapula.—At birth the form of the human scapula more closely resembles the mammalian type in that its breadth, measured from the glenoid cavity to the vertebral border, is greater in comparison with its length than in the adult. This proportion is expressed as follows :—

$$\frac{\text{Breadth from glenoid cavity to vertebral border} \times 100}{\text{Length from medial to inferior angle}} = \text{Scapular index.}$$

The index ranges from 87 in African pygmies, which therefore have proportionately broader scapulæ, to 61 in Eskimos. The average European index is about 65.

Hip Bone.—The relation of the breadth of this bone to its height is computed as follows :—

$$\frac{\text{Iliac breadth} \times 100}{\text{Ischio-iliac height}} = \text{Innominate index.}$$

Man as compared with the apes is distinguished by possessing proportionately broader and shorter hip bones. The index in man ranges from 74 to 90.

Pelvis.—The form of the human pelvis is characterised by an increased proportionate width and a reduced proportionate height or length. The relation of these diameters is expressed by the formula :—

$$\frac{\text{Ischio-iliac height} \times 100}{\text{Greatest breadth between the outer lips of the iliac crests}} = \text{Pelvic breadth-height index.}$$

The average index for white races is 73.

Pelvic Cavity.—The measurements usually taken are those of the superior aperture. In man there is a proportionate increase in the transverse diameter as compared with lower forms :—

$$\frac{\text{Antero-posterior diameter (conjugate) from mid-point of sacral promontory to the posterior margin of pubic symphysis} \times 100}{\text{Greatest transverse width between ilio-pectineal lines}} = \text{Pelvic or brim index.}$$

Turner has classified the indices into three groups :—

Dolichopellic, index above 95 : Australians, Bushmen, Kaffirs.

Mesatipellic, index between 90-95 : Negroes, Tasmanians, New Caledonians.

Platypellic, index below 90 : Europeans and Mongolians generally.

Vertebral Column.—A characteristic feature of man's vertebral column is the pronounced lumbar curve associated with the erect posture in the living. Apart from the consideration of the interposition of the intervertebral fibro-cartilage between the segments, the bodies of the lumbar vertebræ influence and react on the curve by exhibiting differences in their anterior and posterior vertical diameters. Advantage has been taken of this to endeavour to reconstruct the lumbar curve from the dried and macerated bones, but it must be borne in mind that habitual posture or increased range of movements may yield results which are possibly misleading. Thus there is reason for believing that the squatting position, when habitually adopted, may give rise to a compression of the anterior parts of the bodies of the vertebræ which it might be assumed was associated with an absence of or flattening of the lumbar curve, which in fact did not exist during life.

The quality of the curve is estimated from the macerated bones by an index which is computed as follows :—

$$\frac{\text{Sum of posterior vertical diameters of the bodies of five lumbar vertebræ} \times 100}{\text{Sum of anterior vertical diameters of the bodies of five lumbar vertebræ}} = \text{General lumbar index.}$$

The results are classified as follows :—

Kurtorachic, index below 98, displaying a forward convexity: includes Europeans generally, Chinese.

Orthorachic, index between 98 and 102, column practically straight: includes examples of Eskimo and Maori.

Koilorachic, index above 102, displaying a backward convexity: includes Australians, Negroes, Bushmen, and Andamanese.

Sacrum.—Man's sacrum is characterised by its great breadth in proportion to its length. These relations are expressed as follows :—

$$\frac{\text{Greatest breadth of base of sacrum} \times 100}{\text{Length from middle of promontory to middle of anterior inferior border of fifth sacral vertebrae}} = \text{Sacral index.}$$

The diverse forms are grouped as follows :—

Dolichohieric, index below 100, sacra longer than broad: includes Australians, Tasmanians, Bushmen, Hottentots, Kaffirs, and Andamanese.

Platyhieric, index above 100, sacra broader than long: includes Europeans, Negroes, Hindoos, North and South American Indians.

Limb Bones.—The proportionate length of the limb bones to each other and to the body height is of practical interest. It is a matter of common knowledge that the forearms of Negroes are proportionately longer than those of Europeans. Great differences, too, are met with in the absolute and proportionate length of the lower limbs, nor must the relation of these to body height be overlooked. An enumeration of the more important of these indices, and the manner of their computation, will suffice. The proportion of the length of the radius to the length of the humerus is expressed as follows :—

$$\frac{\text{Length of radius} \times 100}{\text{Length of humerus}} = \text{Radio-humeral index.}$$

Sub-divided into three groups :—

Brachykercic, index less than 75: includes Europeans, Lapps, Eskimo.

Mesatikercic, index between 75-80: Chinese, Australians, Polynesians, Negroes.

Dolichokercic, index above 80: Andamanese, Negritos and Fuegians, Bonindae in general.

The proportion of the length of the tibia to the femur is computed by the formula—

$$\frac{\text{Length of tibia from surface of condyle to articular surface for talus} \times 100}{\text{Oblique length of femur}} = \text{Tibio-femoral index.}$$

Sub-divided into two groups :—

Brachyknemic, index 82 and under: includes Europeans and Mongolians generally.

Dolichoknemic, index 83 and over: includes Australians, Negroes, Negritos, American-Indians.

The proportion of the length of the upper limb to that of the lower limb is obtained thus :—

$$\frac{\text{Lengths of humerus + radius} \times 100}{\text{Lengths of femur + tibia}} = \text{Intermembral index.}$$

A comparison between the relative lengths of the upper segments of the limbs is obtained by the following formula :—

$$\frac{\text{Length of humerus} \times 100}{\text{Length of femur}} = \text{Humero-femoral index.}$$

Platymeria (see p. 281).—The amount of compression of the femur is estimated as follows :—

$$\frac{\text{Sagittal diameter of shaft immediately distal to lesser trochanter} \times 100}{\text{Transverse diameter of shaft immediately distal to lesser trochanter}} = \text{Platymeric index.}$$

Platyknemia (see p. 281).—The degree of compression of the tibia is estimated by the formula—

$$\frac{\text{Transverse diameter of shaft at level of nutrient foramen} \times 100}{\text{Antero-posterior diameter of shaft at level of nutrient foramen}} = \text{Platyknemic index.}$$

The index ranges from 60 in a Maori tibia to 80 to 108 in modern French tibiae.

For further and more detailed information relating to the various measurements and indices employed by the physical anthropologist, the reader is referred to Topinard's *Éléments d'Anthropologie*; Sir W. Turner's *Challenger Memoirs*, Part 47, vol. xvi.; and Duckworth's *Morphology and Anthropology*.

APPENDIX E.

DEVELOPMENT OF THE CHONDRO-CRANIUM AND MORPHOLOGY OF THE SKULL.

As has been already stated, the chorda dorsalis or notochord extends forwards to a point immediately beneath the anterior end of the mid-brain. In front of this the head takes a bend so that the large fore-brain overlaps the anterior extremity of the notochord. At this stage of development the cerebral vesicles are enclosed in a membranous covering derived from the mesen-

FIG. 282.—VIEW OF THE CHONDRO-CRANIUM OF A HUMAN FŒTUS 5 CM. IN LENGTH FROM VERTEX TO OCCIPX (about the middle of the third month); the cartilage is coloured blue. The line to the right of the drawing shows the actual size.

chyme surrounding the notochord; this differentiated mesodermal layer is called the primordial membranous cranium. From it the meninges which invest the brain are derived. In lower vertebrates this membranous capsule becomes converted into a thick-walled cartilaginous envelope, the primordial cartilaginous cranium. In mammals, however, only the basal part of this capsule becomes chondrified, the roof and part of the sides remaining membranous. In considering the chondrification of the skull in mammals, it must be noted that part only of the base is traversed by the notochord, viz., that portion which extends from the foramen magnum to the dorsum sellæ of the sphenoid. It is, therefore, conveniently divided into two parts—one posterior, surrounding the notochord, and hence called **chordal**, and one in front, into which the notochord does not extend, and hence termed **prechordal**. These correspond respectively to the vertebral and evertrebral regions of Gegenbauer. In the generalised type, a pair of elongated cartilages called the **para-chordal cartilages** appear on either side of the chorda in the chordal region, similarly in the prechordal region two curved strips of cartilage named the **prechordal cartilages**, or the **trabeculæ cranii of Rathke**, develop on either side of the cranio-pharyngeal canal. In the human embryo, however, this symmetrical arrangement has not hitherto been observed. In man, chondrification of the cranial base commences early in the second month and attains its maximum development about the end of the third month, at which time the **chordal** part of the chondrocranium consists of a ring of cartilage, the ventral part of which is formed by the fusion of two parachordal cartilages, so forming around the chorda dorsalis, a central axial part,

which comprises the basilar portion of the occipital bone. From this there pass extensions which form the lateral parts of the occipital bone, and serve to unite the occipital plate, as this part of the cartilaginous base is sometimes called, to the cartilaginous auditory capsules on either side. These latter are formed by the chondrification of the cochlear and canalicular parts of the labyrinth, which do not develop at the same rate, so that the part around the semi-circular canals is completed much sooner than the cochlear portion; in consequence, at the end of the second month, the facial nerve and the genicular ganglion lie in a groove, to be subsequently converted into a canal, on the vestibular part of the capsule.

The dorsal part of the ring consists of a thin cartilaginous plate, the *tectum posterius*, from which is developed the only part (*i.e.* the inferior part of the occipital squama) of the cranial vault preformed in cartilage. In the membranous tissue from which this plate is developed chondrification at first begins, on either side, by an extension from the posterior aspect of the pars lateralis of the occipital; growing rapidly forwards this ultimately unites with the posterior and dorsal borders of the cartilaginous auditory capsule, from which it is for some time separated by a narrow membranous interval. At a later stage the cartilages of either side unite, dorsal to the foramen magnum, to form the *tectum posterius* or the *tectum synoticum* (Keibel and Mall).

To the axial part of this portion of the chondrified base the chorda dorsalis has the following

FIG. 283.—OSSIFICATION ON BASE AND LATERAL WALLS OF SKULL OF FOUR AND A HALF MONTHS' FETUS (Schultze's method). Cartilage, blue; cartilage-bone, black; membrane-bone, red.

relations: in front of the foramen magnum it runs for a short distance in a groove on the dorsal surface of the occipital plate, then pierces the cartilage so as to lie ventral to it in the retro-pharyngeal tissue, again enters the chondro-cranium by passing dorsalwards in the suture between the occipital plate and sphenoidal cartilage and endo-dorsal to the latter cartilage.

The **prechordal portion** of the cartilaginous basis cranii in man displays the following features: at the third month it is irregularly diamond-shaped in outline, its posterior angle is wedged in between the two auditory capsules and is related to the fore part of the axial portion of the occipital plate. The anterior angle forms the ventral end of the nasal capsule, whilst the lateral angles extend over the orbital cavities and correspond to the tips of the *alæ orbitales* of the sphenoid.

Within this area chondrification takes place as follows (Bardeen). In the region of the posterior angle above referred to a cartilaginous nodule appears anterior and ventral to the end of the chorda dorsalis; from this arises the cartilaginous body of the sphenoid, the further development of which is associated with its union with the anterior end of the median portion of the occipital plate and the formation there, by the appearance of an independent transverse strip of cartilage, of the *dorsum sellæ* of the sphenoid; whilst from its anterior and superior surface on either side there extend forwards strips of cartilage which surround the hypophyseal pocket, and unite in front of it to form the anterior part of the body of the sphenoid, thereby enclosing the hypophyseal canal, which, at first wide, is gradually closed by the chondrification of its walls. It may, however, remain open.

The region occupied by the ala temporalis is slow to chondrify. According to Fawcett, the only part of it which is preformed in cartilage is that which corresponds to the root of the two pterygoid laminae in the adult: this is, perforated by the maxillary division of the trigeminal nerve. According to the same authority, the whole of the lateral pterygoid lamina and that part of the ala temporalis projected into the orbital and temporal fossae are ossified in membrane. So, too, are the foramen ovale and foramen spinosum.

The ala orbitalis, at first much larger than the ala temporalis, is described as chondrifying in the following way. The process begins by the appearance of cartilage posterior to the position of the optic foramen; medially this fuses with the lateral aspect of the anterior part of the body of the sphenoid, laterally it extends into the orbital plate, with the independent cartilaginous centre of which it unites. The foramen opticum is completed by the extension of the cartilage from the side of the anterior extremity of the body of the sphenoid, in front of the nerve, to reach the orbital plate. These three centres fuse to form a single piece of cartilage during the third month.

Anterior to the orbito-sphenoids, the base of the skull is intimately associated with the nasal capsule, and is the last part of the chondro-cranium to become cartilaginous, this change not being effected till the third month. The roof of the capsule is formed by the coalescence of cartilaginous elements appearing, first in the nasal septum by an extension of the cartilage from the ventral surface of the body of the sphenoid and secondly by an independent centre in each lateral wall of the capsule. At first the nasal capsule is open dorsally on either side of the nasal septum in correspondence with the olfactory bulbs, but during the third month the wall of the capsule corresponding to the cribriform plate commences to chondrify around the perforating nerve-fibres, and so the lamina cribrosa is preformed in cartilage. Laterally strips of cartilage (cartilago ethmosphenoidalis) pass backwards from the lateral edges of the cribriform plate to unite it with the anterior edges of the alae orbitales of the sphenoid.

By the third month the nasal capsule has become cartilaginous. As has been stated above, the nasal septum chondrifies by an extension forwards of the ventral part of the body of the cartilaginous sphenoid. On either side of the ventral margin of this septum anteriorly are developed the paraseptal cartilages, which in man persist till after birth. These are connected posteriorly by means of a connective tissue bridge with small pieces of cartilage—the posterior paraseptal cartilages, which are in turn associated with the paranasal cartilages posteriorly, and there in part form the floor of the recessus terminalis or cupola of the cartilaginous nasal capsule (Fawcett). In man, owing to the deficiency of the lamina transversalis anterior, the fenestra narina and the fenestra basalis which pierce the floor of the nasal capsule, on either side of the septum, become confluent and form the fissura rostroventralis of Gaupp. Meanwhile the lateral walls of the nasal capsule are chondrifying independently, forming the paranasal cartilages. These become subsequently united anteriorly with the nasal septum to form the tectum nasi or roof of the nose. At first this is open posteriorly where it is in relation with the olfactory bulb, but later, as has been already described, the tissue around the nerve filaments chondrifies to form the cartilaginous lamina cribrosa. The inferior concha is derived from the cartilage of the lower and lateral part of the nasal capsule, from which, however, it becomes isolated about the seventh month. Above and behind this the middle and superior conchæ, the ethmoidal turbinals, become chondrified, as well as the cartilaginous rudiments which subsequently form the agger nasi, the bulla ethmoidalis, and the concha sphenoidale or ossiculum Bertini.

Throughout life certain parts of the cartilaginous nasal capsule persist as the cartilaginous nasal septum and the cartilages of the alae of the nose, whilst other parts are absorbed and are replaced by surrounding bones of membranous origin.

The various foramina met with in the cranial base are formed either as clefts in the line of union of the several cartilaginous elements, or through inclusion by means of bridging processes derived from these same elements.

From the ventral surface of this cartilaginous platform—formed, as described, by the union of the trabeculae, parachordal cartilages, and cartilaginous auditory capsules—is suspended the cartilaginous framework of the visceral arches, which play so important a part in the development of the face, an account of which is elsewhere given.

A consideration of the facts of comparative anatomy and embryology appears to justify the assumption that the mammalian skull is of twofold origin—that, in fact, it is composed of two envelopes, an outer and an inner, primarily distinct, but which in the process of evolution have become intimately fused together. The inner, called the primordial skull, is that which has just been described, and consists of the chondro-cranium and the branchial skeleton. The outer, which is of dermic origin, includes the bones of the cranial vault and face which are developed in membrane. This secondary skull, which first appears in higher fishes as ossified dermal plates overlying the primary skull, acquires a great importance in the mammalia, as owing to the expansion of the brain and the progressive reduction of the chondro-cranium, these dermal bones become engrafted on and incorporated with the primordial skull, and act as covering bones to the cavities of the cranium and face; for it may be well to point out that these dermal or membrane bones are not necessarily external in position, as over the cranial vault, but also develop in the tissues underlying the mucous membrane of the cavities of the face.

Advantage is taken of this difference in the mode of development of the bones of the skull to classify them according to their origin into **cartilage** or **primordial bones**, and **membrane** or **secondary bones**. These differences in the growth of the bone must not be too much insisted on in determining the homologies of the bones of the skull, as it is now generally recognised that

all bone is of membranous origin, and that whilst in some cases cartilage may become calcified, it never undergoes conversion into true bone, but is replaced by ossific deposit derived from a membranous source. In the subsequent growth of the skull, parts of the cartilaginous cranium persist as the septal and alar cartilages of the nose, whilst for a considerable period the basi-sphenoid and basi-occipital are still united by cartilage. The cartilage also which blocks the foramen lacerum may be regarded as a remnant of the chondro-cranium.

Whilst in many instances the primordial and secondary bones remain distinct in the fully-developed condition, they sometimes fuse to form complex bones, such as the temporal and sphenoid.

Various theories have been advanced to account for the mode of formation of the skull. The earliest of these was called the vertebrate theory, which assumed that the cranium was built up of a series of modified vertebræ, the bodies of which corresponded to the basi-cranial axis, whilst the vertebral arches were represented by the covering bones of the cranium. In view of the more recent researches regarding the composite origin of the skull above referred to, this theory was necessarily abandoned. It gave way to the suggestion of Gegenbaur that the primordial cranium has arisen by the fusion of several segments equivalent to vertebræ, the number of which he determined by noting the metameric arrangement of the cerebral nerves, of which he concluded there were nine pairs, arranged much like spinal nerves, both as to their origin and distribution. The olfactory and optic nerves, though frequently referred to as cerebral nerves, are excluded, since from the nature of their development they are to be regarded as metamorphosed parts of the brain itself. Gegenbaur therefore assumed that that portion of the cranial base which is traversed by the nine pairs of segmentally arranged cerebral nerves must be formed by the fusion of nine vertebral segments; and as the region where the nerves escape corresponds to the part of the chondro-cranium traversed by the notochord, he calls it the vertebral portion of the cranial base, in contradistinction to the trabecular or non-vertebral part which lies in front. This latter he regards as a new formation adapted to receive the greatly-developed brain and afford protection to the organs of sight and smell.

As has been pointed out by Hertwig, there is an essential difference between the development of the axial cartilaginous skeleton of the trunk and head. The former becomes segmented into distinct vertebræ alternating with intervertebral ligaments; whilst the latter, in order to attain the rigidity necessary in this part of the skeleton, is never so divided. It follows from this that the original segmentation of the head is only expressed in three ways, viz., in the appearance of several primitive segments (myotomes), in the arrangement of the cerebral nerves, and in the fundament of the visceral skeleton (visceral arches). According to Froriep, the mammalian occipital corresponds to the fusion of four vertebræ, and there is some reason for supposing that in some classes of vertebrates the occipital region of the primordial cranium is increased by fusion with the higher cervical segments.

The form of skull characteristic of man is dependent on the large proportionate development of the cranial part, which contains the brain, and the reduction in size of the visceral part (face), which protects the organs of special sense. This leads to a decrease in the mass and projection of the jaws, as well as a reduction in the size of the teeth. Associated with the smaller mandible there is a feebler musculature, with a reduced area of attachment to the sides of the skull. In this way the disappearance of the muscular crests and fossæ, so characteristic of lower forms, is accounted for. At the same time the fact that the skull is poised on the summit of a vertical column, leads to important modifications in its structure. The disposition of parts is such that the occipito-vertebral articulation is so placed that the fore and hind parts of the head nearly balance each other, thus obviating the necessity for a powerful muscular and ligamentous mechanism to hold the head erect.

Another noticeable feature in connexion with man's skeleton is the prolonged period during which growth may occur before maturity is reached; this is associated with a more complete consolidation of the skull, since bones, which in lower forms remain throughout life distinct, are in man fused with each other, as exemplified in the case of the presphenoid and postsphenoid, the occipital and the interparietal, to mention one or two instances among many. It is noteworthy, however, that during ontogeny the morphological significance of these bones is clearly demonstrated by their independent ossification.

The points of exit of the various cerebral nerves remain remarkably constant, and in their primitive condition serve to suggest the segmental arrangement of the cartilaginous chondro-cranium already referred to. Owing to the very great modifications which the mammalian skull has undergone in the process of its evolution, it may be pointed out that the passage of the nerves through the dura mater—a derivative, the readers may be reminded, of the primordial membranous cranium (see *ante*)—alone represents the primitive disposition of the nerves. Their subsequent escape through the bony base is a later and secondary development. In some cases the two, membranous or primary and the osseous or secondary foramina, correspond. In other instances the exit of the nerves through the dura mater does not coincide with the passage through the bone.

Of interest in this connexion it may be pointed out that the foramina and canals which traverse the skull are either situated in the line of suture between adjacent bones or in the line of fusion of the constituent parts of which the bone pierced is made up. For example, the superior orbital fissure is situated between the orbito and alisphenoids; the hypoglossal canal between the basi and exoccipitals; the jugular between the petrons, basi, and exoccipital; the optic between the orbito-sphenoid and the presphenoid; the pterygoid between the alisphenoid, medial pterygoid lamina, and the lingula.

APPENDIX F.

MORPHOLOGY OF THE LIMBS.

Development and Morphology of the Appendicular Skeleton.

FIG. 234.—DIAGRAM TO ILLUSTRATE THE HOMOLOGIES OF THE BONES OF THE LIMBS.

The two limb buds of an embryo prior to flexion and rotation.

The anterior or pre-axial border is coloured red; the posterior or post-axial border, blue. B. After the assumption of the foetal position. Flexion and rotation have now taken place. The red and blue lines indicate the altered position of the pre-axial and post-axial borders. C. The fully developed limbs with the flexor aspects directed towards the reader. The coloured lines indicate the effect of the torsion of the upper segment of the limb through quarters of a circle.

The paired limbs first appear in the human embryo about the third week as small buds on either side of the cephalic and caudal ends of the trunk. That these outgrowths are derived from a large number of trunk segments is assumed on the ground that they are supplied by a corresponding number of segmental nerves, and the circumstance that they are more particularly associated with the ventral offsets of these nerves would point to the conclusion that they belong rather to the ventral than the dorsal surface of the body.

At first the surfaces of these limb buds are so disposed as to be directed ventrally and dorsally, the ventral aspect corresponding to the future flexor surface of the limb, the dorsal to the extensor side. At the same time, the borders are directed headwards (pre-axial), and tailwards (post-axial). As the limbs grow, they soon display evidence of division into segments corresponding to the hand and foot, forearm and leg, upper arm and thigh. Coincident with this (about the second month) the cartilaginous framework of the limb is being differentiated. The disposition of these cartilages furnishes a clue to their homologies. In the fore-limb the radius and thumb lie along the pre-axial borders, and correspond to the tibia and great toe, which are similarly disposed in the hind-limb; whilst the ulna and fifth finger are homologous with the fibula and fifth toe, which are in like manner arranged in relation to the posterior (post-axial) border of their respective limbs. Up to this time the limbs are directed obliquely ventralwards. During the third month a change in the position of the limbs takes place, associated with the assumption of the foetal position. Owing to the elongation of the limbs, they become necessarily bent at the elbow and knee, the upper arm inclining downward along the thoracic wall, whilst the thigh is directed upwards in contact with the abdominal parietes. At the same time a rotation of each of these segments of the limb takes place in an inverse direction, so that the pre-axial border of the humerus is turned laterally, whilst the pre-axial border of the femur is turned medially. Assuming that these borders are homologous, it results from this, that the lateral condyle of the humerus corresponds to the medial condyle of the femur. This torsion of the limb is in part effected at the shoulder and hip joints, and to some extent also in the shafts of the bones. Some anatomists hold that this rotation is not confined to the limb, but involves the dorsal part of the limb girdles. Others maintain that there is no evidence that such takes place. In the upper limb, owing to a certain amount of pronation, the

pre-axial (radial) side of the forearm is now directed forwards and somewhat laterally, whilst in the hind limb the pre-axial (tibial) side of the leg is turned backwards and laterally, the pre-axial borders of the hand with thumb, and foot with great toe being in correspondence. In consequence of these changes in the position of the limbs, amounting in all in the upper segments to a rotation through an angle of 90° , the extensor surface of the fore limb is directed backwards, whilst that of the hind limb is directed forwards. In order to homologise the arrangement of the bones in the extended limb, it is necessary to place them so that their flexor or extensor surfaces are similarly disposed. It will then be observed (see diagram) that the medial or tibial side of the leg and foot (primitively pre-axial) corresponds to the lateral or radial side of the forearm and hand (primitively pre-axial), whilst the fibula and lateral border of the foot homologise with the ulnar or medial border of the forearm and hand (primitively post-axial), the result, as previously explained, of the torsion or twisting in opposite directions through an angle of 90° of the upper segment of the limb. In accordance with this view, it will be evident that in the fore limb there is nothing homologous with the patella, whilst in the hind limb there is no part to represent the olecranon.

In the axial mesoderm of each member, differentiation into cartilaginous segments begins about the second month; each of these cartilages becomes invested by a perichondrial layer which stretches from segment to segment, and ultimately forms the ligaments surrounding the joints, which are subsequently developed between the segments. Chondrification first begins in the basal part of the limb, and extends towards the digits.

The homodynamy of the carpal and tarsal elements may be tabularly expressed, and compared with the more generalised types from which they are evolved.

Type.	Hand.	Foot.
Radiale (Tibiale)	= Navicular (body)	= Talus.
Intermedium	= Os lunatum	= Absent, or Os trigonum (?).
Ulnare (Fibulare)	= Os triquetrum	= Calcaneus.
Centrale	= Absent, or fused with Navicular	= Navicular, less its tuberosity.
Carpale (Tarsale), i.	= Greater multangular	= First Cuneiform.
Carpale (Tarsale), ii.	= Lesser multangular	= Second Cuneiform.
Carpale (Tarsale), iii.	= Capitate	= Third Cuneiform.
Carpale (Tarsale), iv. }	= Os hamatum	= Cuboid, plus the peroneal sesamoid.
Carpale (Tarsale), v. }		

The pisiform is omitted from the above table, since it is now generally regarded as being a vestige of an additional digit placed post-axial to the little finger (*digitus post-minimus*). Its homologue in the foot is by some considered as fused with the calcaneus. The tuberosity of the navicular, formed, as has been stated, of three elements, of which the sesamoid bone in the tendon of the *tibialis posterior* may be one, is to be regarded as the homologue of the pre-axial sesamoid in the hand, which probably fuses with the navicular to form its tuberosity. The peroneal sesamoid probably corresponds to the hamulus (sometimes an independent ossicle) of the *os hamatum*. Similarly, on the pre-axial border of the hand and foot, vestiges of a suppressed digit (*prepollex* and *prehallux*) may occasionally be met with. The frequent occurrence of an increase in the number of digits seems to indicate that phylogenetically the number of digits was greater than at present, and included a *prepollex* or *prehallux*, and a *digitus post-minimus*. The correspondence of the metacarpus with the metatarsus and the phalanges of the fingers with those of the toes is so obvious that it is sufficient merely to mention it.

The differences in size, form, and disposition of the skeletal elements of the hand and foot is easily accounted for by a reference to the functions they subserve.

In the hand strength is sacrificed to mobility, thus leading to a reduction in the size of the carpal elements, and a marked increase in the length of the digital phalanges. The freedom of movement of the thumb, and its opposability to the other digits, greatly enhances the value of the hand as a grasping organ. In the foot, where stability is the main requirement, the tarsus is of much greater proportionate size, whilst the phalanges are correspondingly reduced. Since the foot no longer serves as a grasping organ, the great toe is not free and opposable like the thumb.

Limb Girdles.—The free limbs are linked to the axial skeleton by a chain of bones which constitute their girdles. The fundamental form of these limb girdles consists each of a pair of curved cartilages placed at right angles to the axis of the trunk on either side, and embedded within its musculature. Each cartilage has an articular surface laterally, about the middle, for the reception of the cartilage of the first segment of the free limb. In this way each pectoral and pelvic cartilage is divided into an upper or dorsal half and a lower or ventral half. The dorsal halves constitute the scapula and ilium of the pectoral and pelvic girdles respectively. With regard to the ventral halves there is more difficulty in establishing their homologies. The original condition is best displayed in the pelvic girdle; here the ventral segment divides into two branches—one anterior, which represents the pubis, the other posterior, which ultimately forms the ischium. Ventrally, the extremities of these cartilages unite to enclose the obturator foramen. In the pectoral girdle the disposition of the ventral cartilages is not so clear, consisting primitively of an anterior branch or *precoracoid*, and a posterior portion or *coracoid*; these, in higher forms, have undergone great modifications in adaptation to the requirements of the fore limbs. The posterior or *coracoid* element, the homologue of the ischial cartilage in the pelvic girdle, is but feebly represented in man by the *coraco process* and the *coraco-clavicular ligament*.

With regard to the homologue of the pubic element in the pectoral girdle, there is much difference of opinion; in reptiles and amphibia it corresponds most closely to the precoracoid, but it is doubtful what represents it in mammals. According to Goette and Hoffman, the clavicle is a primordial bone, and not, as suggested by Gegenbaur, of secondary or dermic origin. If this be so, it corresponds to the ventral anterior segment of the pectoral girdle, and is therefore homologous with the ventral anterior (pubic) segment of the pelvic girdle. On the other hand, if Gegenbaur's view be accepted, the clavicle has no representative in the pelvic girdle. It must, however, be borne in mind that during its ossification it is intimately associated with cartilage, and that that cartilage may represent the precoracoid bar; nor must too great stress be laid upon the fact that the clavicle begins to ossify before it is preformed in cartilage, since that may be merely a modification in its histogenetic development.

According to another view (Sabatier), the subcoracoid centre (see Ossification of Scapula) is derived from the posterior ventral segment, and corresponds to the ischium, whilst the coracoid process is the remains of the anterior ventral segment (precoracoid), and is homodynamous with the pubis.

In no part of the skeleton does function react so much on structure as in the arrangement of the constituent parts of the pectoral or pelvic girdles. In man, owing to the assumption of the erect position and the bipedal mode of progression, the pelvic girdle acquires those characteristics which are essentially human, viz., its great relative breadth and the expansion of its iliac portions, which serve as a support to the abdominal viscera, and also furnish an extensive origin for the powerful muscles which control the movements of the hip-joint. The stability of the

FIG. 285.—DIAGRAM TO ILLUSTRATE THE HOMOLOGOUS PARTS OF THE SCAPULA AND ILIUM ACCORDING TO FLOWER.

A, ideal type; three-sided rod. B, scapula rotated forward through quarter of a circle (90°), so that the primitive medial or vertebral surface is now directed anteriorly. C, ilium rotated backwards through quarter of a circle so that the primitive medial surface is now turned posteriorly. In the diagram the primitive medial or vertebral surface of each figure is coloured black, the pre-axial surfaces red, and the post-axial surfaces blue.

pelvic girdle is insured by the nature of its union with the axial skeleton, as well as by the osseous fusion of its several parts, and their union in front at the symphysis pubis.

Various attempts have been made to homologue the several parts of the ilium and scapula. All are open to objection; that by Flower is perhaps the most generally accepted. Assuming that the primitive type is represented by a prismatic rod, of which the dorsal end represents either the epiphysial border of the vertebral edge of the scapula or the iliac crest, whilst the ventral end corresponds to the glenoid or acetabular articular areas respectively, the surfaces of the three-sided rod are disposed so that one is vertebral or medial, another pre-axial, and the third post-axial. These surfaces are separated by borders, of which one is lateral, separating the pre-axial and post-axial surfaces, whilst the antero-medial and postero-medial margins separate the pre-axial and post-axial surfaces respectively from the vertebral or medial aspect. It is a necessity of Flower's theory that this part of the girdle undergoes a rotation along with the rest of the limb. Thus in the fore limb the surfaces of the primitive type are turned so that the vertebral surface looks forward, whilst in the case of the hind limb the vertebral surface is turned backward. A study of the accompanying diagram will enable the reader to realise how the ventral surface of the scapula is thus rendered homologous with the gluteal surface of the ilium, for by reference to the type, both these surfaces will be seen to correspond to the post-axial areas of the primitive condition. In accordance with this view the surfaces and borders of the scapula are homologised by Flower, as shewn in the subjoined table:—

SURFACES		
Scapula.	Ideal.	Pelvis.
Supra-spinous fossa	1. Vertebral	Inner surface of ilium behind linea arcuata interna, including the articular surface for the sacrum and the portion of the bone above and below this
Infra-spinous fossa	2. Pre-axial	Internal iliac fossa
Subscapular fossa	3. Post-axial	Gluteal surface of ilium

BORDERS

Axillary border, posterior on most animals (attachment of triceps muscle)	1. Lateral	Anterior border (attachment of rectus muscle)
Spine continued into acromion	2. Antero-medial	Linea arcuata interna continued into pubis
Superior border, anterior in most animals, with scapulo-coracoid notch	3. Postero-medial	Posterior border with greater sciatic notch

Flower's views of this matter were strenuously opposed by Humphry, who maintained that there is strong presumptive evidence against any rotation of the superior parts of the girdles, since it is difficult to suppose that the scapula and ilium can undergo a rotation which is not participated in by the coracoid and ischium. According to this anatomist the homologous parts of the two bones are as stated below :—

Scapula.

Pre-spinal ridge forming the floor of the pre-spinal fossa
 Spine and acromion
 Post-spinal part of scapula forming the floor of the post-spinal fossa
 Posterior angle
 Posterior border
 Medial or ventral surface

Ilium.

Linea ilio-pectinea
 Fore part of the blade and crest of the ilium, with its anterior spine or angle
 Hinder part of blade and crest of ilium
 Posterior spine or angle
 Posterior or sciatic border of ilium
 Inner or true pelvic surface of ilium, including the surface for the articulation of the sacrum

FIG. 286.—DIAGRAM TO ILLUSTRATE THE HOMOLOGOUS PARTS OF THE SCAPULA AND ILIUM, ACCORDING TO HUMPHRY.

A, primitive rod-like ilium of kangaroo, prismatic on section. B, scapula. C, ilium. The corresponding surfaces are similarly coloured.

The difficulty arising in this scheme of attempting to homologise the attachments of the triceps and rectus femoris, Humphry explains by pointing out that the former muscle also arises from the lateral surface of the scapula, whilst the rectus overruns the lateral surface of the ilium above the acetabulum, so that there is a correspondence in the origins of both these muscles from the lateral surface of their respective bones; but in consequence of the rotation of the extensor surfaces of the limbs in opposite directions the triceps has been turned backwards on to the posterior border of the scapula, whilst the rectus has been turned forwards on to the anterior border of the ilium. Sufficient has been said to enable the reader to recognise that all attempts to determine in detail the homologies of these parts are beset with difficulty. It is wiser, therefore, in our present state of knowledge to be content with establishing a general correspondence, and so avoid the error of endeavouring to establish a closer homological relationship than actually exists.

In man, since the erection of the figure no longer necessitates the use of the fore limb as a means of support, the shoulder girdle has become modified along lines which enhance its mobility and determine its utility in association with a prehensile limb. Some of its parts remain independent (clavicle and scapula), and are united by diarthrodial joints, whilst others have

become much reduced in size or suppressed (coracoid-precoracoid, see *ante*). The dorsal part of the girdle (scapula) is not directly united with the axial skeleton as is the ilium, but is only indirectly joined to it through the medium of the clavicle, which is linked in front with the presternum. The same underlying principles determine the differences in mobility and strength between the shoulder, elbow, and wrist, and the hip, knee, and ankle joints of the fore and hind limbs respectively, whilst the utility of the hand is further enhanced by the movements of pronation and supination which occur between the bones of the forearm. In the leg such movements are absent, as they would interfere with the stability of the limb.

THE ARTICULATIONS OR JOINTS.

SYNDESMOLOGY.

By DAVID HEPBURN.

Syndesmology is that branch of human anatomy which treats of the articulations or joints.

A *junctura ossium* (articulation or joint) constitutes a mode of union or connexion subsisting between any two separate segments or parts of the skeleton, whether osseous or cartilaginous, and having for its primary object either the preservation of a more or less rigid continuity of the parts joined together, or else to permit of a variable degree of mobility, subject to the restraints of the uniting media.

Classification of Joints.—In attempting to frame a classification of the numerous joints in the body, several considerations must be taken into account, viz., the manner and sequence of their appearance in the embryo; the nature of the uniting media in the adult, and also the degree and kind of movement permitted in those joints where movement is possible.

In this way we obtain two main subdivisions of joints:—

- (1) Those in which the uniting medium is co-extensive with the opposed surfaces of the bones entering into the articulation, and in which a direct union of these surfaces is thereby effected.
- (2) Those in which the uniting medium has undergone more or less of interruption in its structural continuity, and in which a cavity of greater or less extent is thus formed in the interior of the joint.

To the first group belong all the immovable joints, many of which are only of temporary duration; to the second group belong all joints which possess, as their outstanding features, mobility and permanence.

SYNARTHROSES.

The general characteristics of this group are partly positive and partly negative. Thus, there is uninterrupted union between the opposed surfaces of the bones joined together at the plane of the articulation, *i.e.* there is no trace of a joint cavity, and further, there is an entire absence of movement. Developmentally, these joints result from the approximation of ossific processes which have commenced from separate centres of ossification, and therefore the nature of the uniting medium varies according as the bones thus joined together have originally ossified in membrane or in cartilage. In the former case union is effected by an interposed fibrous membrane continuous with, and corresponding to, the periosteum. To such articulations the term *sutura* (Fig. 287) is applied. In the latter case the uniting medium is a plate of hyaline cartilage. Such articulations are called **synchondroses** (Fig. 288). In all the synchondroses, and in many of the sutures, the uniting medium tends to disappear in the progress of

FIG. 287.—VERTICAL SECTION THROUGH A SUTURE.

ossification, and thus the plane of articulation becomes obliterated, so that direct structural continuity between the osseous segments takes place. The primary features common to all synarthroses are—(a) continuous and direct union of the opposing surfaces; (b) no joint cavity; (c) no movement.

FIG. 288.—SECTION THROUGH THE OCCIPITO-SPHENOID SYNCHONDROSIS.

Sutura.—This form of synarthrosis is found only in connexion with the bones of the skull. In a large number of cases the bones which articulate by suture present irregular interlocking margins, between which there is the interposed fibrous membrane to which reference has already been made. When these interlocking margins present well-defined projections they are said to form a *sutura vera* (true suture); on the other hand, when the opposed surfaces present ill-defined projections, or even flat areas, they are described as *sutura notha* (false suture). In each of these subdivisions the particular

characters of the articulating margins are utilised in framing additional descriptive terms. Thus true sutures may possess interlocking margins whose projections are tooth-like (*sutura dentata*), e.g. in the interparietal suture; saw-like (*sutura serrata*) (Fig. 289), e.g. in the interfrontal suture; ridge-like, or comparable to the parallel ridges on the welt of a boot (*sutura limbosa*). Similarly false sutures may articulate by margins which are scale-like (*sutura squamosa*), e.g. in the squamoso-parietal suture; or by rough opposed surfaces, *sutura harmonia*, e.g. in the suture between the palatine processes of the maxillary bones. There is one variety of synarthrosis which, in the adult, can scarcely be called a suture, although the differences are of minor importance, viz., *schindylesis*, which is an articulation between the edge of a plate-like bone, such as the rostrum of the sphenoid, and the cleft in another, such as the vomer.

FIG. 289.—SUTURA SERRATA.

Synchondrosis.—Illustrations of this group can be found only in the young growing individual, because as age advances and growth ceases, the process of ossification affects the hyaline cartilage which constitutes the uniting medium, and the plane of articulation disappears. Under this heading we may include the planes of junction between all epiphyses and the diaphyses to which they severally belong. The occipito-sphenoid (Fig. 288) and the petro-jugular articulations in the base of the skull provide other well-marked examples.

AMPHIARTHROSES—DIARTHROSES (MOVABLE JOINTS).

The leading features of this group are capability of **movement** and **permanence**. In very few instances do such joints ever become obliterated under normal conditions. Determining their permanence, and regulating the amount of possible movement, there is always more or less of interruption in the continuity of the structures which bind the osseous elements together. That is, there is always some evidence of a *cavum articulare* (joint cavity), although as a matter of course such interruption can never be so extensive as to entirely disassociate the articulating elements. Therefore in all movable joints a new class of structures is found, viz., ligamenta (the **ligaments**), by means of which continuity is maintained even when all the other uniting media have given place to an articular cavity. The further subdivision of this group is founded upon the amount of movement permissible, and the extent to which the articular cavity takes the place of the original continuous uniting medium. Thus we obtain the **amphiarthroses**, or partly movable, and the **diarthroses**, or freely movable.

An **amphiarthrosis** (Fig. 292) presents the following characteristics: (a) partial movement; (b) union by ligaments and by an interposed plate or disc of fibro-cartilage, in the interior of which there is (c) an incomplete or partial joint cavity, which may be lined by a rudimentary *stratum synoviale* (synovial membrane)

whose function it is to secrete a lubricating fluid, the **synovia** or joint-oil; (*d*) a plate of hyaline cartilage coating each of the opposing surfaces of the bones concerned. All the joints belonging to this group occur in the median plane of the body. It includes the symphysis pubis, the joints between the bodies of the vertebrae, and the joint between the manubrium sterni and the body of the sternum.

A **diarthrosis** (Fig. 291) is the most elaborate as well as the most complete form of articulation. It is characterised by (*a*) capability of movement which is more or less free in its range; (*b*) a reduction of the uniting structures to a series of retaining ligaments; (*c*) an articular cavity which is limited only by the surrounding ligaments; (*d*) the constant presence of **synovial membrane**; (*e*) **cartilago articularis** (hyaline encrusting cartilage) which clothes the opposed surfaces of the articulating bones. The majority of the joints in the adult belongs to this group. This series of joints has been subdivided into a number of minor sections, in order to emphasise the occurrence of certain well-marked structural features, or because of the particular nature of the movement by which they are characterised. Although in all diarthroses there is a certain amount of *gliding* movement between the opposed surfaces of the bones which enter into their formation, yet, when this gliding movement becomes their prominent feature, as in most of the joints of the carpus and tarsus, they are termed **arthrodia**. But bones may be articulated together so as to permit of movement in one, two, or more fixed axes of movement, or in modifications of these axes. Thus in **uniaxial joints** the axis of movement may lie in the longitudinal axis of the joint, in which case the **trochoid rotatory form** of joint results, as in the proximal and distal radio-ulnar articulations; or it may correspond with the transverse axis of the articulation, as in the elbow-joint and knee-joint, when the **ginglymus** or **hinge variety** results. If movement takes place about two principal axes situated at right angles to each other, as in the radio-carpal joint, the terms **ellipsoid** (**biaxial** or **condyloid**) are applied. Movements occurring about three principal axes placed at right angles to each other, or in modifications of these positions, constitute **multiaxial joints**, in which the associated structural peculiarities provide the alternative terms of **enarthrosis** or **ball-and-socket joints**.

FIG. 290.—DIAGRAM OF A DIARTHRODIAL JOINT.

STRUCTURES WHICH ENTER INTO THE FORMATION OF JOINTS.

The structures which enter into the formation of joints vary with the nature of the articulation. In every instance there are two or more skeletal elements, whether bones or cartilages, and in addition there are the uniting media, which are either simple or elaborate according to the provision made for rendering the joint more or less rigid, or capable of movement. We have already seen that the uniting medium in **synarthrodial joints** is a remnant of the common matrix, whether fibro-vascular membrane or hyaline cartilage, in which ossification has extended from separate centres. Among the **amphiarthroses** there is still extensive union between the opposing surfaces of the articulating bones, but the character of the uniting medium has advanced from the primitive embryonic tissue to fibrous and fibro-cartilaginous material, as well as hyaline cartilage. These, with very few exceptions, are permanent non-ossifying substances, such as may be seen between the opposing osseous surfaces of two vertebral bodies. The joint cavity, more or less rudimentary, is confined to the centre of the fibro-cartilaginous plate, and may result from the softening of imperfect cleavage of the central tissue. It may also present rudiments of a synovial membrane.

In the **diarthrodial group** the extensive cavity has produced great interruption in the continuity of the uniting structures which originally existed between the

bones forming such a joint. Ligaments have therefore additional importance in this group, for not only do they constitute the uniting media which bind the articulating bones together, but, to a large extent, they form the peripheral boundary of the joint cavity, although not equally developed in all positions. Thus, every diarthrodial joint possesses a fibrous or ligamentous envelope constituting the *fibrous stratum* of the **articular capsule**, which is attached to the adjacent ends of the articulating bones. For special purposes, particular parts of the fibrous stratum may undergo enlargement and thickening, and so constitute strong ligamentous bands, although still forming continuous constituents of the envelope.

The fibrous stratum is lined by a **stratum synoviale** (O.T. **synovial membrane**), the two strata constituting the **capsula articularis**. The synovial stratum is continued from the inner surface of the fibrous stratum to the surface of the intra-articular portion of each articulating bone. The part of the bone included within the joint consists of a "non-articular" portion covered by the synovial layer and an "articular" portion covered by encrusting hyaline cartilage. The latter provides the surface which comes into apposition with the corresponding area of another bone. In its general disposition the synovial layer may be likened to a cylindrical tube open at each end. This layer is richly supplied by a close network of vessels and nerves.

Certain diarthroses present intracapsular structures which may be distinguished as interarticular ligaments and articular discs and menisci (O.T. interarticular fibro-cartilages).

Ligamenta Interarticularia.—Interarticular ligaments extend between, and are attached to, non-articular areas of the intracapsular portions of the articulating bones. They usually occupy the long axis of the joint, and occasionally they widen sufficiently to form partitions which divide the joint-cavity into two compartments, *e.g.* the articulation of the heads of the ribs with the vertebral column, and certain of the costo-sternal joints.

Articular discs and menisci (O.T. interarticular fibro-cartilages) (Fig. 291) are more or less complete partitions situated between and separating opposing articular surfaces, and when complete they divide the joint cavity into two distinct compartments. By its periphery, a disc is rather to be associated with the articular capsule than with the articulating bones, although its attachments may extend to non-articular areas on the latter. Those found in the knee-joint are called **menisci**; those found in other joints are called **articular discs**.

Both interarticular ligaments and articular discs and menisci have their free surfaces covered by the synovial stratum.

Adipose tissue, forming pads of varying size, is usually found in certain localities within the joint, between the synovial stratum and the surfaces which it covers. These pads are soft and pliable, and act as packing material, filling up gaps or intervals in the joint. During movement they adapt themselves to

FIG. 291.—DIAGRAM OF A DIARTHRODIAL JOINT WITH ARTICULAR DISC DIVIDING THE JOINT-CAVITY INTO TWO COMPARTMENTS.

the changing conditions of the articulation.

In addition to merely binding together two or more articulating bones, ligaments perform very important functions in connexion with the different movements taking place at a joint. They do not appreciably lengthen under strains, and thus ligaments may act as inhibitory structures, and by becoming tense may restrain or check movement in certain directions.

Synovial strata, in the form of closed sacs termed **mucous** or **synovial bursæ**, are frequently found in other situations besides the interior of joints. Such bursæ are developed for the purpose of reducing the friction, (*a*) between the integument and certain prominent subcutaneous bony projections, as, for instance, the point of the elbow, or the anterior surface of the patella

(subcutaneous mucous bursæ); (b) between a tendon and some surface, bony or cartilaginous, over which it plays (subtendinous mucous bursæ); (c) between a tendon or a group of tendons and the walls of osteo-fascial tunnels, in which they play (*vaginæ mucosæ tendinum* or *mucous sheaths of tendons*). Subtendinous mucous bursæ are often placed in the neighbourhood of joints, and in such cases it not infrequently happens that there is a direct continuity between the bursa and the synovial stratum which lines the cavity of the joint through an aperture in the articular capsule.

THE DIFFERENT KINDS OF MOVEMENT AT JOINTS.

Reference has already been made to the existence of fixed axes of movement as a basis for the classification of certain forms of diarthrodial joints. Hence it is evident that the movements which are possible at any particular joint depend to a large extent upon the shape of its articular surfaces as well as upon the nature of its various ligaments. Therefore the technical terms descriptive of movements either indicate the directions in which they occur, or else the character of the completed movement.

In the great majority of articulations between short bones, the amount of movement is so restricted, and the displacement of the opposing articular surfaces so slight, that the term **gliding** sufficiently expresses its character.

A **gliding** movement of an extensive kind, for example that of the patella upon the femur, in which the movement largely resembles that of the tyre of a wheel revolving in contact with the ground so that different parts are successively adapted to each other, is called **co-aptation**.

Articulations between long bones, on the other hand, are usually associated with a much freer range of movement, with a corresponding variety in its character. **Rotation** is a movement around an axis which is longitudinal. Sometimes it is the only form of movement which a joint possesses; at other times it is merely one of a series of movements capable of execution at the same joint. **Flexion** or bending is a movement in which the formation of an angle between two parts of the body is an essential feature. As it is possible to perform this movement in relation to two axes, viz., a transverse and an antero-posterior axis, it is necessary to introduce qualifying terms. Thus, when two anterior or ventral surfaces are approximated, as at the hip-, elbow-, or wrist-joints, the movement is called **ventral**, **anterior**, or **palmar flexion**; but if posterior or dorsal surfaces are approximated by the process of bending, then the flexion becomes **posterior** or **dorsi-flexion**, as at the knee- or wrist-joints. Further, at the wrist-joint, the formation of an angle between the ulnar border of the hand and the corresponding aspect of the forearm, produces **ulnar flexion**, and similarly the bending of the hand towards the radial border of the forearm is **radial flexion**.

Extension or straightening consists in obliterating the angle which resulted from flexion. In the case of certain joints, therefore, such as the elbow, wrist, and knee, the segments of the limb occupy a straight line as regards each other when extended.

At the ankle-joint the natural attitude of the foot to the leg is flexion at a right angle. The diminution of this angle by approximating the dorsum of the foot towards the anterior aspect of the leg constitutes *flexion*; whilea ny effort at placing the foot and leg in a straight line, i.e. obliteration of the angle, as in pointing the toes towards the ground and raising the heel, constitutes *extension*.

Abduction is a term which either expresses movement of an entire limb, in a direction away from the median plane of the body, or of a digit, away from the plane of the middle finger in the hand, or the plane of the second toe in the case of the foot.

Adduction is the reverse of abduction, and signifies movement towards the median plane of the body, or towards the planes indicated for the digits of the hand and foot.

Circumduction is a movement peculiarly characteristic of multiaxial or ball-and-socket joints. It consists in combining such angular movements as flexion, extension, abduction, and adduction, so as to continue the one into the other, whereby the joint forms the apex of a cone of movement, and the free end of the limb travels through a circle which describes the base of this cone.

THE DEVELOPMENT OF JOINTS.

Just as the question of structure determines to a large extent the presence or absence of movement in joints, so in tracing their development it will be found that the manner of their appearance forecasts their ultimate destination as immovable or movable articulations.

All joints arise in mesodermic tissue which has undergone more or less differentiation.

When this differentiation has produced a continuous membranous layer, in which ossific centres representing separate skeletal segments make their appearance, we get the primitive form of suture. The plane of the articulation merely indicates the limit of the ossific process extending from different directions. If, again, the differentiation of the mesoblast has resulted in the formation of a continuous cartilaginous layer, in which ossification commences at separate centres, the plane of the articulation is marked out by the unossified cartilage—in other words, the articulation is a synchondrosis. Ultimately this disappears through the extension of the process of ossification.

To some extent sutures also disappear, although their complete obliteration is not usual even in aged people. Developmentally, therefore, synarthroses or immovable joints do not present any special structural element, and, speaking generally, they have only a temporary existence.

The development of all movable joints is in marked contrast to that of synarthroses. Not only are they permanent arrangements so far as concerns normal conditions, but they never arise merely as planes which indicate the temporary phase of an ossific process. From the outset they present distinct skeletal units, from which the special structures of the joint are derived.

The primitive movable joint is first recognised as a mass of undifferentiated mesodermic cells situated between two masses, which have differentiated into primitive cartilage.

The cell-mass which constitutes the joint-unit presents the appearance of a thick cellular disc, the proximal and distal surfaces of which are in accurate apposition with the primitive cartilages, while its circumference is defined from the surrounding mesoderm by a somewhat closer aggregation of the cells of which the disc is composed. From this cellular disc or joint-unit all the structures characteristic of amphiarthrodial and diarthrodial joints are ultimately developed.

Thus, by the transformation of the circumferential cells into fibrous tissue the investing ligaments are produced. Within the substance of the disc itself a transverse cleft, more or less well-defined and complete, makes its appearance. In this manner the disc is divided into proximal and distal segments, separated from each other by an interval which is the primitive articular cavity. This cleft, however, never extends so far as to interrupt the continuity of the circumferential part of the disc which develops into the fibrous tissue of the investing ligaments. From the proximal and distal segments of the articular disc the various structures, distinctive of movable joints, are developed.

Thus, in amphiarthrodial joints the cellular articular disc or primitive joint-unit gives origin to the following structures:—From its circumference, investing ligaments; from its interior, the fibro cartilaginous plate in which an imperfect articular cavity with corresponding imperfect synovial stratum may be found.

In the case of a diarthrodial joint the changes take place on a more extended scale. The articular cavity becomes a prominent feature, in relation to which the surrounding fibrous structures form an investing capsule, lined with a synovial stratum.

When a single cleft arises, but does not extend completely across the longitudinal axis of the articular disc, the undivided portion develops into fibrous interarticular ligaments. On the other hand, when two transverse clefts are formed, that portion of the cellular disc which remains between them becomes transformed into a fibro-cartilaginous disc (or in the case of the knee-joint, menisci), which in its turn may either be complete or incomplete, and thus we may obtain two distinct synovial joint cavities belonging to one articulation.¹

In considering the development of the synovial layer, and the surfaces on which it is found in the interior of a joint, it is necessary to keep clearly in mind that a synovial layer is a special structure, whose function it is to produce a lubricating fluid or synovia, and that, therefore, its position is determined by the essential necessity of proximity to a direct blood-supply. In other words, this condition is provided by all parts of

¹ From a series of observations upon the development of diarthrodial joints, the writer considers that there is evidence to show that the "cellular articular disc" is directly responsible for the production of the epiphyses which adjoin the completed articular cavity, and that, among such amphiarthroses as exist between the bodies of vertebrae, not only the intervertebral fibro-cartilage, but the proximal and distal epiphyses which ultimately unite with the vertebral bodies have a common origin in the joint-unit.

the interior of an articular cavity except the articular encrusting cartilage. Consequently the synovial stratum is absent only from the free surface of articular cartilage, although it forms a thicker layer upon the inner surface of the articular capsule than upon the free surfaces of interarticular ligaments, discs, and menisci.

It is not necessary to suppose that the synovial stratum has disappeared from these articular cartilages as the result of friction, because, notwithstanding constant friction, such parts as the interior of articular capsules or the menisci of the knee-joint have not been denuded of their synovial covering.

As the epiphyses adjoining articular cavities are produced in the joint-units, the attachments of the capsule should be found upon, and restricted to, the non-articular surfaces of the articular epiphyses. While this is the case in their earliest stages, yet, as development advances, considerable variations arise, until, in the adult condition, the capsule of the larger articulations, more particularly of the extremities, is not always restricted to the epiphyses for its attachments. The student will readily perceive and appreciate these variations by comparing the accounts and illustrations of the epiphyses with those of the articulations, and he should note that in some cases the epiphysial line is *extra-capsular*, i.e. the capsular attachment is restricted to the epiphysis; in some the line is *intra-capsular*; and in some the epiphysial line is partly intra-capsular and partly extra-capsular.

MORPHOLOGY OF LIGAMENTS.

From what has been said in connexion with the development of joints, it will be evident that ligaments are essentially products derived from the cellular articular disc.

Nevertheless, in relation to the fully formed joint, many structures are described as ligaments which do not take origin in the manner just indicated. Some of these ligamentous structures remain fairly distinct from the articular capsules with which they are immediately associated; others become thoroughly incorporated with the articular capsules and cannot be separated therefrom, while yet others may be found situated within the capsule of a joint, and thus play the part of interarticular ligaments.

Instances of each of these forms of adventitious ligaments may be readily given. For example, we may instance the expansion of the tendon of the semimembranosus muscle to the oblique ligament of the knee-joint, and the offshoots from the tendon of the tibialis posterior muscle to the plantar aspects of various tarsal bones, as illustrations of structures which play an important part as ligaments, but are not indelibly incorporated with the joint capsule.

Of structures which have become indelibly incorporated with the primitive capsule, we may instance the broad tendinous expansions of the quadriceps extensor muscle around the knee-joint.

The tibial collateral ligament of the same joint is regarded as a detached portion of the tendon belonging to that part of the adductor magnus muscle which takes origin from the ischium, while the fibular collateral ligament of the knee is considered by some to be the primitive femoral origin of the peronæus longus muscle. Another illustration of the same condition is found in the coraco-humeral ligament, which is regarded by some as representing a detached portion of the pectoralis minor muscle.

Two illustrations may be given of structures playing the part of ligaments within the capsule of a joint, although in the first instance they are not developed as ligaments. It is questionable if the ligamentum teres of the hip-joint is an interarticular ligament in the true sense of the term; it has been regarded as the isolated and displaced tendon of the *ambiens* muscle found in birds. In the shoulder-joint, many observers look upon the superior gleno-humeral ligament as representative of the ligamentum teres.

Such structures as the stylo-hyoid ligament and the speno-mandibular ligament, although described as ligaments, are in reality skeletal parts which have not attained their complete ossific development.

Again, certain portions of the deep or muscular fascia of the body which become specialised into restraining and supporting bands (e.g. the ilio-tibial tract of the fascia lata; the stylo-mandibular ligament; the transverse carpal and dorsal carpal ligaments of the wrist-joint; the transverse crural ligament, and lig. laciniatum of the ankle-joint), although called ligaments, have no direct developmental association with articular ligaments.

Lastly, the inguinal ligament of Poupart and the lacunar ligament of Gimbernat, being special developments in connexion with an expanded tendon or aponeurosis, are still further removed from association with an articulation.

LIGAMENTA COLUMNÆ VERTEBRALIS ET CRANII.

Ligaments of the Vertebral Column and Skull.—All vertebræ, with the exception of those which deviate from the common vertebral type, present two sets of articulations whose various parts are arranged upon a uniform pattern. Thus, every pair of typical vertebræ presents an articulation between the bodies, and a pair of articulations between the vertebral arches. With the latter there

are associated various important accessory ligaments which bind together laminae, spinous processes, and transverse processes.

Articulations between Bodies of Vertebrae.—These are amphiarthrodial joints. Singly, they present only a slight degree of mobility, but when this amount of movement is added to that of the whole series, the range of movement of the vertebral

FIG. 292.—MEDIAN SECTION THROUGH A PORTION OF THE LUMBAR PART OF THE VERTEBRAL COLUMN.

column becomes considerable. The articular surfaces are the flattened surfaces of adjacent vertebral bodies. They are bound together by the following structures:—

Fibrocartilagines Intervertebrales (Fig. 292).—Each intervertebral fibrocartilage accommodates itself to the space it occupies between the two vertebral bodies, to both of which it is firmly adherent. The fibro-cartilages, from different

FIG. 293.—ANTERIOR LONGITUDINAL LIGAMENT OF THE VERTEBRAL COLUMN, AND THE COSTO-VERTEBRAL JOINTS AS SEEN FROM THE FRONT.

parts of the vertebral column, vary in vertical thickness, being thinnest from the third to the seventh thoracic vertebra, and thickest in the lumbar region. In the cervical and lumbar regions each fibro-cartilage is thicker anteriorly than posteriorly, thereby assisting in the production of the anterior convexity which characterises the vertebral column in these two regions. In the thoracic region

the fibro-cartilages are thinnest on their anterior aspects in correspondence with the anterior concavity of this section of the vertebral column.

Each fibro-cartilage consists of a circumferential portions, **annulus fibrosus**, formed for the most part of oblique parallel fibres running from one vertebra to the other; horizontal fibres are also found. The axial or central part of the fibro-cartilage, the **nucleus pulposus**, is elastic, soft, and pulpy.

The superior and inferior surfaces of the fibro-cartilage are closely adherent to the adjoining epiphyseal plates of the vertebral bodies, and as ossification advances, the distinction between epiphyseal plates and vertebral body disappears.

As a rule the transverse diameter of the fibro-cartilage corresponds to that of the vertebral bodies which it joins together; but in the cervical region, where the inferior margin of the super-imposed vertebra is overlapped on each side by the one which bears it, the fibro-cartilage does not extend to the extreme lateral margin, and in this position a small diarthrosis may be seen at each lateral margin of the fibro-cartilage.

Lig. Longitudinale Anterius.—The anterior longitudinal ligament (O.T. anterior common ligament) (Fig. 293) consists of a wide stratum of longitudinal fibres which extends from the front of the epistropheus vertebra to the front of the superior segment of the sacrum, and becomes gradually wider from above downwards. It lies on the anterior surfaces of the intervertebral fibro-cartilages, to which it is firmly attached as it passes from one vertebra to the other. Its fibres vary in length. Some are attached to contiguous margins of two adjoining vertebræ; others pass in front of one vertebra to be attached to the next below, and yet others find their lower attachment three or four vertebræ below the one from which they started. None of the fibres are attached to the transverse depression on the anterior surface of a vertebral body.

Lig. Longitudinale Posterius.—The posterior longitudinal ligament (O.T. posterior common ligament) (Fig. 294) is found within the vertebral canal upon the posterior aspect of the vertebral bodies. It consists of longitudinal fibres, and it extends from the sacrum to the epistropheus vertebra, superior to which it is continued to the skull as the *membrana tectoria*. Opposite each intervertebral fibro-cartilage it is attached to the entire width of the adjacent margins of the two vertebral bodies, its fibres being continued over the posterior surface of the fibro-cartilage. In the lumbar and thoracic regions the width of the ligament is considerably reduced opposite the back of each vertebral body, and thus it forms a series of dentate projections along both of its margins; but in the cervical region the width of the ligament is more uniform. One or two large thin-walled veins escape from the body of each vertebra under cover of this ligament.

Articulations between Vertebral Arches.—The vertebral arch of each typical vertebra carries two pairs of articular processes, by means of which it articulates with adjacent vertebral arches. The articulations between these processes are true diarthroses of the arthrodial variety.

The distinctive characters of these articular surfaces, as regards their shape and direction in the different groups of vertebræ, have been referred to in the section on osteology.

All these articulations are provided with complete but very thin-walled **capsulæ articulares**, which are thinnest and loosest in the cervical region, where also the movements are freest. Each capsule is lined with a **stratum synoviale**.

Associated with these joints between vertebral arches are certain ligaments which are accessory to the articulations, although they are quite distinct from the capsule.

FIG. 294.—POSTERIOR LONGITUDINAL LIGAMENT OF THE VERTEBRAL COLUMN.

The laminae of adjoining vertebrae are bound together by the **ligamenta flava** (O.T. **subflava**) (Fig. 295), which consist of yellow elastic fibres. The ligamenta flava close the vertebral canal in the intervals between the laminae. Each ligament is attached superiorly to the anterior aspect of one lamina at a short distance above its inferior border, and inferiorly it is attached to the posterior aspect of the subjacent lamina.

In the thoracic region, where the imbrication of adjoining laminae is a prominent feature, these ligaments are not so distinctly visible from behind as they are in the regions where imbrication of the laminae is not so marked.

Laterally they extend as far as the articular capsules, while medially the margins of the ligaments of opposite sides meet under cover of the root of the spinous process.

Contiguous spinous processes are also attached to each other by **ligamenta interspinalia** (**interspinous ligaments**) (Fig. 292). These are strongest in the lumbar, and weakest in the thoracic region. Each consists of layers of obliquely interlacing fibres which spring from near the tips of the two adjacent spinous process

and radiate to their opposing margins. In the antero-posterior direction they extend from the base to the tip of the spinous process.

The **ligamenta supraspinalia** (**supra-spinous ligaments**) (Fig. 292) consist of longitudinal bands of fibres of varying lengths. They extend from spine to spine, being attached to their tips, and are situated superficial to, although in continuity with, the **ligamenta interspinalia**.

In the cervical region this series of ligaments is extensively developed, where they project backwards from the spinous processes between the muscles of the two sides of the neck in the form of an elastic partition called the **ligamentum nuchæ**.

FIG. 295.—LIGAMENTA FLAVA AS SEEN FROM THE FRONT AFTER REMOVAL OF THE BODIES OF THE VERTEBRÆ BY SAWING THROUGH THE ROOTS OF THE VERTEBRAL ARCHES.

The antero-posterior extent of the **ligamentum nuchæ** increases as it approaches the occiput, where it is attached to the external occipital crest from the external occipital protuberance to the posterior border of the foramen magnum. Its posterior margin is free, and extends from the external occipital protuberance to the spine of the vertebra prominens.

Between the transverse processes there are **ligamenta intertransversaria**, which consist of vertical fibres extending from the postero-inferior aspect of one transverse process to the superior margin of that next below. These ligaments are generally absent from the cervical and upper thoracic regions.

Sacro-coccygeal Symphysis.—The last piece of the sacrum is joined to the first piece of the coccyx by an intervertebral fibro-cartilage, and the junction is rendered more secure by the presence of certain strong ligaments. A **lig. sacro-coccygeum anterius**, continuous with the **lig. longitudinale anterius**, is placed in front. A **lig. sacro-coccygeum posterius**, which stretches downwards from the sharp border of the lower opening of the sacral canal, strengthens the joint behind. A

lig. sacrococcygeum laterale supports the joint on each side, whilst strong bands pass between the cornua of the two bones and constitute the **interarticular ligaments**.

Intercoccygeal Joints.—So long as they remain separate, the different pieces of the coccyx are joined by intervertebral fibro-cartilages and by anterior and posterior ligaments.

Movements of the Vertebral Column.—Although the amount of movement permissible between any two vertebræ is extremely limited, yet the total range of movement capable of being attained by the entire vertebral column is very considerable.

Flexion may occur both forwards and backwards at the articulations of vertebral bodies, but more freely in the lumbar and cervical regions than in the thoracic region, where the limited amount of intervertebral fibro-cartilage and the imbrication of the laminae and spines restrict the movement. Backward flexion is most pronounced in the cervical region, and forward flexion in the lumbar region. Between the articular surfaces of the articulations between vertebral arches a variety of movements are permitted, dependent upon the directions of these surfaces. Thus **lateral flexion** is permitted in the lumbar, but not in the cervical, or dorsal regions. Again, in the lumbar region **rotation** does not occur, owing to the shape of the articular processes, while it is possible in the thoracic region. In the cervical region the shape and position of the articular surfaces prevent the occurrence both of lateral flexion and of rotation as isolated movements, but a combination of these two movements may take place, whereby rotatory movement in an oblique median axis results. Finally, in the lumbar region, by combining the four forms of flexion, viz., forward, backward, and lateral, a certain amount of **circumduction** is possible.

ARTICULATIO ATLANTOEPISTROPHICA.

Between the atlas and epistropheus vertebræ three diarthroses occur. Two of them are situated laterally, in relation to the articular processes, and are called

FIG. 296.—MEDIAN SECTION THROUGH THE ATLANTO-OCIPITAL AND ATLANTO-EPISTROPHICAL JOINTS.

arthrodial diarthroses, because of the flattened nature of the articulating surfaces. The third articulation is median in position. It is found between the smooth anterior surface of the dens of the epistropheus and the articular facet on the posterior aspect of the anterior arch of the atlas. This joint is a rotatory diarthrosis.

Ligamenta.—Each of the joints is furnished with a **capsula articularis**, whereby the articular cavity is circumscribed. In the case of the lateral articulations, each articular capsule presents a distinct band, named the **accessory ligament**, which is situated within the vertebral canal (Fig. 297), and passes downwards and inwards from the lateral mass of the atlas to the superior aspect of the body of the epistropheus.

The following additional ligaments constitute the leading bonds of union:—

Lig. Obturatorium Atlantoepistrophica Anterior.—The anterior covering atlanto-epistropheal ligament (O.T. anterior atlo-axoid ligament) (Fig. 296) is a membranous structure which is thin laterally, but strong in the median plane, where it is thickened by a prolongation of the lig. longitudinale anterius. It extends from the anterior arch of the atlas to the front of the body of the epistropheus.

Lig. Obturatorium Atlantoepistrophica Posterior.—The posterior covering atlanto-epistropheal ligament (O.T. posterior atlo-axoid ligament) (Fig. 296) occupies the position which is elsewhere taken by the ligamenta flava. It extends from the posterior arch of the atlas to the upper border of the vertebral arch of the epistropheus.

Lig. Transversum Atlantis.—The transverse ligament of the atlas (Figs. 296 and 297) is a strong band, placed transversely, which arches backwards behind the neck of the dens of the epistropheus. By its extremities it is attached to the tubercle on the medial aspect of each lateral mass of the atlas. A thin plate of fibro-cartilage is developed in its central part.

A **stratum synoviale (synovial membrane)** lines each of the three articular capsules, and in addition a synovial sac is developed between the dens and the lig. transversum atlantis. This is more extensive than the synovial cavity between the dens and the atlas.

ARTICULATIO ATLANTO-OCCIPITALIS.

There are two articulations between the atlas and the occipital bone. Each is a diarthrosis in which movement takes place in relation to two axes, viz., the

FIG. 297.—DISSECTION FROM BEHIND OF THE LIGAMENTS CONNECTING THE OCCIPITAL BONE, THE ATLAS, AND THE EPISTROTHEUS WITH EACH OTHER.

transverse and the antero-posterior. The condyle of the occipital bone is bi-convex, and fits into the bi-concave superior articular surface of the atlas, while the long axes of the two joints are directed horizontally forwards and medially.

Ligamenta.—Each articulation is provided with a *capsula articularis* which is thin but complete. It is attached to the rough non-articular surfaces surrounding the articular areas on the atlas and occipital bone.

The following supplementary ligaments are the chief structures which bind the atlas to the occipital bone:—

The **membrana atlanto-occipitalis anterior (anterior occipito-atloid membrane)** (Fig. 296) is a strong although thin membrane, attached inferiorly to the anterior arch of the atlas, and superiorly to the anterior half of the circumference of the foramen magnum. Laterally it is in continuity with the articular capsules, while in the median plane, where it extends from the anterior tubercle of the atlas to the basilar part of the occipital bone, it presents a specially well-defined thickened band which might be regarded as a separate accessory ligament or as the beginning of the anterior longitudinal ligament of the vertebræ.

The **membrana atlanto-occipitalis posterior (posterior occipito-atloid membrane)** (Fig. 296) is another distinct but still thin membrane which is attached superiorly to the posterior half of the circumference of the foramen magnum, and inferiorly to the upper border of the posterior arch of the atlas. Laterally it also is continuous with the articular capsules. On each side of the median plane its inferior border

is arched in relation to the vertebral groove, and is therefore to some extent free, in order to permit the passage of the posterior ramus of the first cervical nerve and the vertebral artery. Not infrequently this arched border becomes ossified, thus converting the groove on the bone into a foramen.

A *synovial stratum* lines each of the articular capsules.

There is no direct articulation between the epistropheus and the occipital bone, but union between them is effected by means of the following accessory ligaments:—

The *membrana tectoria* (Fig. 296) is situated within the vertebral canal, and is usually regarded as the upward continuation of the posterior longitudinal ligament of the vertebral bodies. It extends from the posterior surface of the body of the epistropheus to the basilar groove on the superior surface of the basilar part of the occipital bone, spreading laterally on the circumference of the foramen magnum. Some of its deepest fibres are attached to the atlas immediately above the atlanto-epistropheal articulation.

Subjacent to the *membrana tectoria* there is the *ligamentum cruciatum atlantis* (Fig. 297), a structure which is very closely associated with the *lig. transversum atlantis*. It consists of a *crus transversum*, formed by the superficial fibres of the transverse ligament of the atlas; a *crus inferius*, consisting of median longitudinal fibres which are attached below to the posterior surface of the body of the epistropheus, and above to the *crus transversum*; and a *crus superius*, also median and longitudinal, whose fibres extend from the *crus transversum* upwards to the posterior surface of the basilar part of occipital bone, immediately subjacent to the *membrana tectoria*.

Ligamenta Alaria.—The alar ligaments (O.T. check ligaments) (Fig. 297) are two very powerful, short, and somewhat rounded bands. They are attached medially to the sides of the summit of the dens, and laterally to the tubercle on the medial aspect of the condylar portions of the occipital bone.

Ligamentum Apicis Dentis.—The ligament of the apex of the dens (O.T. middle odontoid) (Fig. 297) consists of fibres running vertically upwards from the apex of the dens to the median part of the anterior margin of the foramen magnum. This ligament to some extent represents an intervertebral fibro-cartilage, in the centre of which remains of the notochord may be regarded as present.

Even in advanced life a small lenticular mass of cartilage, completely surrounded by bone, persists in the plane of fusion between the dens and the body of the epistropheus.

Movements at these Joints.—At the joints between occipital bone and atlas the movements are very simple, and consist essentially of movements whereby the head is elevated and depressed upon the vertebral column (nodding movements). In addition a certain amount of oblique movement is possible, during which great stability is attained by resting the anterior and posterior parts of opposite condyles upon corresponding parts of the atlas.

The head and the atlas rotate together upon the epistropheus, the pivot of rotation being the dens, and the amount of rotation is limited by the *ligamenta alaria*. No rotation can occur between the occiput and atlas, and stability between atlas and epistropheus is best attained after a slight amount of rotation, similar to the oblique movement between occipital bone and atlas.

FIG. 298.—MANDIBULAR JOINT.

ARTICULATIO MANDIBULARIS.

The mandibular joint (O.T. **temporo-mandibular**) is an arthrodial **diarthrosis**. It occurs between the mandibular fossa of the temporal bone and the condyle of the mandible. These two articular surfaces are markedly dissimilar both in size and shape. In its general outline the articular surface of the head of the

mandible is cylindrical, having its long axis directed from the medial side laterally and forwards. On the other hand, the mandibular fossa is concavo-convex from behind forwards. Its articular surface includes the tuberculum articulare—the eminence at the base of the anterior root of the zygoma. The articular surfaces of the bones are clothed with hyaline encrusting cartilage, whilst the articular cavity is divided into a superior and inferior part by a disc of fibro-cartilage.

Ligaments.—The joint is invested by an **articular capsule** which is quite complete, but is very thin on the medial side. The lateral part of the fibrous stratum of the capsule—the **temporo-mandibular liga-**

FIG. 299.—SECTION THROUGH THE MANDIBULAR JOINT.

ment (O.T. **external lateral**) (Fig. 298)—is divisible into anterior and posterior portions which are attached superiorly to the root tubercle and inferior border of the zygomatic process of the temporal bone, and inferiorly to the lateral side and posterior border of the neck of the mandible. The direction of its fibres is downwards and backwards.

Within the capsule there is a disc of fibro-cartilage, the **discus articularis** (Fig. 299), which is moulded upon the condyle of the mandible below, and on the articular surface of the temporal bone above. It thus compensates for the incongruity between the articular surfaces of the two bones. The disc is attached circumferentially to the capsule. It is widest in the transverse direction, thicker posteriorly than anteriorly, and thinnest towards the centre, where it may be perforated. Its anterior margin is intimately associated with the insertion of the external pterygoid muscle.

A **synovial stratum** lines each of the compartments into which the joint cavity is divided by the disc. As a rule these membranes are separate from each other, but they become continuous when the disc is perforated. The superior synovial stratum is larger and more loosely disposed than the lower.

Situated on the medial aspect of the joint, but at a short distance from it, and quite distinct from the capsule, there is an accessory band called the **lig. sphenomandibulare** (Fig. 300). Superiorly the **spheno-mandibular ligament** (O.T. **internal lateral**) is attached to the angular spine of the sphenoid bone, and inferiorly to the inferior as well as the posterior border or lingula of the inferior alveolar foramen. It is not an articular ligament in the true sense; for, instead of being connected with the joint, it is developed in the tissue surrounding part of Meckel's cartilage.

FIG. 300.—SPHENO-MANDIBULAR LIGAMENT OF THE MANDIBULAR JOINT.

Portions of the following structures are found in the interval between the speno-mandibular ligament and the ramus of the mandible—viz., the external pterygoid muscle; internal maxillary vessels; inferior alveolar vessels and nerve; middle meningeal vessels; auriculo-temporal nerve; and sometimes a deep portion of the parotid gland.

Movements of the Mandible.—The nature of the movements which the mandible can perform is determined partly by the character of the articular surfaces of the mandibular joint, and partly by the fact that, while the two joints always act simultaneously, they may also, to some extent, perform the same movement alternately.

When movement takes place through the long or transverse horizontal axis of each joint, the mandible may be elevated, as in clenching the teeth, or it may be depressed, as in gaping. In the latter movement the condyle leaves the mandibular fossa, and, along with the disc, it moves forwards until they rest upon the tuberculum articulare. Meantime the chin describes the arc of a circle, of which the centre or point of least movement corresponds to the position of the inferior alveolar foramen, and thus the structures which enter at that foramen are protected against stretching. Coincidentally with the forward movement of the condyle, it glides in a revolving manner upon the inferior aspect of the disc.

At any stage in the movement of depressing the chin the mandible may be protruded, so that the inferior incisor teeth are projected in front of the upper set, a movement which results from the condyles of the mandible being drawn forwards upon the articular tubercles. A similar relation of the condyle to the articular tubercle occurs during the exaggerated depression of the mandible which results from yawning, in which position the articulation is liable to be dislocated. When the two joints perform the same movement alternately, a certain amount of lateral motion results, from the fact that the long axis of each joint presents a slight obliquity to the transverse axis of the skull, and consequently a grinding or oblique movement in the horizontal plane is produced. Excessive depression, with the risk of dislocation, is resisted by the fibres of the temporo-mandibular ligament, which becomes tense.

In all movements of the mandible the disc conforms closely to the position of the condyle, and they move forwards and backwards together, but at the same time the disc does not restrict the movements of the condyle. Thus while the disc, along with the condyle, is gliding upon the temporal aspect of the joint, the condyle itself revolves upon the inferior surface of the disc.

CRANIAL LIGAMENTS NOT DIRECTLY ASSOCIATED WITH ARTICULATIONS.

Lig. Stylomandibulare.—The stylo-mandibular ligament (Figs. 298 and 300) is a specialised portion of the deep cervical fascia which extends from the anterior aspect of the tip of the styloid process of the temporal bone to the posterior border of the angle of the mandible, between the insertions of the masseter and internal pterygoid muscles.

Lig. Pterygospinosum.—The pterygo-spinous ligament is a membrane extending from the upper part of the posterior free margin of the lateral pterygoid lamina, posteriorly and slightly laterally, to the angular spine of the sphenoid. An interval is left between its upper border and the floor of the skull for the outward passage of those branches of the inferior maxillary nerve which supply the external pterygoid, temporal, and masseter muscles. This ligament has a tendency to ossify either wholly or partially.

Lig. Stylohyoideum.—The stylo-hyoid ligament may be regarded as the downward continuation of the styloid process of the temporal bone. Inferiorly it is attached to the lesser cornu of the hyoid bone. It is not infrequently ossified, in which case it constitutes the epihyal bone found in many animals.

THE JOINTS OF THE THORAX.

Articulationes Costovertebrales (Costo-vertebral Articulations).—The typical rib articulates with the vertebral column both by its head and by its tubercle. Thus, two sets of articulations, with their associated ligaments, exist between the ribs and the vertebræ, but each set is constructed upon a common plan, with the exception of certain joints situated at the upper and lower ends of the series, where the ribs themselves deviate from the typical form.

ARTICULATIONES CAPITULORUM.

The articulations of the heads of the ribs with the bodies of the vertebræ (Fig. 293) are all diarthroses, which, from their somewhat hinge-like action, may be classed as ginglymoid.

The head of every typical rib is wedge-shaped, and presents two articular facets, an upper and a lower, separated from each other by an antero-posterior ridge which abuts against an intervertebral fibro-cartilage, while the articular facets articulate with similar surfaces on the contiguous margins of the two vertebræ adjoining the fibro-cartilage. These surfaces form a wedge-shaped depression or cup, the bottom of which is more elastic than the sides, and thus an arrangement is provided which tends to reduce the shock of blows upon the walls of the chest.

Each of these articulations is provided with an articular capsule which surrounds and encloses the joint, and is attached to contiguous non-articular margins on the head of the rib and the two vertebral bodies. On its anterior or ventral aspect the capsule presents three radiating fasciculi which collectively form the *lig. capituli costæ radiatum* (radiate ligament of the head of the rib (O.T. stellate)) (Fig. 293). These fasciculi radiate from a centre on the anterior surface of the head of the rib, so that the middle fasciculus becomes attached to the intervertebral fibro-cartilage while the upper and lower fasciculi proceed to the adjacent margins of the two vertebræ between which the fibro-cartilage is situated, and with which the rib articulates. To a slight extent these radiating fasciculi pass under cover of the lateral margin of the anterior longitudinal ligament of the vertebral bodies. In those joints in which the head of the rib does not articulate with an intervertebral fibro-cartilage the central fasciculus of the radiate ligament is wanting, but the other two retain the same general arrangement.

Lig. Capituli Costæ Interarticulare.—The interarticular ligament of the head of the rib consists of short transverse fibres within the capsule. These are attached, on the one hand, to the ridge which intervenes between the two facets on the head of the rib, and on the other to the lateral aspect of the intervertebral fibro-cartilage. This ligament is not a disc or meniscus, but merely an interarticular ligament, of width sufficient to divide the joint cavity into an upper and a lower compartment. It is absent from those joints which do not articulate with an intervertebral fibro-cartilage, *i.e.* from those ribs which articulate with the body of only one vertebra.

The interarticular ligament is supposed to represent the lateral end of a ligament which, under the name of the *lig. conjugale costarum*, connects the heads of the ribs of certain mammals across the posterior aspect of the intervertebral fibro-cartilage, and, in the human subject, until the seventh month of fetal life, connects the posterior aspects of the necks of a pair of ribs with each other across the median plane.

A *stratum synoviale* lines each joint cavity, and therefore, in all cases where the joint is divided into two compartments, each one has its own synovial lining.

ARTICULATIONES COSTOTRANSVERSARIÆ.

In the *costo-transverse* joints the tubercle of each *typical* rib articulates with the transverse process of the lower of the two thoracic vertebræ with which the head of the rib is associated. Near the tip of the transverse process there is an articular facet, on its anterior aspect, for articulation with the corresponding facet on the medial articular part of the rib tubercle. The joint so formed is an arthrodial diarthrosis.

The joint cavity is surrounded by a comparatively feeble *capsula articularis*, which is attached immediately beyond the margins of the articular facets, and in which no special bands can be distinguished.

A simple *stratum synoviale* lines the capsule in all cases where the latter is present.

The following accessory ligaments, in connexion with this joint, strengthen and support the articulation :—

Ligamentum Costotransversarium Anterius.—The anterior *costo-transverse* ligament (O.T. superior) (Fig. 293) consists of strong bands of fibres which are attached to the superior border of the neck of the rib, extending from the head laterally to the non-articular part of the tubercle. All these fibres may be traced upwards. Those situated nearest to the head of the rib proceed obliquely upwards and laterally, to be attached to the transverse process immediately above, but with

extensions to the adjoining rib and its costo-transverse articular capsule. Others proceed almost vertically upwards to the adjoining transverse process, while those which ascend from the upper surface of the tubercle pass obliquely upwards and inwards to reach the postero-inferior aspect of the adjoining transverse process. Some posterior fibres connected with the transverse process at its junction with the lamina are called the **posterior costo-transverse ligament**.

Lig. Tuberculi Costæ.—The ligament of the tubercle of the rib is a band of transverse fibres applied to the postero-lateral aspect of the capsule. By one end these fibres are attached to the tip of the transverse process behind its articular facet, and by the other to the external rough surface of the tubercle of the rib.

Lig. Colli Costæ.—The ligament of the neck of the rib (O.T. middle costo-transverse ligament) consists of short fibres which stretch from the posterior aspect of the neck of the rib, backwards and medially, to the anterior aspect of the transverse process, but, in addition, a proportion of the fibres passes to the posterior aspect of the inferior articular process of the upper of the two vertebræ with which the head of the rib articulates.

The following exceptions to the general plan of rib-articulation indicated above must be noted:—

1. There is no articulation between the eleventh and twelfth ribs and the transverse processes of the corresponding vertebræ.
2. The anterior costo-transverse ligament is wanting from the first rib, and is either rudimentary or wanting in the case of the twelfth rib.
3. The lig. colli costæ is rudimentary in the eleventh and twelfth ribs.

The **ligamentum lumbocostale** extends from the inferior surface of the base of the transverse process of the first lumbar vertebra to the inferior surface of the neck of the twelfth rib, as well as to the inferior surface of the transverse process of the twelfth thoracic vertebra.

ARTICULATIONES COSTOCHONDRALES.

Each rib possesses an unossified portion, termed its costal cartilage. As age advances, this cartilage may undergo a certain amount of superficial ossification, but it never becomes entirely transformed. The line of demarcation between bone and cartilage is clear and abrupt, and usually the bone forms an oval cup, in which the end of the cartilage is retained by means of the continuity which exists between the periosteum and the perichondrium. There is no articulation in the proper sense between the rib and its cartilage, although a synovial cavity has occasionally been found between the first rib and its cartilage.

ARTICULATIONES INTERCHONDRALES.

Interchondral joints are arthrodial diarthroses, and they are found between adjoining margins of certain of the costal cartilages, viz., from the fifth to the eighth or ninth. The cartilages which thus articulate develop flattened, somewhat conical, prolongations of their substance, and thereby the intercostal spaces are interrupted where these flat articular facets abut against each other. Each joint is closed by a surrounding **articular capsule**, the superficial and thoracic aspects of which are specially strengthened by **external** and **internal interchondral ligaments**. These bands extend obliquely between adjacent cartilages.

A **stratum synoviale** lines each joint capsule.

ARTICULATIONES STERNOCOSTALES.

The upper seven pairs of costal cartilages, as a rule, extend to the lateral margins of the sternum to form **sterno-costal joints**. Of these, the *first pair* is implanted directly upon the manubrium sterni. The ossific process ends abruptly in connexion with the rib, and also ceases as suddenly in connexion with the sternum, and hence the cartilage does not normally present an articulation at either end. From the *second to the seventh* pairs of ribs inclusive, the sterno-costal joints are constructed upon the type of arthrodial diarthroses, although, in the case

of the sixth and seventh cartilages, the joint cavity is always small, and is frequently obliterated.

The sternal end of each of these costal cartilages presents a slight antero-posterior ridge which fits into a shallow V-shaped depression upon the lateral margin of the sternum. With the exception of the sixth cartilage, they articulate opposite the lines of union between the primary segments of the sternum; the sixth articulates upon the side of the lowest segment of the body of the sternum.

Each joint is enclosed by a **capsula articularis**, the fibrous stratum of which is attached to the adjacent borders of the articulating elements. Specially strong fibres distinguish the superficial and deep aspects of the capsule.

The **lig. sternocostale radiatum** (O.T. **anterior costo-sternal ligament**) (Fig. 301) is composed of strong fibres which radiate from the anterior surface of the costal cartilage, near its sternal end, to the front of the sternum. The ligaments of opposite sides interlace with each other, and so cover the front of the sternum with a felted membrane—the **membrana sterni**.

FIG. 301.—STERNO-CLAVICULAR AND STERNO-COSTAL JOINTS.

The **lig. sternocostale posterius** (posterior costo-sternal ligament)—also a part of the capsule—has attachments similar to the foregoing, but the arrangement of its fibres is not so powerful.

The **ligamentum costoxiphoideum** passes from the front of the upper part of the xiphoid process, obliquely upwards and laterally to the front of the seventh, and sometimes to the front of the sixth costal cartilage.

Within the capsules of these joints **ligamenta sternocostalia interarticularia** (interarticular ligaments) (Fig. 301) may be found. Their disposition is somewhat uncertain, for whereas, in the case of the second pair of cartilages, they invariably divide the joint cavity into two distinct compartments—an upper and a lower—such an arrangement is very uncertain in the other joints, and they occasionally, especially in the cases of the sixth and seventh cartilages, entirely obliterate the joint cavity. These ligaments extend horizontally between the ends of the costal cartilages and the side of the sternum.

The **stratum synoviale** is found wherever a joint cavity is developed, and therefore there may be one or two synovial strata, according to the presence or absence of a proper interarticular ligament. When the joint cavity is obliterated by the fibrous structure which represents the interarticular ligament, a synovial stratum is also absent.

ARTICULATIONES STERNI.

Primarily the sternum consists of an elongated plate of hyaline cartilage, which becomes subdivided into segments by the process of ossification.

The four segments of which the body of the sternum is originally composed unite with each other after the manner of typical synchondroses.

Similarly the xiphoid process and the body ultimately become united. It is not usual to find the joint between the manubrium and the body obliterated by the ossification of the two bony segments. Even in advanced life it remains open, and the joint, which is named the **synchondrosis sternalis**, partakes of the nature of an amphiarthrosis (Fig. 301), although a joint cavity is not found under any circumstances in the plate of fibro-cartilage which intervenes between the manubrium and the body of the sternum.

The **membrana sterni**, to which reference has already been made, assists in strengthening the union between the different segments of the sternum.

Movements of the Ribs and Sternum.—These movements may be considered either independently of, or as associated with, respiration.

In the former condition the ribs move in connexion with flexion and extension of the vertebral column, being more or less depressed and approximated in the former, and elevated or pulled apart in the latter case. Considered in connexion with respiration, it is necessary to observe that, to all intents and purposes, the vertebral column and the sternum are rigid structures. Next, we must remember that the heads of all the ribs occupy fixed positions, and similarly the anterior ends of seven pairs of cartilages are fixed to the lateral margins of the sternum. The ribs thus form arches, presenting a large amount of obliquity from behind forwards. Therefore, during inspiration, when the rib is elevated, the arch becomes more horizontal, and the transverse diameter of the chest is increased. At the same time, the anterior ends of the sternal ribs tend to thrust the sternum forwards and upwards; but the nature of the attachment of the first pair of ribs to the sternum, as well as the attachment of the diaphragm to the xiphoid process, prevents this movement from becoming excessive, and hence the sternum becomes a line of resistance to the forward thrust of the ribs. As a consequence, the ribs rotate upon themselves about an oblique axis which passes downwards, laterally, and posteriorly through the capitular joint and the neck of the rib anterior to the costo-transverse joint.

In this way increase, both of the antero-posterior and transverse diameters of the thorax, is provided for, although the amount of increase is not equally pronounced in all planes. Thus at the level of the first rib very little eversion is possible, because the axis of rotation is nearly transverse, and therefore any increase in the transverse or antero-posterior thoracic diameters at this level may be disregarded, although a certain amount of elevation of the manubrium sterni and anterior end of the first rib is evident.

Below the level of the sixth rib elevation and rotation of the rib during inspiration are usually said to be complicated by a certain amount of backward movement, due to the character of the costo-transverse joint, until, in the case of the last two ribs, which are destitute of costo-transverse joints, a movement backwards is almost entirely substituted for elevation. It is probable, however, that the movements of the asternal ribs exactly correspond to those of the sternal series, and that by the contraction of the costal digitations of the diaphragm the anterior ends of the false ribs are provided with fixed positions comparable to those supplied by the sternum to the ribs of the sternal series.

We may therefore say that during inspiration the ribs move upwards and laterally between their fixed ends, while as a whole the rib rotates, and its anterior end is thrust slightly forwards.

During expiration these movements are simply reversed.

THE ARTICULATIONS OF THE SUPERIOR EXTREMITY.

The bony arch formed by the clavicle and scapula articulates directly with the axial skeleton only at one point, viz., the sterno-clavicular joint.

ARTICULATIONS OF THE CLAVICLE.

ARTICULATIO STERNOCLAVICULARIS.

The **sterno-clavicular joint** is an example of an arthrodial diarthrosis. The articular surfaces concerned in its formation present the following appearances:—

1. The sternal end of the clavicle is somewhat triangular in outline, having its most prominent angle directed inferiorly and posteriorly. The anterior and

posterior sides of the triangle are slightly roughened for the attachment of ligaments, while the base or inferior side is smooth and rounded, owing to the prolongation of the articular surface to the inferior aspect of the bone. In the antero-posterior direction the articular surface tends to be concave, while vertically it is slightly convex.

2. An articular facet, situated on the superior lateral angle of the manubrium sterni, but in a plane slightly behind the supra-sternal notch, articulates with the clavicle. This facet is considerably smaller than the clavicular facet with which it articulates.

3. The superior surface of the first costal cartilage close to the sternum also participates to a small extent in the articulation.

It should be noted that the articular surfaces of the clavicle and sternum are covered mainly by *fibro-cartilage*.

A *capsula articularis* is well marked on all sides except inferiorly, where it is very thin. The epiphyseal line of the clavicle is intra-capsular.

Lig. Sternoclaviculare Anterius.—The *anterior sterno-clavicular ligament* (Fig. 301) forms part of the fibrous stratum of the articular capsule, and consists of short fibres which extend obliquely inferiorly and medially from the anterior aspect of the sternal end of the clavicle to the adjoining anterior surface of the sternum and the anterior border of the first costal cartilage.

Lig. Sternoclaviculare Posterius.—The *posterior sterno-clavicular ligament* also forms part of the fibrous stratum of the capsule, and consists of similarly disposed, but not so strong as the anterior ligament, oblique fibres situated on the posterior aspect of the articulation.

Discus Articularis.—A *fibro-cartilaginous articular disc* (Fig. 301) divides the joint cavity into two compartments. It is nearly circular in shape, and adapts itself to the articular surfaces between which it lies. It is thickest at the circumference and thinnest at the centre, where it occasionally presents a perforation, thereby permitting the two synovial cavities to inter-communicate. By its circumference it is in contact with, and adherent to, the surrounding capsule, but its superior margin is attached to the apex of the articular surface of the clavicle, while by its inferior margin it is fixed to the sternal end of the first costal cartilage.

Two *accessory ligaments* are associated with this joint, viz., the *interclavicular* and the *costo-clavicular*.

Lig. Interclaviculare.—The *interclavicular ligament* (Fig. 301) is a structure of considerable strength, forming a broad band of fibrous tissue which is attached to the superior rounded angle or apex of the sternal end of the clavicle as well as to the adjacent margins of the articular surface. Its fibres pass across the interclavicular notch to become attached to corresponding parts of the opposite clavicle, but in their course they dip down into the supra-sternal notch, in which many of them are fixed to the sternum. In this way their presence neither bridges nor obliterates the notch between the two clavicles, and the ligament really becomes a superior sterno-clavicular ligament for each joint.

Lig. Costoclaviculare.—The *costo-clavicular ligament* (Fig. 301) consists of short, strong fibres which are attached inferiorly to the superior surface of the first costal cartilage. They pass obliquely upwards, laterally and posteriorly, to a rough impression situated on the inferior aspect of the sternal end of the clavicle, and are distinct from the articular capsule. Occasionally a bursa is found in the interior of this ligament.

As a rule there is a *synovial stratum* lining each of the two joint cavities (Fig. 301), separated from each other by the articular disc. Sometimes, however, the two membranes establish continuity through a perforation in the disc.

ARTICULATIO ACROMIOCLAVICULARIS.

The *acromio-clavicular joint* is another instance of an arthrodial diarthrosis. It is situated between the acromial end of the clavicle and the medial aspect of the acromion. Each articular surface is an oval, flattened facet, covered with *fibro-cartilage*.

The **ligaments** which surround this small joint form a complete articular capsule, of which the superior and inferior parts are specially strong, and are therefore named the **superior and inferior acromio-clavicular ligaments** (Fig. 303). These consist of short fibres passing between the adjacent rough margins of the two bones in the positions indicated by their names.

An **articular disc**, which is nearly always incomplete, and may occasionally be wanting, is usually found within the joint cavity, where it lies obliquely, with its superior margin farther from the median plane than its inferior margin, and having its borders attached to the surrounding capsule. Frequently the disc is wedge-shaped, with its base directed upwards and its apex free.

A **synovial stratum** is found forming either a single or a double sac, according to the condition of the disc. Complete division of the joint cavity, however, is rare.

Ligamentum Coracoclaviculare.—Accessory to this articulation there is the strong **coraco-clavicular ligament** which binds the acromial end of the clavicle to the coracoid process of the scapula. It is readily divisible into two parts, viz., lig. conoideum and the lig. trapezoideum.

The **conoid ligament** (Fig. 303) is situated medial to and slightly posterior to the trapezoid. It is narrow and pointed at its inferior end, by which it is attached to the superior aspect of the coracoid process, in close proximity to the scapular notch. Its superior end widens out in the manner expressed by its name, and is attached to the coracoid tuberosity of the clavicle.

The **trapezoid ligament** (Fig. 303) is attached inferiorly to the superior surface of the posterior half of the coracoid process, lateral and anterior to the attachment of the conoid ligament. Superiorly it is attached to the ridge on the inferior surface of the acromial end of the clavicle. Its lateral and medial borders are free. Its anterior surface is principally directed upwards, and its posterior surface, to a similar extent, looks downwards.

A **mucous or synovial bursa** usually occupies the re-entrant angle between these two ligaments.

Movements at the Clavicular Joints.—The movements of the medial end of the clavicle at the **sterno-clavicular joint** are limited in their range, owing to the tension of the ligaments. When the shoulder is raised or depressed the acromial end of the clavicle moves upwards and downwards, whilst its sternal end glides upon the surface of the articular disc; when, on the other hand, the shoulder is carried forwards or backwards, the sternal end of the clavicle along with the articular disc moves upon the sternal facet. In addition to these movements of elevation, depression, forward movement and backward movement of the clavicle, there is also allowed at the sterno-clavicular joint a certain amount of circumduction of the clavicle.

The part which is played by certain of the ligaments in restraining movement requires careful consideration. The **costo-clavicular ligament** checks excessive elevation of the shoulder, and restrains within certain limits both backward and forward movement of the clavicle. When the clavicle is depressed, as in cases where a heavy weight, such as a bucket of water, is carried in the hand, it receives support by resting upon the first rib, and the tendency for the medial end of the bone to start up out of its sternal socket is obviated by the tension of the articular disc, the **interclavicular ligament**, and the **anterior and posterior sterno-clavicular ligaments**.

The **articular disc** not only acts as a cushion which lessens the shock of blows received upon the shoulder, but it also acts as a most important bond of union, and prevents the medial end of the clavicle from being driven upwards upon the top of the sternum when force is applied to its lateral end.

The movements at the **acromio-clavicular joint** are of such a kind as to allow the inferior angle, and to some extent the vertebral border of the scapula, to remain more or less closely applied to the chest-wall during the various movements of the shoulder. The strong connexion between the coracoid process and the acromial end of the clavicle, by means of the conoid and trapezoid ligaments, renders it necessary that the scapula should follow the clavicle in its various excursions. The presence of the acromio-clavicular joint, however, enables the scapula to change its position somewhat with reference to the clavicle as the shoulder is moved. Thus, when the shoulder is raised and depressed, a marked difference takes place in the angle between the two bones; again, when the shoulder is thrown forwards or backwards, these movements can be performed without altering in a material degree the direction of the glenoid cavity of the scapula, or in other words, the socket of the shoulder-joint.

The **conoid and trapezoid ligaments** set a limit upon the movements of the scapula at the acromio-clavicular joint. They both, but more particularly the trapezoid ligament, prevent the acromion from being carried medially below the lateral end of the clavicle when blows fall upon the lateral aspect of the shoulder.

LIGAMENTS OF THE SCAPULA.

These ligaments are not directly connected with any articulation.

Lig. Coracoacromiale.—The coraco-acromial ligament (Fig. 302) completes the arch between the coracoid process and the acromion, and thus provides a secondary socket for the greater protection and security of the shoulder-joint. It is a flat triangular structure stretched tightly between its lines of attachment. By its base it is fixed to a varying amount of the postero-lateral border of the coracoid process, and by its narrower apical end to the tip of the acromion, immediately lateral to the acromio-clavicular joint. Its surfaces look upwards and downwards, and its free borders laterally and medially. It is thinnest in the centre, where it is sometimes perforated by a prolongation of the tendon of the pectoralis minor muscle.

Lig. Transversum Scapulæ Superius.—The superior transverse scapular ligament (O.T. suprascapular ligament) is a distinct but short flat band which bridges the scapular notch. It may be continuous with the conoid ligament, and it is frequently ossified. As a rule the foramen completed by this ligament transmits the supra-scapular nerve, while the transverse scapular vessels pass superior to the ligament to reach the supraspinous fossa.

A small duplicate of this ligament may often be found bridging the foramen on its costal aspect, subjacent to which small branches of the transverse scapular artery return from the supraspinous to the subscapular fossa.

Lig. Transversum Scapulæ Inferius.—The inferior transverse scapular ligament (O.T. spino-glenoid ligament) consists of another set of bridging fibres which are situated on the posterior aspect of the neck of the scapula. By one end they are attached to the lateral border of the scapular spine, and by the other to the adjacent part of the posterior aspect of the head of the scapula. The suprascapular nerve and the transverse scapular vessels pass subjacent to this ligament.

ARTICULATIO HUMERI.

The **shoulder-joint** is one of the largest as well as the most important of the joints of the upper limb. It is an example of the enarthrodial, *i.e.* ball-and-socket, variety of a diarthrosis, and, at the cost of a certain amount of security, it has obtained an extended range of movement.

The bones which enter into its formation are the glenoid cavity of the scapula and the head of the humerus.

The glenoid cavity is a shallow piriform articular surface, having its narrow end directed upwards and slightly forwards. The superior half of the anterior margin of the fossa is characterised by a shallow notch which accommodates the narrow part of the subscapularis muscle as it runs laterally to its insertion. At the apex of the cavity there is a flat area for the attachment of the long tendon of the biceps brachii muscle. The head of the humerus is hemispherical and articular, while, lateral to its articular margin, there is a slight constriction (the anatomical or true neck of the humerus), which is most strongly marked in relation to the greater and lesser tubercles of the humerus.

Under ordinary conditions the two articular surfaces are maintained in apposition by muscular action, aided by atmospheric pressure, and thus, when the muscles are removed, the bones fall asunder to the full extent of the restraining ligaments. Only a small part of the head of the humerus is in contact with the glenoid cavity at any particular moment, because the humeral head is much larger than the cavity, but, by reason of the shallow character of the cavity, all parts of the two articular surfaces may successively be brought into contact with each other.

In the position of rest, as the limb hangs parallel to the vertical axis of the trunk, the inferior aspect of the neck of the humerus is brought into close relation with the inferior part of the glenoid cavity.

Labrum Glenoidale.—The labrum glenoidale (O.T. glenoid ligament) (Fig. 303) deepens the glenoid cavity, and thus extends the articular surface. It is situated within the fibrous stratum of the articular capsule, and to some slight extent increases the security of the articulation. It consists of a strong ring of dense fibrous

tissue attached to the free margin of the glenoid cavity. Many of its fibres are short, and pass obliquely from the inner to the outer aspect of the ridge, so that its attached base is broader than its free edge, and therefore in cross section it appears somewhat triangular. The long tendon of the biceps, which arises from the apex of the glenoid cavity, becomes to a considerable extent incorporated with the labrum glenoidale.

Capsula Articularis.—The fibrous stratum (O.T. capsular ligament) (Fig. 302) of the articular capsule presents the general shape which is characteristic of the corresponding part in other ball-and-socket joints, viz., a hollow cylinder. By its proximal end the fibrous stratum is attached to the circumference of the glenoid cavity, external to the labrum glenoidale, and also, to a considerable extent, to the labrum glenoidale itself.

By its distal end it is attached to the neck of the humerus, and therefore beyond the articular area of the head. The fibrous stratum is strongest on its superior aspect, while inferiorly, where the neck of the bone is least defined, it

FIG. 302.—CAPSULE OF THE SHOULDER-JOINT AND CORACO-ACROMIAL LIGAMENT.

extends distally for a short distance upon the humeral shaft. Its fibres for the most part run longitudinally, but a certain number of them pursue a circular direction.

The greater part of the epiphyseal line of the proximal end of the humerus is extra-capsular, but it is intra-capsular on the medial side of the bone.

A prolongation of the fibrous stratum, the **transverse humeral ligament** presenting both longitudinal and transverse fibres, bridges that part of the intertubercular groove which is situated between the tubercles of the humerus. At this point an interruption in the fibrous stratum, beneath the transverse humeral ligament, permits the long tendon of the biceps to escape from its interior. In addition to the opening just referred to, there is another very constant deficiency in the superior and anterior part of the fibrous stratum, where the narrowing tendon of the subscapularis muscle is brought into contact with a bursa formed by a protrusion of the synovial stratum. This defect in the fibrous stratum has its long axis in the direction of the longitudinal fibres. Occasionally there is a similar but smaller opening under cover of the tendon of the infraspinatus muscle. Through the two latter openings the joint cavity communicates with bursæ situated between the capsule and the muscles referred to.

The tendons of the subscapularis, supraspinatus, and infraspinatus muscles fuse with, and so strengthen, the articular capsule as they approach their respective insertions.

On the superior aspect of the articulation the capsule is augmented by an

accessory structure, the *ligamentum coracohumerale* (Fig. 302). By its proximal end, which is situated immediately above the glenoid cavity, but subjacent to the coraco-acromial ligament, it is attached to the lateral border of the root of the coracoid process, while its distal end is attached to the humeral neck close to the greater tubercle. This ligament forms a flattened band, having its posterior and inferior border fused with the articular capsule, but its anterior and superior margin presents a free edge, slightly raised above the level of the capsule. This structure is believed to represent that portion of the pectoralis minor to which reference has already been made in connexion with the coraco-acromial ligament (p. 320).

The *coraco-glenoid ligament* is another accessory structure, which is not always present. It springs from the coracoid process along with the former ligament, and extends to the superior and posterior margin of the head of the scapula.

Gleno-humeral Ligaments (Fig. 303).—If the articular capsule is opened from behind, and the head of the humerus removed, it will be seen that the longitudinal fibres of the anterior part of the fibrous stratum are specially developed in the form of thick flattened bands which extend from the anterior border of the glenoid cavity to the anterior aspect of the neck of the humerus. These gleno-humeral ligaments are three in number, and occupy the following positions: the

FIG. 303.—CAPSULAR LIGAMENT OF SHOULDER-JOINT CUT ACROSS AND HUMERUS REMOVED.

superior is placed *above* the aperture in the front of the capsule; the *middle* and *inferior* on the antero-inferior aspect of the capsule, and *below* the aperture mentioned.

The superior gleno-humeral ligament, which some believe to represent the *ligamentum teres* of the hip-joint, springs, along with the middle gleno-humeral band, from the superior part of the cavity. The inferior ligament is the strongest of the three, and springs from the inferior part of the anterior margin of the glenoid.

Intra-capsular Structures.—1. The *labrum glenoidale*, already described. 2. The long tendon of the biceps passes laterally from its attachment to the apex of the glenoid cavity and the adjoining part of the *labrum glenoidale*, above the head and neck of the humerus, to escape from the interior of the capsule by the opening between the tubercles of the humerus, subjacent to the transverse humeral ligament.

A *synovial stratum* (Fig. 304) lines the fibrous stratum of the capsule, and extends from the margin of the glenoid cavity to the humeral attachments of the fibrous stratum, where it is reflected towards the margin of the articular cartilage. It is therefore important to note that the inferior aspect of the humeral neck has the most extensive clothing of the synovial stratum. Further, the synovial stratum envelops the intra-capsular part of the tendon of the biceps, and although this tubular sheath is prolonged upon the tendon into the proximal part of the

intertubercular sulcus, yet the closed character of the synovial cavity is maintained. Thus, while the tendon is within the capsule, it is not within the synovial cavity. The synovial stratum is continuous with those bursæ which communicate with the joint cavity through openings in the fibrous stratum of the capsule.

Bursæ (a) *Communicating with the Joint Cavity.*—Practically there is only one bursa which is constant in its position, viz., the subscapular, between the capsule and the tendon of the subscapularis muscle. It varies considerably in its dimensions, but its lining membrane is always continuous with the synovial stratum of the capsule (Figs. 301 and 302), and therefore it may be regarded merely as a prolongation of the articular synovial stratum. Occasionally a similar but smaller bursa occurs between the capsule and the tendon of the infraspinatus muscle.

(b) *Not communicating with the Joint Cavity.*—The subdeltoid or sub-acromial bursa is situated between the muscles on the superior aspect of the shoulder-joint on the one hand and the deltoid muscle on the other. It is an extensive bursa, and is prolonged subjacent to the acromion and the coraco-acromial ligament. It does not communicate with the shoulder-joint, but it greatly facilitates the movements of the proximal end of the humerus against the inferior surface of the coraco-acromial arch.

Movements at the Shoulder-Joint.—A ball-and-socket joint permits of a great variety of movements, practically in all directions; but if these movements are analysed, it will be seen that they resolve themselves into movements around **three** primary axes at right angles to each other, or around axes which are the possible combinations of the primary ones.

Thus, around a transverse axis, the limb may move forwards (**flexion**) or backwards (**extension**). Around an antero-posterior axis it may move laterally, *i.e.* away from the median plane of the trunk (**abduction**), or medially, *i.e.* towards, and to some extent up to, the median plane (**adduction**).

Around a vertical axis, the humerus may rotate upon its axis in a medial or lateral direction to the extent of a quarter of a circle.

Since these axes all pass through the shoulder-joint, and since each may present varying degrees of obliquity, it follows that very elaborate combinations are possible until the movement of **circumduction** is evolved. In this movement the head of the humerus acts as the apex of a cone of movement with the distal end of the humerus, describing the base of the cone.

The range of the shoulder-joint movements is still further increased owing to the mobility of the scapula as a whole, and owing to its association with the movements of the clavicle already described.

FIG. 304.—VERTICAL SECTION THROUGH THE SHOULDER-JOINT.

ARTICULATIO CUBITI.

The **elbow-joint**¹ provides an instance of a diarthrosis capable of performing the movements of flexion and extension around a single axis placed transversely, *i.e.* a typical ginglymus diarthrosis or hinge-joint.

The bones which enter into its formation are the humerus, ulna, and radius. The trochlea of the humerus articulates with the semilunar notch of the ulna (**articulatio humeroulnaris**); the capitulum of the humerus articulates with the shallow depression or cup on the proximal aspect of the head of the radius (**articulatio humeroradialis**). The articular cartilage clothing the trochlea of the humerus terminates in a sinuous or concave margin both anteriorly and posteriorly, so that it does not line either the coronoid or the olecranon fossa. Medially, it merely rounds off the medial margin of the trochlea, but laterally it is continuous with the encrust-

¹ The articulatio cubiti or elbow-joint includes the humero-radial, humero-ulnar, and the proximal radio-ulnar joints; but, for convenience, the description given here is limited to the humero-radial and humero-ulnar joints.

ing cartilage covering the capitulum, to the margin of which the cartilage extends in all directions, and thus it presents a convex edge in relation to the radial fossa. The cartilage which lines the semilunar notch of the ulna presents a transverse interruption, considerably wider on its medial as compared with its lateral aspect. Thereby the coronoid and olecranon segments of the notch are separated from each other. The cartilage which clothes the coronoid segment is continuous with that which clothes the radial notch of the ulna. The shallow cup-shaped depression on the head of the radius is covered with cartilage which rounds off the margin, and is prolonged without interruption upon the vertical aspect of the head, extending to its most distal level on that part opposed to the radial notch of the ulna.

Capsula Articularis.—

Taken as a whole, the ligaments form a complete **fibrous stratum** of the articular capsule, which is not defective at any point, although it is not of equal thickness throughout, and certain bands of fibres stand out distinctly because of their greater strength.

The common epiphyseal line for the trochlea, capitulum, and the lateral epicondyle of the humerus, is partly intra-capsular and partly extra-capsular; that for the medial epicondyle is extra-capsular. The epiphyseal line of the olecranon is intra-capsular only anteriorly, and it may be altogether extra-capsular.

Lig. Anterius.—The **anterior ligament** (Fig. 305) consists of a layer whose fibres run in several directions—obliquely, transversely, and longitudinally—and of these the vertical fibres are of most importance. It is attached proximally to the proximal

FIG. 305.—ANTERIOR VIEW OF ELBOW-JOINT.

margins of the coronoid and radial fossæ; distally, to the margins of the coronoid process and to the annular ligament of the proximal radio-ulnar joint, but some loosely arranged fibres reach as far as the neck of the radius. The marginal portions of this ligament, which are situated in front of the capitulum and the medial margin of the trochlea respectively, are much thinner and weaker than the central part. Fibres of origin of the brachialis muscle are attached to the front of this ligament.

Lig. Posterius.—The **posterior ligament** is an extremely thin, almost redundant layer. Proximally it is attached, in relation to the margin of the olecranon fossa, at a varying distance from the trochlear articular surface, and distally to the summit and sides of the lip of the olecranon. Laterally some of its fibres pass from the posterior aspect of the capitulum to the posterior border of the radial notch of the ulna. This ligament derives material support from, and participates in the movements of, the triceps brachii muscle, since they are closely adherent to each other in the region of the olecranon.

Lig. Collaterale Ulnare.—The **ulnar collateral ligament** (O.T. internal lateral)

(Figs. 305 and 306) is a fan-shaped structure of unequal thickness, but its margins, which are its strongest bands, are continuous with the adjoining parts of the anterior and posterior ligaments. By its proximal end it is attached to the anterior, distal, and posterior aspects of the medial epicondyle of the humerus. By its broad distal end it is attached to the medial margin of the semilunar notch, so that the *anterior band* is associated principally with the medial margin of the coronoid process, and the *posterior band* with the medial margin of the olecranon, while the intermediate weaker portion sends its fibres downwards to join a *transverse band*, sometimes very strong, which bridges the notch between the adjoining medial margins of the coronoid process and the olecranon.

Lig. Collaterale Radiale.—The radial collateral ligament (O.T. *external lateral*) (Fig. 305) is a strong flattened band attached proximally to the distal and

FIG. 306.—ELBOW-JOINT (Medial Aspect).

posterior aspects of the lateral epicondyle of the humerus. It completes the continuity of the articular capsule on the lateral side, and blends distally with the lig. annulare radii, on the surface of which its fibres may be traced both to the anterior and posterior ends of the radial notch of the ulna. Both of the collateral ligaments are intimately associated with the muscles which take origin from the medial and lateral epicondyles of the humerus.

Synovial Pads of Fat (Fig. 307).—Internal to the fibrous stratum of the articular capsule, there are several pads of fat situated between it and the synovial stratum. Small pads are so placed as to lie immediately in front of the coronoid and radial fossæ, but a larger one projects towards the olecranon fossa.

A **stratum synoviale** (Fig. 307) lines the entire fibrous stratum and clothes the pads of fat referred to above, as well as those portions of bone enclosed within the capsule which are not covered by articular cartilage. By its disposition the elbow and the proximal radio-ulnar joints possess a common joint cavity. It should be specially noted that the proximal part of the neck of the radius is surrounded by this synovial layer.

Movements at the Elbow-Joint.—The movements of the radius and ulna upon the humerus have already been referred to as those characterising a uniaxial joint constructed on the plan of a hinge. In this case the axis of the joint is obliquely transverse, so that in the extended position the humerus and ulna form an obtuse angle open towards the radius, whereas in the

flexed position the hand is carried medially in the direction of the mouth. Extreme flexion is checked by the soft parts in front of the arm and of the forearm coming into contact, and extreme extension by the restraining effect of the ligaments and muscles. In each case the movement is checked before either the coronoid process or the olecranon come into contact with the humerus.

FIG. 307.—VERTICAL SECTION THROUGH THE HUMERO-ULNAR PART OF THE ELBOW-JOINT.

upon the head of the radius are always in varying degrees of contact. The head of the radius participates in the movements of flexion and extension, and is most closely and completely in contact with the humerus during the position of semi-flexion and semi-pronation. In complete extension a very considerable part of the capitulum is uncovered by the radius.

The capitulum and the opposing surface

THE RADIO-ULNAR JOINTS.

These articulations, which are two in number, are situated at the proximal and distal ends of the radius and ulna. They provide an adaptation whereby the radius rotates around a longitudinal axis in the movements of pronation and supination, and hence this form of uniaxial diarthrosis is termed lateral ginglymus.

Articulatio Radioulnaris Proximalis.—The proximal radio-ulnar joint forms a part of the articulatio cubiti or elbow-joint. The articular surfaces which enter into its formation are the radial notch of the ulna and the lateral aspect of the head of the radius. In each case the articular cartilage is continuous with an articular surface entering into the formation of the humero-radial and humero-ulnar joints, consequently the joint cavity is continuous with the cavities of these joints, and therefore, in a sense, it lies within the cover of the articular capsule of the elbow-joint; but its special feature is the annular ligament of the radius.

Lig. Annulare Radii.—The annular ligament of the radius (O.T. orbicular ligament) (Figs. 305 and 308) has been mentioned above as the distal line of attachment of the radial collateral ligament and the ligaments on the front and back of the elbow-joint.

It is a strong, well-defined structure, attached by its extremities to the volar and dorsal margins of the radial notch of the ulna, and thus it forms nearly four-fifths of an osseo-tendinous circle or ring. This circle is somewhat wider at the proximal than at the distal margin of the annular ligament of the radius, which, by encircling the proximal part of the neck of the radius, tends to prevent

displacement of the head of that bone in a distal direction. The distal margin of this ligament is not directly attached to the radius.

The **synovial stratum** is continuous with that which lines the elbow-joint. It closes the joint cavity at the distal unattached margin of the annular ligament, where it is somewhat loosely arranged in its reflexion from the ligament to the neck of the radius. The epiphyseal line at the proximal end of the radius is intra-capsular.

Articulatio Radioulnaris Distalis.—The distal radio-ulnar joint is situated between the lateral aspect of the head of the ulna and the ulnar notch on the medial side of the distal end of the radius. In addition, it includes the distal surface of the head of the ulna, which articulates with the proximal surface of a triangular articular disc by means of which the joint is excluded from the radio-carpal articulation.

Discus Articularis.—The triangular articular disc (Figs. 309 and 311), besides presenting articular surfaces to two separate joints, is an important ligament concerned in binding together the distal ends of the radius and ulna. It is attached by its apex to the depression at the lateral side of the root of the styloid process of the ulna, and by its base to the sharp line of demarcation between the ulnar notch and the carpal articular surface of the radius.

Capsula Articularis.—The fibrous stratum is very imperfect, and consists of scattered fibres, termed the **anterior** and **posterior radio-ulnar ligaments** (Fig. 310). These ligaments pass transversely between adjoining non-articular surfaces on the radius and ulna, and are of sufficient length to permit of the movements of the radius in pronation and supination.

The **synovial stratum** completes the closure of the joint cavity. It forms a loose bulging projection (**recessus sacciformis**), passing proximally between the distal ends of the shafts of the radius and ulna, and it also clothes the proximal surface of the articular disc (Fig. 311). The cavity of this joint is quite distinct from that of the radio-carpal articulation, except when the articular disc presents a perforation.

Between the proximal and distal radio-ulnar articulations there are two **accessory ligaments**, viz., the **interosseous membrane** and the **chorda obliqua**, which connect together the shafts of the radius and ulna.

Membrana Interossea Antibrachii.—The **interosseous membrane of the forearm** (Fig. 306) is a strong fibrous membrane which stretches across the interval between the radius and ulna, and is firmly attached to the interosseous crest of each. Distally it extends to the distal limit of the space between the bones, whilst

FIG. 308.—ANNULAR LIGAMENT OF THE RADIUS.

FIG. 309.—CARPAL ARTICULAR SURFACE OF THE RADIUS, AND ARTICULAR DISC OF THE WRIST.

proximally it only reaches a point about one inch distal to the tuberosity of the radius. A gap, called the *hiatus interosseus*, is thus left between its proximal margin and the chorda obliqua, and through this the dorsal interosseous vessels pass backwards between the bones to reach the dorsal aspect of the forearm. The fibres which compose the interosseous membrane run for the most part distally and medially from the radius to the ulna, although on its dorsal aspect several bands may be observed stretching in an opposite direction. The interosseous membrane

augments the surface available for the origin of the muscles of the forearm; it braces the radius and ulna together; and when shocks are communicated from the hand to the radius, owing to the direction of its fibres, the interosseous membrane transmits these, to some slight extent, to the ulna.

Chorda Obliqua.—The oblique chord (Fig. 306) is a slender fibrous band of very varying strength which springs from the lateral part of the coronoid process of the ulna, and stretches obliquely distally and laterally to the radius where it is attached immediately distal to the tuberosity of the radius.

Movements of the Radius on the Ulna.—The axis around which the radius moves is a longitudinal one, having one end passing through the centre of the head of the radius and the other through the styloid process of the ulna and the line of the ring-finger. In this axis the head of the radius is so secured that it can only rotate upon the radial notch of the ulna within the annular ligament of the radius, and consequently the radial head remains upon the same plane as the ulna; but the distal end of the radius being merely restrained by the articular disc, is able to describe nearly a half-circle, of which the apex of this ligament is the centre. In this movement the radius carries the hand from a position in which the palm is directed forwards, and in which the radius and ulna lie parallel to each other (**supination**), to one in which the palm is directed backwards, and the radius lies diagonally across the front of the ulna (**pronation**).

The ulna is unable to rotate upon a long axis, but while the radius is travelling through the arc of a circle from lateral to medial side in front of the ulna, it will usually be seen that the ulna appears to move through the arc of a smaller circle in the reverse direction, viz., from medial to lateral side. If the humerus is prevented from moving at the shoulder-joint, a very large proportion, if not the entire amount, of this apparent movement of the ulna will disappear. At the same time some observers maintain that it really occurs at the elbow-joint, associated with lateral movement during slight degrees of flexion and extension at that joint.

ARTICULATIO RADIOCARPEA.

The **radio-carpal joint** is a bi-axial diarthrosis, frequently called a condyloid joint.

The articular elements which enter into its formation are: on its *proximal side*, the carpal surface of the distal end of the radius, together with the distal surface of the discus articularis; on its *distal side*, the proximal articular surfaces of the navicular, lunate, and triquetral bones. The articular surface of the radius is concave both in its antero-posterior and transverse diameters, in order to adapt itself to the opposing surfaces of the navicular and lunate, which are convex in the two axes named. In the ordinary straight position of the hand the articular disc is in contact with the lunate bone, and the proximal articular surface of the triquetral bone is in contact with the capsule of the joint. When, however, the hand is bent towards the ulna the triquetral bone is carried laterally as well as the lunate and navicular and the articular disc comes into contact with the triquetral. The articular surface of the radius is subdivided by an antero-posterior, slightly elevated ridge, into a lateral triangular facet which usually articulates with the navicular, and a medial quadrilateral facet for articulation with a portion of the lunate bone.

In the intervals between the navicular, lunate, and triquetral bones, the continuity of the articular surfaces is usually maintained by the presence of interosseous ligaments which are situated upon the same level as the articular cartilage.

Capsula Articularis.—An articular capsule completely surrounds the joint. It is somewhat loosely arranged, and its fibrous stratum permits of subdivision into the following four portions:—

Lig. Radiocarpeum Laterale.—The lateral radio-carpal ligament (O.T. *external lateral*) (Fig. 310) is a well-defined band which is attached by one end to the tip of the styloid process of the radius, and by the other to a rough area at the base of the tuberosity of the navicular bone, *i.e.* lateral to its radial articular surface.

Lig. Ulnocarpeum Mediale.—The medial ulno-carpal ligament (O.T. *internal lateral*) (Fig. 310) is also a distinct rounded structure, having one end attached to the tip of the styloid process of the ulna, and the other to the rough non-articular border of the triquetral bone, some of its fibres being prolonged to the pisiform bone.

Lig. Radiocarpeum Volare.—The volar radio-carpal ligament (O.T. *anterior ligament*) (Fig. 310) is attached proximally to the volar margin of the distal end

of the radius, as well as slightly to the base of the styloid process of the ulna. Some transverse fibres may be seen, but the greater number pass obliquely distally and medially to the volar non-articular surfaces of the navicular, lunate, and triquetral bones, while some of them may even be continued as far as the capitate bone. Those fibres from the ulna run obliquely laterally. On its deeper aspect this ligament is closely adherent to the volar border of the articular disc of the distal radio-ulnar articulation.

Lig. Radiocarpum Dorsale.—The dorsal radio-carpal ligament (O.T. posterior ligament) extends from the dorsal margin

of the distal end of the radius, in an oblique direction distally and medially, to the dorsal non-articular areas on the proximal row of the carpal bones. The slip to the latter assists in forming the fibrous sheath through which the tendon of the extensor carpi ulnaris muscle travels to its insertion. The principal bundle of fibres is connected with the triquetral bone.

The *stratum synoviale* (Fig. 311) is simple, and is confined to the articulation, except in those cases in which the articular disc is perforated, or in which one of the interosseous ligaments between the carpal bones of the first row is absent. The epiphyseal lines at the distal ends of radius and ulna are extra-capsular.

Movements at the Radio-carpal Joint.—The radio-carpal joint affords an excellent example of a bi-axial articulation, in which a long transverse axis of movement is situated more or less at right angles to a short axis placed in the antero-posterior direction. The nature of the movements which are possible around these two axes is essentially the same in both cases, viz., **flexion** and **extension**. The movements around the longer transverse axis are anterior or volar flexion, extension, and its continuation into dorsi-flexion. Around the shorter antero-posterior axis we get movements which result from combined action by certain flexor and extensor muscles, whereby the radial or ulnar borders of the hand may be approximated towards the corresponding borders of the forearm. Lateral movement also may be possible to a slight extent. The range of movement in connexion with either of the principal axes is largely a matter of individual peculiarity, for, with the exception of the lateral ligaments, there is no serious obstacle to the cultivation of greater mobility at the radio-carpal joint.

ARTICULATIONES INTERCARPEÆ.

Carpal Joints.—The articulations subsisting between the individual carpal bones are all diarthroses, and although the total amount of movement throughout the series is considerable, yet the extent of movement which is possible between the two rows or between any two carpal bones is extremely limited. For this reason, as well as because of the nature of the movement, these articulations are called gliding joints (arthrodia).

It is advisable to consider, *first*, the articulations between individual bones of the proximal row; *second*, the articulations between the separate bones of the distal row; *third*, the articulation of the proximal and distal rows with each other; *fourth*, the pisiform articulation.

FIG. 310.—LIGAMENTS ON VOLAR ASPECT OF RADIO-CARPAL, CARPAL, AND CARPO-METACARPAL JOINTS.

The **proximal row of carpal articulations** (Fig. 311) comprises the joints between the navicular, lunate, and triquetral bones. On their adjacent aspects these bones are partly articular and partly non-articular.

Three sets of simple but strong, although short, ligamentous bands bind these three carpal bones together, and form an investment for three sides of their intercarpal joints. These are—(1) the **ligamenta intercarpea volaria** (anterior or volar ligaments), two in number, which consist of transverse fibres passing between the adjacent rough volar surfaces of the bones; (2) the **ligamenta intercarpea dorsalia** (posterior or dorsal ligaments), also two in number, and composed of similar short transverse fibres passing between the adjacent dorsal surfaces; (3) the **ligamenta intercarpea interossea** (interosseous ligaments) (Fig. 310), again two in number, and transverse in direction, situated on a level with the proximal articular surfaces, and extending from the volar to the dorsal aspect of the bones while attached to non-articular areas of the opposing surfaces. The radio-carpal joint is entirely shut off from the intercarpal joints, and also from the joint between the two rows of carpal bones, except in rare cases, when an interosseous ligament is wanting.

The **distal row of carpal articulations** (Fig. 311) includes the joints between the greater multangular, lesser multangular, capitate, and hamate bones. Articular facets occur on the opposing faces of the individual bones.

Associated with this row there are again simple bands of considerable strength, and presenting an arrangement similar to that seen in the proximal row. As in the former case, they invest the intercarpal articulations, except on the proximal aspect, where they communicate with the transverse carpal joint, and on the distal aspect, where they communicate with the carpo-metacarpal joint cavity.

The **ligamenta intercarpea volaria** (anterior or volar ligaments) are three in number. They extend in a transverse direction between contiguous portions of the rough volar surfaces of the bones. The **ligamenta intercarpea dorsalia** (posterior or dorsal ligaments), also three in number, are similarly disposed on the dorsal aspect. The **ligamenta intercarpea interossea** (interosseous ligaments) (Fig. 311) are two or three in number. That which joins the capitate to the os hamatum is the strongest; that between the lesser multangular and the capitate bone is situated towards the dorsal parts of their opposing surfaces; the third, situated between contiguous non-articular surfaces of the greater and lesser multangular bones, is always the feeblest, and is frequently absent.

The **transverse carpal articulation** (Fig. 311) is situated between the proximal and distal rows of the carpus. The bones of the proximal row present the following characters on their distal aspect. The lateral part of the articular surface is deeply concave, both in the antero-posterior and in the transverse directions, but the medial part of the same surface is concavo-convex, more especially in the transverse direction.

Proximally, the articular surfaces of the distal row of carpal bones present an irregular outline. That part pertaining to the greater and lesser multangular bones is concave in the antero-posterior and transverse directions, and lies at a considerably more distal level than the portion belonging to the capitate and os hamatum, which is, moreover, markedly convex in the antero-posterior and transverse directions, with the exception of the most medial part of the os hamatum, where it is concavo-convex in both of these directions.

This articulation is invested by a complete short articular capsule (Fig. 310) which binds the two rows of the carpus together, and sends prolongations to the investing capsules of the proximal and distal articulations. The ligament, as a whole, is very strong, and individual bands are not readily defined, although certain special bands may be described. The **lig. carpi radiatum** (radiate carpal ligament (volar ligament)) radiates from the capitate bone to the navicular, triquetral, and pisiform bones. The interval between the capitate and lunate is occupied by oblique fibres, some of which pass from navicular to triquetral, while these are joined by others, prolonged obliquely distally and medially, from the radial end of the anterior radio-carpal ligament. By these different bands the volar aspect of the joint is completely closed.

The **ligamenta intercarpea dorsalia** (dorsal ligaments) are more feeble than the

volar. They form a thin, loosely arranged stratum, in which the only noteworthy bands are one which joins the navicular to the capitate, and another which joins the triquetral to the os hamatum.

Lig. Collaterale Carpi Radiale.—The radial collateral carpal ligament (O.T. external lateral) (Fig. 310) extends between contiguous rough areas on the lateral aspects of the navicular and greater multangular bone. By its margins it is continuous both with the volar and dorsal ligaments.

Lig. Collaterale Carpi Ulnare.—The ulnar collateral carpal ligament (O.T. internal lateral) (Fig. 310) is arranged like the former in regard to its margins, and by its ends it is attached to the contiguous rough ulnar surfaces of the triquetral and the os hamatum.

Both of these collateral ligaments are directly continuous with the corresponding collateral ligaments of the radio-carpal joint.

A **lig. interosseum** (interosseous ligament) (Fig. 311) is occasionally found within the capsule, extending across the joint cavity between the capitate and the navicular.

Articulatio Ossis Pisiformis.—The pisi-triquetral articulation is an arthrodial diarthrosis. The mutual articular surfaces of the two bones are flattened and circular, and permit of only a small amount of gliding movement.

The joint is provided with a thin but complete **articular capsule**, the fibrous stratum of which is specially strengthened distally by two strong bands, viz., lig. piso-hamatum and lig. pisometacarpeum (Fig. 310). Both of these bands extend from the distal and medial aspect of the pisiform to adjoining parts of the hook of the os hamatum and base of the fifth metacarpal bone respectively. To a great extent these ligamentous bands may be regarded as extensions of the insertion of the tendon of the flexor carpi ulnaris muscle, which is attached to the proximal part of the pisiform bone. Looked at as ligaments, however, they are specially strong to prevent the displacement of the pisiform bone during contraction of the muscle inserted into it.

The **synovial strata** (synovial membranes) (Fig. 311) of the carpal joints are two in number. Of these, one is restricted to the pisi-triquetral articulation, and is correspondingly simple, although occasionally the joint cavity may communicate with that of the radio-carpal joint.

The other synovial stratum is associated with the transverse carpal joint which extends transversely between the two rows of carpal bones, with prolongations into the intervals between the adjoining bones of each row, i.e. the intercarpal articulations. It is, therefore, an elaborate cavity, which may be still further extended, by the absence of interosseous ligaments, so as to reach the radio-carpal and carpo-metacarpal series of joints. The first condition is rare, but the second is not uncommon, and results from the absence of the interosseous ligament between the greater and lesser multangular bones, or of that between the lesser multangular and the capitate bone.

FIG. 311.—FRONTAL SECTION through the radio-carpal, carpal, carpo-metacarpal, and intermetacarpal joints, to show joint cavities and interosseous ligaments (diagrammatic).

ARTICULATIONES INTERMETACARPEÆ.

Intermetacarpal Joints.—The four medial metacarpal bones articulate with each other at their proximal ends or bases, between the opposing surfaces of which joint cavities are found—arthrodial diarthroses. These cavities are continuous with the carpo-metacarpal joint (not yet described), and hence the ligamentous arrangements only enclose three aspects of each joint.

Three strong **transverse ligaments** (Figs. 310 and 311) bind adjacent volar, dorsal, and interosseous areas of the bases of the metacarpal bones, and hence they are called **ligamenta basium** (oss. metacarp.) **volaria, dorsalia et interossea**. A synovial stratum is associated with each of these joints, but it may be regarded as a prolongation from the carpo-metacarpal articulation.

ARTICULATIONES CARPOMETACARPEÆ.

Carpo-metacarpal Joints.—The articulation of the metacarpal bone of the thumb with the greater multangular differs in so many respects from the articulation between the other metacarpal bones and the carpus, that it must be considered separately.

(A) The **articulatio carpometacarpea pollicis** (Figs. 310 and 311) is the joint between the disto-lateral surface of the greater multangular and the proximal surface of the base of the first metacarpal bone. Both of these surfaces are saddle-shaped, and they articulate by mutual co-aptation.

The joint cavity is surrounded by an **articular capsule**, in the fibrous stratum of which we may recognise volar, dorsal, lateral, and medial bands, the last being the strongest and most important.

A **synovial stratum** lines the fibrous stratum, and the joint cavity is isolated and quite separate from the other carpal and carpo-metacarpal articulations.

At this joint movements occur around at least three axes. Thus, around a more or less transverse axis, **flexion** and **extension** take place; in an antero-posterior axis **abduction** and **adduction** (movements which have reference to the middle line of the hand) are found; while a certain amount of **rotation** is possible in the longitudinal axis of the digit. The very characteristic movement of **opposition**, in which the tip of the thumb may be applied to the tips of all the fingers, results from a combination of flexion, adduction, and rotation, and by combining all the movements possible at the various axes a considerable degree of **circumduction** may be produced.

(B) The **articulationes carpometacarpeæ digitorum** are the joints between the bases of the four medial metacarpal bones and the four bones of the distal row of the carpus. They are all arthrodial diarthroses, and the opposed articular surfaces present alternate elevations and depressions which form a series of interlocking joints. The joint cavities between the carpal bones of the distal row, and also the more extensive intermetacarpal joint cavities, open into this articulation.

This series of joints is invested by a common articular capsule which is weakest on its radial side, but is otherwise well defined. Its fibres arrange themselves in small slips, which pass obliquely in different directions, and vary in number for each metacarpal bone. Thus the **ligamenta carpometacarpea volaria** (**volar carpo-metacarpal ligaments** (O.T. **oblique palmar**)) (Fig. 310) usually consist of one slip for each metacarpal bone, but there may be two slips, and the third metacarpal bone frequently has three, of which one lies obliquely in front of the tendon of the flexor carpi radialis muscle.

The **ligamenta carpometacarpea dorsalia** (**dorsal carpo-metacarpal ligaments** (O.T. **oblique dorsal**)) are similar short bands, of greater strength and clearer definition, by which the index metacarpal is bound to the greater and lesser multangular bones; the middle metacarpal to the capitate, and frequently to the lesser multangular; the ring metacarpal to the capitate and os hamatum, and the metacarpal of the 5th finger to the os hamatum.

Ligamenta interossea (**interosseous ligaments**), one or sometimes two in number, occur within the capsule. They are usually situated in relation to one or both of the contiguous margins of the bases of the third and fourth metacarpal bones, from which they extend proximally to adjacent margins of the capitate and os hamatum. Occasionally they are sufficiently developed to divide the joint cavity into radial and ulnar sections.

The **synovial stratum** (Fig. 311) is usually single and lines the fibrous stratum, but, as already explained, it has prolongations into the intermetacarpal and intercarpal series of joints. In connexion with the intercarpal series, the frequent absence of the interosseous ligament between the greater and lesser multangular bones permits the free communication of this joint cavity with that of the transverse carpal joint.

ARTICULATIONES METACARPOPHALANGÆ.

Metacarpo-phalangeal Joints.—In the case of the pollex this joint is constructed on the plan of a ginglymus diarthrosis; the four corresponding joints of the fingers are also diarthroses of a slightly modified ball-and-socket variety. With the exception of the metacarpal bone of the pollex, each metacarpal bone has a somewhat spherical head articulating with a shallow oval cup upon the base of the first phalanx. It is important to note that the articular surface upon the head of each of these metacarpal bones is wider on the volar aspect and narrower on the dorsal aspect. The articulation in the thumb presents features similar to those of an interphalangeal joint.

Each joint possesses a **capsula articularis** (Fig. 312) which presents very different degrees of strength in different aspects of the articulation. Thus, on the dorsal aspect, it cannot be demonstrated as an independent structure, but the necessity for dorsal ligaments is to a large extent obviated by the presence of the strong flattened expansions of the extensor tendons.

The epiphyseal lines are extra-capsular.

Ligamenta Collateralia.—The **collateral ligaments** (O.T. **internal** and **external lateral**) (Fig. 312) are strong cord-like bands which pass from the tubercles and adjacent depressions on the sides of the heads of the metacarpal bones to the contiguous non-articular areas on the bases of the proximal phalanges. They are intimately connected on their volar aspects with the volar ligaments.

Ligamenta Accessoria Volaria.—The **volar accessory ligaments** (O.T. **palmar ligaments**) consist of thick plates of fibro-cartilage loosely connected to the metacarpal bones, but firmly adherent to the phalanges. They are placed between the collateral ligaments, to both of which they are in each case connected. Each plate is grooved on the volar surface for the long flexor tendons, whilst on its dorsal or joint surface it supports and glides upon the head of the metacarpal bone during flexion and extension of the joint. In the case of the thumb this plate of fibro-cartilage is usually replaced by sesamoid bones, and in the case of the index finger one such sesamoid nodule is frequently found at the radial side of the plate.

An important accessory ligament is found in connexion with the four medial metacarpo-phalangeal articulations, viz. :—

Ligamenta Capitulum (Oss. Metacarpalium) Transversa.—The **transverse ligament** of the heads of the metacarpal bones (or **transverse metacarpal ligament**) binds together the distal extremities of the four medial metacarpal bones. The name is applied to three sets of transverse fibres of great strength which are situated in front of the three medial interosseous spaces. These fibres are continuous with the **ligamenta accessoria volaria** (volar metacarpo-phalangeal ligaments) at their lateral margins.

A **stratum synoviale** lines the **capsula articularis** of each joint.

FIG. 312.—METACARPO-PHALANGEAL AND INTERPHALANGEAL JOINTS.

ARTICULATIONES DIGITORUM MANUS.

Interphalangeal Joints.—Of these joints there are two for each finger and one for the thumb. They all correspond, in being ginglymus diarthroses in which the trochlear character of their articular surfaces is associated with one axis of movement directed transversely.

In their general arrangement they correspond with each other, and to a large extent with the metacarpo-phalangeal series already described. Each is provided with a definite **articular capsule** (Fig. 312), of which the volar and cord-like lateral portions are well marked, while on the dorsal aspect the extensor tendons act as the chief support. The volar portions contain fibrous plates of considerable thickness, and are attached to the two collateral ligaments and to the intervening rough surface on the distal phalanges, while their proximal margins are not attached to bone. Each ligament has its lateral margins prolonged proximally to the adjacent sharply defined lateral ridges on the phalangeal shafts.

The **collateral ligaments** (Fig. 312) are strong, rounded, short bands, continuous with the preceding, and attached to the non-articular sides of adjacent heads and bases of the phalanges.

Each joint possesses a **synovial stratum** which lines its fibrous stratum, but its arrangement presents no special peculiarity. The epiphyseal lines of the bases of the phalanges are extra-capsular.

MOVEMENTS OF THE CARPAL, INTERMETACARPAL, METACARPO-PHALANGEAL AND INTERPHALANGEAL JOINTS.

The amount of movement which is possible at individual joints of the intercarpal, intermetacarpal, and carpo-metacarpal series is extremely limited, both on account of the interlocking nature of the articular surfaces and the restraining character of the ligamentous bands. Taken as a whole, however, the movements of the carpus and metacarpus enable the hand to perform many varied and important functions. This is largely due to the greater mobility of those joints on the radial and ulnar borders of the hand, as well as to the general elasticity of the arches formed by the carpus and metacarpus. These conditions particularly favour the movements of opposition and prehension. In the opposite direction, *i.e.* when pressure is applied from the volar aspect, the metacarpal and carpal arches tend to become flattened, but great elasticity is imparted by the tension of the various ligaments.

The four medial metacarpo-phalangeal joints are ball-and-socket joints, and movements of **volar-flexion** and **extension** are freely performed about a transverse axis. In exceptional cases a certain amount of **dorsi-flexion** is possible. About an antero-posterior axis movements occur which are usually referred to the middle line of the hand, and hence called **abduction** and **adduction**, but in consequence of the difference in the width of the articular surface on the dorsal and volar aspects of the heads of the four medial metacarpal bones it is only possible to obtain abduction when the joints are extended, while in the flexed position the joints become locked and abduction is impossible.

The movements of the index finger are less hampered than in the case of the others, but each of them can perform a modified kind of **circumduction**.

The metacarpo-phalangeal joint of the thumb and all the interphalangeal joints are uniaxial or hinge-joints acting about a transverse axis, which permits of **volar-flexion** and **extension** being freely performed, but **dorsi-flexion** is, as a rule, entirely prevented by the volar and lateral ligaments.

ARTICULATIONES ET LIGAMENTA CINGULI
EXTREMITATIS INFERIORIS.

Articulations and Ligaments of the Pelvis.—Although we may consider the pelvis as a separate part of the skeleton, yet it is essential to remember that the bones which enter into its composition belong to the vertebral column (sacrum, coccyx) and the lower limb (hip bone). Accordingly, the articulations, with their corresponding ligaments, may be arranged as follows:—

- (a) Those by which the segments of the coccyx are joined together (already described, *v.* p. 310);
- (b) That by which the sacrum articulates with the coccyx (already described, *v.* p. 309);

- (c) Those by which the sacrum articulates with the last lumbar vertebra (Lumbo-sacral joints);
- (d) Those by which the hip bones are attached to the vertebral column (Sacro-iliac joints);
- (e) That by which the hip bones are attached to each other (Symphysis pubis).

ARTICULATIONES SACROLUMBALES.

Lumbo-sacral Joints.—The articulation of the sacrum with the fifth lumbar vertebra is constructed precisely on the principle of the articulations between two typical vertebræ, and the usual ligaments associated with such joints are repeated. There is, however, an additional accessory ligament, termed the **lateral lumbo-sacral ligament**. This extends from the anterior aspect of the inferior border of the transverse process of the last lumbar vertebra, downwards and slightly laterally, to the front of the lateral aspect of the ala of the sacrum, close to the sacro-iliac joint. Further, a variable membranous band extends between the lateral aspect of the inferior part of the body of the last lumbar vertebra and the front of the ala of the sacrum. This band lies in front of the anterior ramus of the fifth lumbar nerve.

ARTICULATIO SACROILIACA.

Each hip bone articulates with the sacral section of the vertebral column on each side through the intervention of a diarthrosis, termed the **sacro-iliac joint**.

FIG. 313.—FRONTAL SECTION OF PELVIS.

This joint is formed between the contiguous auricular surfaces of the sacrum and ilium. Each of these surfaces is more or less completely clothed with hyaline articular cartilage. The joint cavity, which is little more than a capillary interval, may be crossed by fibrous bands.

The *cavum articulare* (joint cavity) is surrounded by ligaments of varying thickness and strength, which constitute the fibrous stratum of its **articular capsule**. Thus, its anterior part is thin, and consists of short but strong fibres which pass between adjoining surfaces on the ala of the sacrum and the iliac fossa of the hip bone; they form the **anterior sacro-iliac ligament**. On the posterior aspect there are three ligaments. The **interosseous sacro-iliac ligament** (Fig. 313) consists of numerous strong fasciculi, which pass from the rough area on the medial aspect of the ilium, above and behind its auricular surface, downwards and medially to the transverse tubercles and the depressions behind the first and second segments of the sacrum. This ligament is of great strength, and with its fellow

FIG. 314.—POSTERIOR VIEW OF THE PELVIC LIGAMENTS AND OF THE HIP-JOINT.

it is responsible for suspending the sacrum and the weight of the superimposed trunk from the hip bones.

The **long posterior sacro-iliac ligament** (Fig. 314) is a superficial thickened portion of the interosseous ligament. It consists of a definite band of fibres passing from the posterior superior iliac spine to the transverse tubercles of the third and fourth segments of the sacrum.

The **short posterior sacro-iliac ligament** consists of superficial fibres of the interosseous ligament passing from the posterior superior iliac spine to the first and second transverse tubercles of the sacrum.

The **articular cavity** of this joint is very imperfect and rudimentary.

Several accessory ligaments are associated with the articulation of the hip bone to the sacral section of the vertebral column.

Lig. Iliolumbale.—The ilio-lumbar ligament (Fig. 314), which is merely the thickened anterior lamina of the lumbo-dorsal fascia, extends from the tip of the transverse process of the last lumbar vertebra, almost horizontally laterally, to the inner lip of the iliac crest at a point a short distance behind its highest level. A proportion of these fibres is attached to the medial rough surface of the ilium between the iliac crest and the auricular impression. To these the name of the lig. *iliolumbale inferius* is applied.

Lig. Sacrotuberosum.—The sacro-tuberous ligament (O.T. great sacro-sciatic lig.) (Fig. 314) is somewhat triangular in outline. It occupies the interval between the sacrum and the hip bone, and is attached medially to the posterior inferior spine of the ilium; to the posterior aspect of the transverse tubercles and lateral margins of the third, fourth, and fifth segments of the sacrum, as well as to the side of the first segment of the coccyx. It passes downwards and laterally, becoming narrower as it approaches the ischium, near to which, however, it again expands, to be attached to the medial side of the tuber ischiadicum, immediately below the groove for the tendon of the obturator internus muscle, *i.e.* the lesser sciatic notch. A continuation of the medial border of the ligament—the *processus falciformis* (Fig. 314)—runs upwards and forwards on the medial aspect of the ramus of the ischium.

The ligamentum sacrotuberosum is believed by many to represent the original or proximal end of the long or ischial head of the biceps femoris muscle.

Ligamentum Sacrospinosum.—The sacro-spinous ligament (O.T. small sacro-sciatic lig.) (Figs. 314 and 313) is situated in front, and in a measure under cover of the sacro-tuberous ligament. Triangular in form, it is attached by its base to the last two segments of the sacrum and the first segment of the coccyx, and by its pointed apex to the tip and superior aspect of the spina ischiadica. This ligament is intimately associated with the coccygeus muscle, and by some it is regarded as being derived from it by fibrous transformation of the muscle fasciculi.

By the sacro-tuberous and sacro-spinous ligaments the two sciatic notches of the hip bone are converted into foramina. Thus the sacro-spinous ligament (lig. sacrospinosum) completes the boundaries of the greater sciatic foramen (foramen ischiadicum majus); while the sacro-tuberous ligament (lig. sacrotuberosum), assisted by the sacro-spinous ligament (lig. sacrospinosum), closes the lesser sciatic foramen (foramen ischiadicum minus).

SYMPHYSIS OSSIIUM PUBIS.

The anterior wall of the osseous pelvis is completed by the articulation of the bodies of the two pubic bones, which constitutes the *symphysis pubis*. This joint conforms in its construction to the general plan of an amphiarthrosis. Thus it is median in position; each pubic bone is covered by a layer of hyaline cartilage, which closely adapts itself to the rough tuberculated surface of the pubic bone; while between these two hyaline plates there is an interposed fibro-cartilage called the *lamina fibrocartilaginea interpubica*, in the interior of which there is usually a vertical antero-posterior cleft. This cavity, which is placed nearer the posterior than the anterior aspect of the joint, does not appear until between the seventh and tenth years, and as it is not lined by a synovial stratum, it is supposed to result from the breaking down of the interpubic lamina.

Lig. Pubicum Anterius.—The anterior pubic ligament (Fig. 313) is a structure of considerable thickness and strength. Its superficial fibres, which are derived very largely from the tendons and aponeuroses of adjoining muscles, are oblique, and form an interlaced decussation. The deeper fibres are short, and extend transversely from one pubic bone to the other.

Lig. Pubicum Posterius.—The posterior pubic ligament (Fig. 313) is very weak and consists of scattered fibres which extend transversely between contiguous pubic surfaces posterior to the articulation.

Lig. Pubicum Superius.—The superior pubic ligament also is weak; it consists of transverse fibres passing between the two pubic crests.

Lig. Arcuatum Pubis.—The arcuate ligament of the pubis (O.T. inferior or subpubic ligament) occupies the arch of the pubis, and is of considerable strength. It gives roundness to the pubic arch and forms part of the inferior aperture of the pelvis. It has considerable vertical thickness immediately below the interpubic fibro-cartilage, to which it is attached. Laterally it is attached to adjacent sides of the descending rami of the pubis. Its inferior border is free, and separated from the fascia inferior of the urogenital diaphragm by a transverse oval interval, through which the dorsal vein of the penis passes backwards to the interior of the pelvis.

FASCIA DIAPHRAGMATIS UROGENITALIS INFERIOR.

The inferior fascia of the urogenital diaphragm (O.T. superficial layer of the triangular ligament) is a membranous structure which occupies the pubic arch below and distinct from the arcuate ligament of the pubis. It assists in completing the pelvic walls anteriorly in the same manner that the obturator membrane does laterally. Indeed, these two structures occupy the same morphological plane. The fascia presents two surfaces—one superficial or perineal, the other deep or pelvic—and both of these surfaces are associated with muscles. Its lateral borders are attached to the sides of the pubic arch, while its base is somewhat ill-defined, by reason of its fusion with the fascia of Colles in the urethral region of the perineum.

The apex of the fascia is truncated, free, and well defined, constituting the transverse perineal ligament, above which there is the interval for the dorsal vein of the penis. It is pierced by a number of vessels and nerves, but the principal opening is situated in the median plane one inch below the pubic arch, and transmits the urethra.

MEMBRANA OBTURATORIA.

The obturator membrane (Fig. 316) occupies the obturator foramen. It is attached to the pelvic aspect of the circumference of this foramen. It consists of fibres irregularly arranged and of varying strength, so that sometimes it almost appears fenestrated. At the highest part of the foramen it is incomplete and forms a U-shaped border, between which and the bony circumference of the foramen the obturator canal is formed. In this position the membrane is continuous with the parietal pelvic fascia which clothes the medial side of the obturator internus muscle, above the superior free margin of the muscle. From the lateral or femoral aspect of the membrane some of its fibres are prolonged to the antero-inferior aspect of the capsule of the hip-joint.

Mechanism and Movements of the Pelvis.—The human pelvis presents a mechanism the principal requirement of which is stability and not movement, for, through the pelvis, the weight of the trunk, superimposed upon the sacrum, is transmitted to the lower limbs. Moreover, its stability is largely concerned in the maintenance of the erect attitude. The movements of its various parts are therefore merely such as are consistent with stability, without producing absolute rigidity.

The two hip bones, being bound together by powerful ligaments at the pubic articulation, constitute an inverted arch, of which the convexity is directed downwards and forwards, while its piers are turned upwards and backwards, and considerably expanded in relation to the posterior parts of the iliac bones. Between the piers of this inverted arch the sacrum is situated. This bone is in no sense a key-stone to an arch, because, as may readily be seen in antero-posterior transverse section, the sacrum is wider in front than behind, and the superposed weight naturally tends to make the sacrum fall towards the pelvic cavity, and so fit less closely between the hip bones. The sacrum is in reality an oblique platform, in contact with each hip bone through its articular auricular surfaces, and in this position it is suspended by the interosseous and posterior sacro-iliac ligaments, and kept securely in place by the "grip" due to the irregularity of the opposed surfaces of the two sacro-iliac articulations. Since the weight of the trunk is transmitted to the anterior and superior end of this sacral platform, there is a natural tendency for the sacrum to revolve upon the transverse axis which passes through its sacro-iliac joints. If this were permitted, the promontory of the sacrum would rotate downwards and forwards towards the pelvic cavity, as really does occur in certain deformities. This revolution or tilting downwards of the anterior part of the sacrum is prevented by the action of the sacro-tuberous and sacro-spinous ligaments, extending from the ischial tuberosity to the posterior and inferior end of the suspended platform of the sacrum. Not only so, but these ligaments, acting on a rigid sacrum, tend to hold up the weight upon the sacral promontory.

The various ligaments passing between the last lumbar vertebra and the sacrum and ilium retain the weight of the trunk in position upon the anterior end of the sacrum, and resist its tendency to slip forwards and downwards towards the pelvic cavity. The entire weight of the trunk and pelvis is transmitted to the heads of the thigh bones in the most advantageous position, both for effectiveness and the strengthening of the inverted back of the hip bones, for it will be evident that the heads of the femora thrust inwards upon the convex side of the arch, very much at the place where the arches are weakest, viz., at the springing of the arch from its piers. The forces which tend to cause movement of the pelvic bones during parturition act from within the pelvis, and have for their object the increase of the various pelvic diameters, in order that the foetal head may more readily be transmitted. For this purpose the wedge-like dorsal surface of the sacrum is driven backwards, and a certain amount of extra space may thereby be obtained. An important factor, however, in the increase of the pelvic capacity at this period is found in the relaxation of its various ligaments.

ARTICULATIONES EXTREMITATIS INFERIORIS.

ARTICULATIO COXÆ.

The Hip-Joint.—The human body provides no more perfect example of an enarthrodial diarthrosis than the hip-joint. Combined with all that variety of movement which characterises a multi-axial joint, it nevertheless presents great stability, which has been obtained by simple arrangements, for restricting the range of its natural movements. This stability is of paramount importance for the maintenance of the erect attitude, and the mechanical adaptations whereby this result is obtained are such that the erect attitude may be preserved without any great degree of sustained muscular effort.

Articular Surfaces.—The head of the femur is globular in shape, and considerably exceeds a hemisphere.

It is clothed with hyaline articular cartilage on those parts which come into direct contact with the acetabulum. There is frequently more or less of extension of the articular cartilage from the head to the adjoining anterior part of the neck, an extension which is accounted for by the close and constant apposition of this portion of the neck with the posterior aspect of the ilio-femoral ligament. The limit of the articular cartilage covering the head is indicated by a sinuous border. Further, there is an absence of articular cartilage from the fovea or pit on the head of the femur.

The acetabulum is a deep cup-shaped cavity which presents a notch on its antero-inferior margin. The interior of the cup is lined with a ribbon-like band of articular cartilage which extends to the brim of the cavity, but does not cover its floor. This articular ribbon-shaped band is widest on its superoposterior aspect, and narrowest at the anterior margin of the acetabular notch.

Lig. Transversum Acetabuli.—The transverse ligament (Fig. 315) bridges the acetabular notch, and consists of strong transverse fibres which are attached to

FIG. 315.—DISSECTION OF THE HIP-JOINT.

Bottom of the acetabulum removed, and capsule of the joint thrown laterally towards the trochanters.

both of its margins, but more extensively to the postero-inferior. This ligament does not entirely fill the notch, but leaves an open interval between its inferior border and the bottom of the notch through which vessels and nerves enter the cup. The acetabular aspect of this ligament constitutes an articular surface.

The acetabulum is deepened by the **labrum glenoidale** (O.T. cotyloid ligament) (Figs. 315 and 316), which consists of a strong ring of fibro-cartilaginous tissue attached to the entire rim of the cup. The attached surface of the ring is broader than its free edge, and, moreover, the latter is somewhat contracted, so that the ligament grasps the head of the femur which it encircles. Its fibres are partly oblique and partly circular in their direction. By the former it is firmly implanted on the rim of the acetabulum and the lig. transversum acetabuli; by the latter the depth of the cup is increased through the elevation of its edge, and its mouth slightly narrowed. By one surface this ligament is also articular.

Capsula Articularis.—An articular capsule (Figs. 315 and 316) completely invests the joint cavity. Its fibrous stratum is of great strength, although it is not of equal thickness throughout, being considerably thicker on the supero-anterior aspect than at any other part. Unlike the corresponding structure of the shoulder-joint, it does not permit of the withdrawal of the head of the femur from contact with the acetabular articular surfaces, except to a very limited extent. Its fibres are arranged both in the circular and in the longitudinal direction, the former, known as the **zona orbicularis**, being best marked posteriorly, while the longitudinal fibres stand out more distinctly in front, where they constitute special ligaments. Looked at as a whole, the fibrous stratum of the capsule has the following attachments: *proximally* it surrounds the acetabulum, on the superior and posterior aspects of which it is attached directly to the hip bone, while on the anterior and inferior aspects it is attached to the non-articular surfaces of the labrum glenoidale and transverse ligaments of the acetabulum; *distally* it encircles the neck of the femur, where it is attached in front to the intertrochanteric line; above, to the medial aspect of the root of the greater trochanter; below, to the lower part of the neck of the femur, in close proximity to the lesser trochanter; behind, to the line of junction of the lateral and middle thirds of the neck of the femur. It is a matter of some importance to note that only part of the posterior surface of the neck of the femur is enclosed within the articular capsule. The femoral attachments of the fibrous stratum of the capsule vary considerably in their strength, being particularly firm above and in front, but much weaker below and posteriorly, where the orbicular fibres are well seen. Many fibres of the fibrous stratum, are reflected from its deep aspect proximally upon the neck of the femur, where they form ridges, and to these the term **retinacula** (Fig. 315) is applied.

The epiphyseal line of the head of the femur is intra-capsular; the epiphyseal lines of the two trochanters are extra-capsular.

The longitudinal fibres of the fibrous stratum of the capsule are arranged so as to form certain definite bands, viz. :—

(1) **Lig. Iliofemorale.**—The ilio-femoral ligament (Fig. 316) consists of a triangular set of fibres attached proximally, by their apex, to the inferior part of the anterior inferior iliac spine and the immediately adjoining part of the rim of the acetabulum, and distally, by their base, to the intertrochanteric line of the femur. This ligament is the thickest part of the fibrous stratum, but its sides are more pronounced than its centre, especially towards its base. Consequently the ilio-femoral ligament presents some resemblance to an inverted Y (λ); and therefore was formerly named the Y-shaped ligament of Bigelow.

The lateral or upper limb of the ilio-femoral ligament may be somewhat extended by the inclusion of additional longitudinal fibres, and described as the **ilio-trochanteric** ligament. This band arises from the anterior part of the dorsum of the acetabulum, and extends to the femoral neck, close to the anterior end of the medial surface of the greater trochanter.

(2) **Lig. Pubocapsulare.**—The pubo-capsular ligament (Fig. 316) is composed of some bands of fibres of no great strength, which extend from the lateral end of the superior ramus of the pubis, the ilio-pectineal eminence, the obturator crest and the obturator membrane, to lose themselves for the most part in the capsule, although

a certain proportion of them may be traced to the inferior aspect of the femoral neck, where they adjoin the distal attachment of the ilio-femoral ligament.

(3) **Lig. Ischiocapsulare.**—The ischio-capsular ligament consists of a broad band of short, fairly strong longitudinal fibres, which, by their proximal ends, are attached to the ischium between the lesser sciatic notch and the obturator foramen, while their distal ends become merged in the zona orbicularis of the general capsule.

Within the capsule, and quite distinct from it, there are the ligamentum teres and the Haversian gland.

Lig. Teres Femoris.—The round ligament (Fig. 315) is a strong, somewhat flattened band of fibrous tissue, attached by one end to the superior half of the pit or depression on the head of the femur. By its medial end it is attached to the lower edge of the articular surface of the transverse ligament, with extensions to the opposite borders of the acetabular notch, but chiefly to the posterior or ischial border. This ligament varies very greatly in its strength and development in different subjects, and in certain rare cases it is absent.

The so-called **Haversian gland** occupies the bottom or non-articular area of the acetabulum. It consists of a mass of fat covered by the synovial stratum of the joint. This pad of fat is continuous with the extra-capsular fat through the passage subjacent to the transverse ligament of the acetabulum.

A **synovial stratum** lines the fibrous stratum of the capsule from which it is reflected to the neck of the femur along a line which corresponds to the femoral attachments of the fibrous stratum. Thus the synovial stratum clothes more of the femoral neck anteriorly than in any other position. Posteriorly, where the fibrous stratum is feebly attached to the neck of the femur, the synovial stratum may be seen from the outside of the capsule. The synovial stratum extends close up to the articular margin of the head of the femur, and on the superior and inferior aspects of the neck it is gathered into loose folds upon the retinacula. These folds or plicæ synoviales are best marked along the line of synovial reflection, and do not reach as far as the femoral head. At its acetabular end the synovial stratum is prolonged from the inside of the capsule to the outer non-articular surface of the labrum glenoidale and transverse ligament, upon which it is continued as a lining for their acetabular or articular surfaces, and further, it provides a covering for the fat at the bottom of the acetabular fossa, as well as a complete tubular investment for the ligamentum teres femoris.

Occasionally the **synovial bursa**, which is subjacent to the tendon of the ilio-*poas* muscle, communicates with the interior of the hip-joint through an opening

FIG. 316.—DISSECTION OF THE HIP-JOINT FROM THE FRONT.

in the anterior wall of the capsule (Fig. 316), situated between the pubo-capsular ligament and the medial or lower limb of the ilio-femoral ligament.

Movements at the Hip-Joint.—The movements which occur at the hip-joint are those of a multiaxial joint. These are **flexion, extension, abduction, adduction, rotation, and circumduction**. The range of each of these movements is less extensive than in the case of the shoulder-joint, because, at the hip, the freedom of movement is subordinated to that stability which is essential alike for the maintenance of the erect attitude and for locomotion. When standing at rest in the erect attitude the hip-joint occupies the position of **extension**, and as the weight of the trunk is transmitted in a perpendicular which falls behind the centres of the hip-joints, both the erect attitude and the extended position are maintained to a large extent mechanically, by means of the tension of the ilio-femoral ligament, without sustained muscular action. Moreover, the tension of this ligament is sustained by the pressure of the front of the head and neck of the femur against its synovial surface. In this association of parts it is important to note that the articular cartilage of the femoral head may be, and in certain races is, prolonged to the front of the femoral neck; and further, that the constant friction does not destroy the synovial stratum of the capsule. Again, the same mechanism which preserves the erect attitude prevents an excessive degree of extension or dorsiflexion. In movement forwards, *i.e.* ventral flexion, the front of the thigh is approximated to the anterior abdominal wall. The amount of this movement depends upon the position of the knee-joint, because when the latter is flexed the thigh may be brought into contact with the abdominal wall, whereas when the knee-joint is straightened (*i.e.* extended) the tension of the hamstring muscles greatly restricts the amount of flexion at the hip-joint. **Abduction and adduction** are likewise much more restricted than at the shoulder-joint. **Abduction** is brought to a close by the tension of the pubo-capsular band and the lower part of the capsule, and, in addition, the upper aspect of the neck of the femur locks against the margin of the acetabulum. Excessive **adduction** is prevented by the tension of the upper band of the ilio-femoral ligament and the upper part of the capsule. **Rotation** or movement in a longitudinal axis may be either medially, *i.e.* towards the front, or laterally, *i.e.* toward the back. In the former the movement is brought to a close by the tension of the ischio-capsular ligament and posterior part of the capsule, aided by the muscles on the back of the joint; in the latter—rotation laterally—the chief restraining factor is the lateral or upper limb of the ilio-femoral ligament. The total amount of rotation is probably less than 60°.

Circumduction is only slightly less free than at the shoulder, but it is complicated by the preservation of the balance upon one foot.

The value and influence of the ligamentum teres femoris are not easily estimated, because it may be absent without causing any known interference with the usefulness of the joint. In the erect attitude this ligament lies lax between the lower part of the femoral head and the acetabular fat. In the act of walking it is rendered tense at the moment when the pelvis is balanced on the summit of the supporting femur. Analysis of this position shows the femur to be adducted, with probably, in addition, a small amount of flexion (*i.e.* bending forwards) and medial rotation. Again, this ligament is said to be tense when the thigh is rotated laterally. The equivalent of this movement is doubtless found in the rotation of the pelvis, which occurs in the act of walking at the moment of transition from the toe of the supporting foot to the heel of the advancing foot. The interest connected with this ligament is perhaps rather morphological than physiological. It is believed by some to represent the tendon of a muscle which in birds occupies a position external to the joint capsule.

ARTICULATIO GENU.

The **knee-joint** is the largest articulation in the body, and its structure is of a very elaborate nature. The part it plays in maintaining the erect attitude materially influences its construction, and special arrangements are provided for the mechanical retention of the joint in the extended position in view of the fact that the line of gravity falls in front of the centre of the articulation. Its principal axis of movement is in the transverse direction, consequently it belongs to the ginglymus or hinge variety of the diarthroses. At the same time a slight amount of rotation of the tibia in its long axis is permitted during flexion; but while this fact is of considerable importance in the study of certain accidents to which the joint is liable, as well as in the study of its comparative morphology, it is not sufficiently pronounced to interfere with its classification as a hinge-joint.

Articular surfaces pertaining to the femur, tibia, and patella enter into the formation of the knee-joint. The articular surface of the femur extends over a large part of both condyles, and may be divided into patellar and tibial portions by faintly-marked, almost transverse grooves, which pass across the articular surface immediately in front of the intercondylar notch. As a rule marginal indentations of the articular surface render the positions of these transverse grooves more distinct.

The **patellar portion** (Fig. 317) is situated anteriorly, and is common to both condyles, although developed to a larger extent in association with the lateral condyle, on which it ascends to a more proximal level than on the medial condyle. This surface is trochlear, and forms a vertical groove bordered by prominent borders.

The **tibial portion** of the articular surface of the femur is divided into two articular areas, in relation to the distal aspects of the two condyles, by the wide non-articular intercondyloid notch. These two surfaces are for the most part parallel, but in front the medial tibial surface turns obliquely laterally as it passes into continuity with the patellar trochlea, while posteriorly, under certain circumstances, *e.g.* the squatting posture, the articular surface of the medial condyle may extend to the adjoining portion of the popliteal area of the bone.

FIG. 317.—DISSECTION OF THE KNEE-JOINT FROM THE FRONT: PATELLA THROWN DISTALLY.

When the joint is in the position of extreme flexion, the patella is brought into direct contact with that part of the articular surface on the medial condyle which bounds the intercondyloid notch upon its medial and anterior aspects. This relationship is indicated by the presence of a distinct semilunar facet on the cartilage in that situation (Fig. 317). The articular surface of the femur may therefore be regarded as presenting **femoro-patellar** and **femoro-tibial** areas.

The **patella** presents on its posterior aspect a transversely elongated oval articular facet and a distal rough, triangular, non-articular area. The articular facet is divided into two principal portions by a prominent rounded vertical ridge. Of these the lateral is the wider. A less pronounced and nearly vertical ridge marks off an additional facet called the medial perpendicular facet, close to the medial margin of the articular surface. Two faint transverse ridges cut off narrow proximal and distal facets from the general articular surface without encroaching on the narrow, most medial vertical facet (Goodsir) (Fig. 317).

The head of the **tibia** presents on its superior aspect two condylar articular surfaces, separated from each other by a non-articular antero-posterior area, which is wider anteriorly and posteriorly than in the middle, where it is elevated to form a bifid *eminentia intercondyloidea*.

The **lateral condylar facet** is slightly concavo-convex from before backwards

and slightly concave transversely. This surface is almost circular, and extends to the free lateral border of the tibial condyle, where it is somewhat flattened. Posteriorly the articular surface is prolonged downwards on the condyle in relation to the position occupied by the tendon of the popliteus muscle. The **medial condylar facet** is oval in outline, and distinctly concave both in its antero-posterior and transverse diameters.

Ligaments.—Like all diarthroses, this joint is invested by an envelope or capsula articularis, which does not, however, entirely surround the articular cavity, for it is absent as a fibrous stratum proximal to the articular cavity, subjacent to the tendon of the quadriceps extensor muscle. Its specially named bands are not

FIG. 318.—THE KNEE-JOINT. POSTERIOR VIEW.

of themselves sufficient to form a complete investment, and the fibrous stratum, which largely consists of augmentations from the fascia lata and the tendons of surrounding muscles, supplies the defective areas. Thus, anteriorly, on each side of the patella and the ligamentum patellæ, expansions of the vasti tendons and fascia lata, constituting the **collateral patellar ligaments**, are evident. On the lateral side of the joint the fibular collateral ligament is hidden within a covering derived from the ilio-tibial tract of the fascia lata. On the medial side expansions from the tendons of the sartorius and semi-membranosus muscles augment the articular capsule, which here becomes continuous with the ligamentum collaterale tibiale. Posteriorly the articular capsule also receives augmentation from the tendon of the semi-membranosus muscle, but it is very thin subjacent to the origins of the gastrocnemius muscle, where it covers the posterior parts of the condyles. Not unfrequently the articular capsule presents an opening of communication between

the interior of the articular cavity and a bursa which lies under cover of the medial head of the gastrocnemius muscle.

The epiphyseal line of the distal end of the femur is partly intra-capsular and partly extra-capsular; that of the proximal end of the tibia is extra-capsular.

Ligamentum Patellæ.—The *ligamentum patellæ* or anterior ligament (Fig. 318) is a powerful flattened band, attached proximally to the apex and adjoining margins of the patella, and distally to the rough anterior tuberosity at the proximal end of the shaft of the tibia. This ligament also serves as a tendon of insertion for the quadriceps extensor muscle, and a certain number of the fibres of the tendon may be observed to run distally as a thin fibrous covering for the anterior surface of the patella. The deep surface of the tendon is separated from the front of the head of the tibia by a synovial bursa, and proximal to this it rests upon the infra-patellar pad of fat, which is placed between the tendon and the synovial stratum of the joint.

The *ligamentum posterius posterior* (ligament) (Fig. 318) is a compound structure of unequal strength, and those portions by which it establishes continuity with the lateral parts of the articular capsule are remarkably thin. It is attached proximally to the popliteal surface of the femur, close to the intercondyloid notch, with lateral extensions to the non-articular areas immediately proximal to the posterior articular margins of the two condyles, where it is closely associated with the origins of the gastrocnemius muscle.

Distally it is attached to the rough non-articular posterior border of the head of the tibia, where, to its fibular side, it presents an opening of exit for the tendon of the popliteus muscle (Fig. 318).

The tendon of insertion of the semi-membranosus muscle contributes an important expansion which augments the posterior ligament on its superficial aspect. This expansion—*lig. popliteum obliquum*—passes obliquely proximally and laterally to lose itself in the general ligament, but it is most distinct in the region between the femoral condyles, where it may present proximal and distal arcuate borders (*lig. popliteum arcuatum*). A number of vessels and nerves perforate this ligament, and hence it presents a number of apertures.

Lig. Collaterale Tibiale.—The tibial collateral ligament (O.T. internal lateral) (Figs. 317 and 318) is a well-defined, strong, flat band which is applied to the medial side of the knee-joint, and is rather wider in the middle than at either end. It is frequently regarded as consisting of two portions—an anterior or long portion, and a posterior or short one. The two parts arise close together from the medial epicondyle, immediately distal to the adductor tubercle. The **short** or **posterior portion** passes distally and slightly backwards, to be attached to the postero-medial aspect of the medial part of the tibia proximal to the groove for the semi-membranosus tendon. The **long** or **anterior portion** inclines somewhat forwards, and extending distally superficial to the tendon of the semi-membranosus, it is attached to the proximal part of the medial surface of the shaft of the tibia distal to the level of the tuberosity.

On its superficial aspect the tibial collateral ligament is augmented by prolongations from the tendons of the semi-membranosus and sartorius muscles, but is separated by a bursa from the tendons of the gracilis, semi-tendinosus, and sartorius. Its deep surface is adherent to the convex edge of the meniscus medialis, but more distally the distal and medial articular vessels intervene between the ligament and the shaft of the tibia.

Lig. Collaterale Fibulare.—The fibular collateral ligament (O.T. external lateral) (Figs. 317 and 318) is a distinct rounded band which is under cover of the ordinary capsule, and yet well separated from the articular cavity by intervening objects. It is attached proximally to the lateral epicondyle, immediately proximal to the groove occupied by the tendon of the popliteus muscle, superficial to which the ligament extends distally to be attached to the lateral side of the head of the fibula, in front of the styloid process. In its course it splits the tendon of insertion of the biceps femoris (Fig. 317), the portions of which are fixed to the head of the fibula on either side of the ligament, and a bursa may intervene between the tendon and the ligament. The distal lateral articular vessels pass

forwards subjacent to this ligament and proximal to the head of the fibula. Unlike the tibial collateral ligament, it is not attached to the corresponding meniscus.

The *ligamentum laterale externum breve seu posterius* (Fig. 317) is an inconstant structure which is attached by its proximal end immediately behind the preceding, and subjacent to the lateral head of the gastrocnemius muscle. It likewise passes superficial to the popliteal tendon, and is affixed distally to the apex capituli of the fibula.

The **intra-articular structures** of the knee-joint are more important and more numerous than in any other joint of the body.

Ligamenta Cruciata Genu.—The cruciate ligaments (O.T. crucial ligaments) are two strong, rounded, tendinous bands, which extend from the non-articular area

FIG. 319.—THE KNEE-JOINT OPENED FROM BEHIND BY THE REMOVAL OF THE POSTERIOR LIGAMENT.

on the proximal surface of the head of the tibia to the non-articular sides of the intercondyloid notch of the femur. These interarticular ligaments are distinguished from each other as the anterior or lateral and the posterior or medial. They cross each other like the limbs of an X, yet they remain distinct throughout, and each has its own partial synovial covering. They lie within the articular capsule, and extend between non-articular surfaces in relation to the longitudinal axis of the limb.

The *ligamentum cruciatum anterius* (Figs. 317, 319, and 320) is attached distally to the medial part of the rough, depressed area in front of and close to the intercondyloid eminence of the tibia. It passes obliquely proximally, laterally, and backwards to the medial non-articular surface of the lateral condyle, where it finds attachment far back in the posterior part of the intercondyloid notch. This

ligament is tense in the position of extension, and therefore it assists in maintaining the erect attitude.

The **ligamentum cruciatum posterius** (Figs. 317, 319, and 320) is somewhat shorter than the preceding. It is attached distally to the posterior part of the depressed surface behind the intercondyloid eminence of the tibia and close to the popliteal notch. Its fibres pass obliquely proximally, forwards, and medially, to be inserted into the lateral non-articular surface of the medial condyle, far forwards towards the anterior margin of the intercondyloid notch. It is rendered tense in the position of flexion.

The **semilunar menisci** are two in number—a medial and a lateral—placed horizontally between the articular surfaces of the femur and tibia. In general outline they correspond to the circumferential portions of the tibial facets upon which they rest. Each has a thick, convex, fixed border in relation to the periphery of the joint, and a thin, concave, free border directed towards the interior of the joint. Neither of them is sufficiently large to cover the whole of the tibial articular surface upon which it rests. The proximal and distal surfaces of each meniscus are smooth and free, and each terminates in an anterior and a posterior fibrous horn or cornu.

Meniscus

Medialis.—

The medial meniscus (O.T. internal semilunarfibro-cartilage) (Figs. 319 and 320) forms

very nearly a semicircle. It is attached by its anterior horn to the non-articular surface on the head of the tibia, in front of the tibial attachment of the anterior cruciate ligament, and by its posterior horn to the non-articular surface immediately in front of the tibial attachment of the posterior cruciate ligament. The deep or posterior part of the tibial collateral ligament is attached to its periphery.

Meniscus Lateralis.—The lateral meniscus (O.T. external semilunar fibro-cartilage) (Figs. 319 and 320) is attached by its anterior horn to the non-articular surface of the tibia in front of the intercondyloid eminence, where it is placed to the lateral side, and partly under cover of the tibial end of the anterior cruciate ligament. By its posterior horn it is attached to the interval between the two tubercles which surmount the intercondyloid eminence, *i.e.* in front of the attachment of the posterior horn of the meniscus medialis. This fibro-cartilage, with its two horns, therefore forms almost a complete circle. Posteriorly it is attached by its periphery to the posterior ligament, but on the lateral side it is separated from the fibular collateral ligament by the tendon of the popliteus muscle, and on this aspect its periphery is free.

The two horns of the lateral meniscus are embraced by the two horns of the medial meniscus, and, while the anterior cruciate ligament has its tibial attachment almost between the anterior horns of the two menisci, the tibial attachment of the posterior cruciate ligament is situated behind the posterior horns of the two menisci.

Both menisci possess certain accessory attachments. Thus the lateral meniscus sends a large bundle of fibres from its convex posterior border to augment the posterior aspect of the posterior cruciate ligament by which these fibres are

FIG. 320.—PROXIMAL END OF TIBIA WITH MENISCI AND ATTACHED PORTIONS OF CRUCIATE LIGAMENTS.

conducted to the femur. Again, the convex or peripheral margins of each meniscus possess certain attachments to the deep surface of the fibrous stratum of the capsule on its medial and posterior aspects, as has already been explained, but, in addition, they are attached to the non-articular circumference of the tibial head by short fibrous bands known as the *ligamenta coronaria*. Lastly, a rounded band which varies in strength, the *lig. transversum genu* (transverse ligament) (Figs. 317 and 320), stretches between the anterior convex margins of the two menisci, crossing the front part of the non-articular area on the tibial head in its course.

The *stratum synoviale* of the knee-joint is not only the largest, but the most elaborately arranged of its kind in the body. It not only lines the fibrous stratum of the capsule articularis, but it forms a more or less extensive covering for the intra-capsular ligaments and the free surface of the *infra-patellar pad of fat*. This pad acts as a wedge which fits into the interval between the patella, tibia, and femoral condyles, and the synovial stratum upon its surface forms a band or fold which extends from the region distal to the level of the patellar articular surface to the anterior part of the intercondyloid notch. It is named the *plica synovialis patellaris*. At its femoral end it is narrow and attenuated, but at its patellar end it expands on each side to form wing-like fringes or membranes—the *plicæ alares*—medial and lateral. These folds are more or less loaded with fat.

Apart from these special foldings, the synovial stratum lines the deep surface of the common extensor tendon, and extends for a variable distance proximal to the patella. This extension of the articular cavity almost always communicates with a large bursa situated still more proximally on the front of the femur. Tracing the synovial stratum distally, it will be found to cover both surfaces of the two menisci. The peripheral or convex margins of these menisci are only covered by this membrane where they are unattached to the capsule. A prolongation invests the intracapsular portion of the tendon of the popliteus muscle, and separates this tendon from the posterior part of the tibial head, besides intervening between the lateral meniscus and the head of the tibia.

From the posterior part of the articular cavity the synovial stratum extends forwards, and provides a partial covering for the cruciate ligaments between which a bursa may be found.

This somewhat complicated arrangement of the synovial stratum may be readily comprehended if it is borne in mind that it really represents the fusion of three separate synovial cavities, which in some animals are permanently distinct. These are indicated in the two femoro-tibial and the single femoro-patellar parts of the articulation.

The articular cavity may communicate with *bursæ* situated in relation to the medial head of the gastrocnemius muscle and the tendon of the semi-membranosus muscle, besides the large supra-patellar bursa already described. Lastly, there may be intercommunication between this articular cavity and that of the proximal tibio-fibular articulation.

Movements at the Knee-Joint.—In studying the movements which may occur at the human knee-joint, it is necessary to bear in mind that the lower limb of man is primarily required for purposes of support and locomotion. The principal requirement of the former function is stability accompanied by rigidity, whereas in the latter function the special desideratum is regulated and controlled mobility. Thus, in the same joint, two entirely opposite conditions have to be provided. The stable conditions of support are chiefly concerned in the maintenance of the erect attitude, and the mechanism associated therewith does not call for the exertion of a large degree of sustained muscular effort.

In standing erect the attitude of the limb is that of extension, which mainly concerns the femoro-tibial parts of the joint. In this position the force of gravity acts along a vertical line which falls in front of the transverse axis of the joint, and therefore any tendency to flexion, *i.e.* bending backwards, is mechanically counteracted by the application of a force which tends to produce bending forwards (so-called over-extension). This, however, is absolutely prohibited in normal states of the joint, by the tension of the posterior and collateral ligaments aided by the anterior cruciate ligament. The value of this fact may be seen by observing the effect produced by giving the joint a sudden push from behind, which causes an immediate reversal of the positions of the transverse and vertical axes, whereby the body weight at once produces flexion of the joint.

The menisci and the infra-patellar pad of fat also assist in maintaining extension, by reason of their close adaptation to, and packing round the condyles as these rest upon the tibia.

The anterior margin of the intercondyloid fossa is also brought into contact with the front of the anterior cruciate ligament.

In the position of extension the patella is retained at such a proximal level in relation to the trochlear surface of the femur, that the distal articular facets of the patella are in contact with the trochlea.

During locomotion the movements of the knee-joint are somewhat intricate, for both the femoro-tibial and the femoro-patellar sections of the joint are brought into action. The principal movement which results is flexion, with which there is associated, both at its beginning and ending, a certain amount of screw movement or rotation. Flexion and rotation occur at the femoro-tibial sections of the joint, whereas the movement at the femoro-patellar portion produces a regulating and controlling influence upon flexion.

Taking these factors separately, we observe that each femoral condyle adapts itself to a shallow cup formed by the corresponding tibial condyle and meniscus, and as the two femoral condyles move simultaneously and parallel to each other, there is more than the characteristic hinge-joint action, for each femoral condyle glides and rolls in its cup "like a wheel restrained by a drag" (Goodsir) when the movement of bending occurs. Thus the different parts of the condyles are successively brought into relation with the transverse axis of the joint while it passes from extension to flexion and *vice versa*. From the fact that the medial femoral condyle is longer than the lateral, it is believed that extension is completed by a movement of rotation whereby the joint becomes locked, and the anterior cruciate, the posterior and the collateral ligaments, become tense. A similar rotation initiates the movement of flexion, and unlocks the joint by relaxing the ligaments just mentioned.

Since the tibia and foot are fixed in the act of walking, it is the femur which rotates upon the tibia in passing from extension to flexion and *vice versa*; and as relaxation of the ilio-femoral ligament is essential for this rotation, some observers are of opinion that the body weight falls behind the transverse axis of the knee-joint, as in the case of the hip-joint, and consequently that extension of the knee-joint is maintained by the ilio-femoral ligament, as it is not possible to bend the knee without first having bent the hip-joint.

During flexion and extension the menisci glide along with the condyles, so as to maintain their close adaptation and preserve their value as packing agents. When the movement of flexion is completed, the condyles are retained upon the tibia, and prevented from slipping off by the tension of the posterior cruciate ligament. In this position a small degree of rotation of the tibia, both medially and laterally, is also permissible.

The regulating and controlling influence of the femoro-patellar portion of the articulation is brought into play during the movements of flexion and extension. In the latter position the distal pair of patellar facets is in apposition with the proximal part of the femoral trochlea. As flexion advances, the middle pair of facets adapt themselves to a deeper area of the trochlea, into which the patellar keel fits. When flexion is still further advanced, the proximal pair of patellar facets will be found fitting into that part of the trochlea adjoining the intercondyloid notch; and finally, when flexion is complete, the patella lies opposite the intercondyloid notch, while the forward thrust of the longer medial femoral condyle brings its semilunar facet (Goodsir) into apposition with the somewhat vertical facet at the medial border of the patella. The wedge-like influence of the patella is most marked, for it is only in the position of extension that it can be moved from side to side. The movements of the patella may be described as gliding and co-adaptation, as it slips or rocks from one pair of facets to another in its progress along the trough of the femoral trochlea.

ARTICULATIONES TIBIOFIBULARES.

The Tibio-Fibular Joints.—The proximal and distal ends of the fibula articulate with the tibia. Primarily, the fibula is required to form a strong lateral support for the ankle-joint, and therefore its articulations are so arranged as to provide a certain amount of elasticity without any sacrifice of the rigidity necessary for security. Hence the amount of movement is very small, but what there is enables these joints to be classified as arthrodial diarthroses.

Articulatio Tibiofibularis.—The proximal tibio-fibular joint is formed, on the one hand, by a flat oval or circular facet which is situated upon the postero-lateral aspect of the lateral condyle of the tibia, and is directed distally and posteriorly; on the other hand, by a similar facet on the proximal surface of the head of the fibula in front of the apex capituli.

An articular capsule (Fig. 317) invests the joint, and it may be regarded as holding the articular surfaces in apposition, although certain special bands receive separate designations. Occasionally there is an opening in the stratum fibrosum by which communication is established between the articular cavity and the knee-joint through the intermediation of the synovial prolongation, subjacent to the tendon of the popliteus muscle.

The proximal epiphyseal line of the fibula is extra-capsular.

Lig. Capituli Fibulæ Anterius.—The anterior ligament of the head of the fibula (Fig. 317) is a strong flat band whose fibres extend from the anterior aspect of the fibular head, proximally and medially, to the adjoining part of the condyle of the tibia.

Lig. Capituli Fibulæ Posterior.—The posterior ligament of the head of the fibula (Fig. 319) is a similar, but weaker band, passing proximally and medially from the posterior aspect of the fibular head to the posterior aspect of the lateral condyle of the tibia, where they are attached immediately distal to the opening in the capsule of the knee-joint, from which the tendon of the popliteus muscle escapes.

Equally strong but much shorter bands are found on the proximal and distal aspects of the joint. The former is intimately associated with the tendon of the

FIG. 321.—ANKLE-JOINT DISSECTED FROM BEHIND WITH PART OF THE ARTICULAR CAPSULE REMOVED.

biceps flexor cruris muscle which strengthens the proximal aspect of the joint, and here also is found the occasional opening by which it communicates with the knee-joint.

The **synovial stratum** is in certain cases continuous with that of the knee-joint in the manner already described.

Membrana Interossea Cruris.—The interosseous membrane (Figs. 317 and 321) plays the part of an accessory ligament both for the proximal and the distal tibio-fibular joint. It is attached to the interosseous borders on the shafts of the tibia and fibula, and binds them together. The general direction of its fibres is from the tibia distally and laterally to the fibula, but many fibres pass in the opposite direction. The membrane may extend upwards until it comes into contact with the ligaments of the proximal tibio-fibular joint, but there is always a vertical oval aperture in its proximal part for the forward passage of the anterior tibial vessels.

This aperture (Fig. 317), which is about one inch long, adjoins the shaft of the fibula at a point rather less than one inch distal to its head. Towards the distal end of the leg the distance between the tibia and the fibula rapidly diminishes, and consequently the width of the interosseous membrane is correspondingly reduced, so that it is tense throughout its entire length. In the distal part of the membrane there is a small opening for the passage of the perforating peroneal vessels. There is no sharply marked demarcation between the interosseous membrane and the interosseous ligament which connects the distal ends of the tibia and fibula—the one, indeed, may be said to run into the other.

Syndesmosis Tibiofibularis.—The distal tibio-fibular joint is not on all occasions provided with articular cartilage, so that it may either be a separate articulation, or it may merely present a series of ligaments which are accessory to the (ankle-joint), because it is clear that, under any circumstances, the object aimed at in this articulation is to obtain additional security for the ankle-joint. The articular surface on the tibia, when present, constitutes a narrow articular strip on the lateral side of the distal end of the bone, and the joint-cavity is practically an upward extension of the ankle-joint. The corresponding fibular facet is continuous with the extensive articular area, by means of which the fibula articulates with the talus. By far the greater part of the opposing surfaces of tibia and fibula are, however, non-articular and rough.

The supporting ligaments are of great strength.

Lig. Malleoli Lateralis Anterior.—The anterior ligament of the lateral malleolus (O.T. anterior inferior tibio-fibular ligament) (Fig. 322) consists of strong fibres which pass obliquely distally and laterally from the front of the distal end of the tibia to the front of the lateral malleolus.

Lig. Malleoli Lateralis Posterior.—The posterior ligament of the lateral malleolus (O.T. posterior inferior tibio-fibular ligament) (Figs. 321 and 322) is equally strong, and passes in a similar direction between corresponding posterior surfaces.

Lig. Malleoli Lateralis Distale.—The distal ligament of the lateral malleolus (O.T. transverse inferior tibio-fibular ligament) (Figs. 321 and 322) stretches between the posterior border of the distal end of the tibia and the proximal end of the pit on the medial and posterior aspect of the lateral malleolus.

Ligamentum Interosseum.—An interosseous ligament, powerful and somewhat extensive, connects the contiguous rough non-articular surfaces. Proximally, as already mentioned, it is continuous with the interosseous membrane. Anteriorly and posteriorly it comes into contact with the more superficial ligaments. Distally it descends until it comes into intimate association with the articular cavity.

A **synovial stratum** is found lining the small articular cavity, but it is always a direct prolongation from that which lines the ankle-joint.

ARTICULATIONES PEDIS.

ARTICULATIO TALOCRURALIS.

The **ankle-joint** is a ginglymus variety of a diarthrosis. The bones which enter into its formation are the distal ends of the tibia and fibula, with the articular areas on the superior, lateral, and medial surfaces of the talus. The tibia and fibula, aided by the distal ligament of the lateral malleolus, form a three-sided socket within which the talus is accommodated. The roof or most proximal part of the socket, which is wider in front than behind, is formed chiefly by the quadrilateral articular surface which characterises the distal end of the tibia, but towards its postero-lateral margin the distal ligament of the lateral malleolus assists in its formation. Here also the tibial articular surface is continuous with the narrow articular facet already described as forming part of the tibio-fibular syndesmosis. The medial wall of the socket is formed by the articular facet on the lateral side of the medial malleolus, and there is no interruption of the articular cartilage between the roof and medial wall. The lateral wall of the socket is quite separate from the foregoing parts, and consists of a large triangular facet upon the medial side

of the lateral malleolus. This facet is situated immediately in front of the deep pit which characterises the posterior part of this surface of the fibula.

A small lunated facet is frequently found upon the anterior surface of the distal end of the tibia, particularly among those races characterised by the adoption of the "squatting" posture. When this facet exists it is continuous with the anterior margin of the roof of the socket, and it articulates with a similar facet upon the superior surface of the neck of the talus in the extreme flexion of the ankle-joint which "squatting" entails.

The articular surface upon the body of the talus adapts itself to the tibio-fibular socket, and presents articular facets corresponding to the roof and sides of the socket. Thus the superior surface of the talus possesses a quadrilateral articular area, wider in front than behind, distinctly convex in the antero-posterior direction, and slightly concave transversely. In addition, towards its postero-lateral margin, there is also a narrow antero-posterior facet corresponding to the distal ligament of the lateral malleolus. The articular cartilage of this superior surface is continued without interruption to the tibial and fibular sides of the bone, although the margins of the superior area are sharply defined from the facets on

the sides, the lateral of which is triangular in outline, while the medial is piriform, but in each case the surface is vertical.

FIG. 322.—ARTICULAR SURFACES OF TIBIA AND FIBULA WHICH ARE OPPOSED TO THE TALUS.

Ligaments.—The ligaments form a complete investment for the joint, *i.e.* a *fibrous stratum* of an articular capsule in which the individual parts vary considerably in strength, and are described under separate names. Their proximal attachments are

restricted to the epiphyses of the distal ends of the tibia and fibula, and the epiphyseal lines are therefore extra-capsular.

The **anterior ligament** is an extremely thin membrane, containing very few longitudinal fibres. It extends from the distal border of the tibia to the proximal border of the head of the talus, passing in front of a pad of fat which fills up the hollow above the neck of that bone.

The **posterior ligament** is attached to contiguous non-articular borders of the tibia and talus. Many of its fibres radiate medially from the lateral malleolus. This aspect of the joint is strengthened by the strong, well-defined, distal ligament of the lateral malleolus already described in connexion with the tibio-fibular syndesmosis.

The **lateral ligament** (Figs. 321, 322, and 324) is very powerful, and is divisible into three fasciculi, which are distinguished from each other by names, descriptive of their chief points of attachment.

Lig. Talofibulare Anterius.—The anterior fasciculus is the shortest. It extends from the anterior border of the lateral malleolus to the talus immediately in front of its lateral articular surface.

Lig. Calcaneofibulare.—The middle fasciculus is a strong and rounded cord. It is attached by one end to the front of the tip of the lateral malleolus, and by the other to the lateral side of the calcaneus immediately proximal to the groove for the peroneal tendons.

Lig. Talofibulare Posterius.—The posterior fasciculus is the strongest. It runs transversely between the distal part of the fibular fossa on the medial aspect of the malleolus and the posterior surface of the talus, where it is attached to the posterior process and the adjoining rough surface. Sometimes this process is detached from the talus, and represents a separate bone—the *os trigonum*.

Lig. Deltoideum.—The deltoid ligament is the medial ligament of the ankle-joint (Figs. 322 and 323). It has the general shape of a delta, and is even stronger

than the lateral ligament. It is attached proximally to a marked impression on the distal part of the medial malleolus, and below, in a continuous layer, to the navicular, talus or calcaneus. In it we may recognise the following special bands—(a) the *lig. talotibiale anterius*, which extends from the front of the medial malleolus to the neck of the talus; (b) the *lig. talotibiale posterius*, stretching between the back of the medial malleolus and the postero-medial rough surface of the talus; (c) the *lig. tibionaviculare*, which extends from the tip of the medial malleolus to the medial side of the navicular body; (d) the *lig. calcaneotibiale*, which extends between the tip of the medial malleolus and the medial side of the sustentaculum tali; (e) *lig. talotibiale profundum*, which consists of deeper fibres extending from the tip of the medial malleolus to the medial side of the talus.

A **synovial stratum** lines the fibrous stratum of the articular capsule and, as

FIG. 323.—ANKLE AND TARSAJ-JOINTS FROM THE TIBIAL ASPECT.

already described, the articular cavity extends into the interval between the tibia and fibula distal to the tibio-fibular interosseous ligament. Both at the front and back of the ankle-joint, as well as proximally in the angle formed by the three bones, the synovial membrane covers pads of fat.

Movements at the Ankle-Joint.—In the erect attitude the foot is placed at right angles to the leg; in other words, the normal position of the ankle-joint is **flexion**. Those movements which tend to diminish the angle so formed by the dorsum of the foot and the front of the leg are called **dorsiflexion**, while those which tend to increase the angle, *i.e.* to straighten the foot upon the leg, are called **extension**. As a matter of fact neither dorsiflexion nor extension is ever completely carried out, and the range of movement of which the foot is capable is limited to about 90°. These movements occur about an obliquely transverse axis, as is indicated by the natural lateral pointing of the toes. The weight of the body falls slightly anterior to the ankle-joint, so that a certain amount of muscular action is necessitated in order to maintain the foot at right angles to the leg; but additional stability is obtained from the obliquity above mentioned.

When the foot is raised from the ground, muscular action tends naturally to produce a certain amount of extension. When the foot is extended, as in standing on the toes, the posterior narrow part of the talus moves forwards into the wider part of the interval between the tibia and fibula, whereas in dorsiflexion, as in raising the anterior part of the foot from the ground, the widest part of the talus is forced back between the tibia and fibula; but notwithstanding the difference between these two movements, the fibula remains in close contact with the talus by reason of the action of the *ligamentum malleoli lateralis distale* and the posterior talo-fibular ligament, so that lateral movement is prevented.

It is doubtful whether lateral movement at the ankle-joint can be obtained by any natural movement of the foot, although it is generally believed that in the position of partial extension a small amount of side-to-side movement may be produced by the application of external force. "This apparent play" of the ankle-joint during extension "is really due to oscillation of the small bones of the foot on each other, largely of the navicular on the talus, but also of the cuboid on the calcaneus. Excessive mobility of these latter is restrained by an important function of the posterior tubercle of the cuboid which locks into a notch in the calcaneus" (Blake).

ARTICULATIONES INTERTARSEÆ.

The **intertarsal joints** are all diarthroses in which the gliding movement is characteristic, as in the carpus. With the view of obtaining a proper conception of the many beautiful mechanical principles involved in the construction of the foot, it is necessary to study these articulations with considerable attention to detail.

FIG. 324.—LIGAMENTS ON THE LATERAL ASPECT OF THE ANKLE-JOINT AND ON THE DORSUM OF THE TARSUS.

Articulatio Talocalcanea.—The talus and calcaneus articulate with each other in the talo-calcaneal joint.

This joint is situated between the inferior facet on the body of the talus and a corresponding facet on the superior aspect of the posterior part of the calcaneus. On each bone the articulation is limited in front by a wide, deep groove which runs obliquely across each bone from the medial to the lateral side and forwards.

The supporting and investing ligaments form the fibrous stratum of an **articular capsule**, consisting for the most part of short fibres, but the joint derives additional strength from the calcaneo-fibular ligaments of the ankle-joint. The fibrous stratum of the capsule is subdivided into the following talo-calcaneal bands:—

The **ligamentum talocalcaneum anterius** consists of a band of short fibres placed immediately in relation to the anterior end of the deep groove which bounds the articular facets. They are attached to the antero-lateral aspect of the neck of the talus, from which they extend downwards to the adjacent superior surface of the calcaneus.

The **ligamentum talocalcaneum laterale** (Fig. 324) is in continuity with the posterior border of the preceding ligament, and it is placed parallel to, but on

a deeper plane than, the calcaneo-fibular ligament of the ankle-joint. It consists of short fibres passing between the adjacent rough lateral margins of the two bones.

The **ligamentum talocalcaneum posterius** (Fig. 324) closes the joint-cavity on its posterior aspect. It consists of fibres which radiate from the posterior aspect of the posterior process of the talus to the superior surface of the calcaneus, immediately behind the articular facet.

The **ligamentum talocalcaneum mediale** lies obliquely on the medial side of the joint, and consists of fibres which extend from the medial posterior tubercle of the talus to the posterior roughened border of the sustentaculum tali. Some of its fibres become continuous with the plantar calcaneo-navicular ligament.

The **ligamentum talocalcaneum interosseum** (Fig. 325) closes the antero-medial aspect of the joint. It is the strongest of the series of ligaments entering into the capsule. Compared with it the other bands are, comparatively speaking, insignificant. Its attachments are to the bottom of each groove, so that it occupies the tarsal canal formed by these opposing grooves.

A **synovial stratum** lines the fibrous stratum, and it is distinct from other tarsal synovial membranes.

Articulatio Talocalcaneonavicularis. — This is one of the most important of the joints of the foot, not only because the talus is here situated in relation to the summit of the antero-posterior arch of the foot, but because the head of the talus is received into a composite socket made up of the sustentaculum tali, the navicular, and the plantar calcaneo-navicular ligament.

The articular surface on the head of the talus presents anteriorly a convex rounded facet for articulation with the navicular, inferiorly a convex facet which rests upon the sustentaculum tali, and intermediate between these two there is a triangular facet which articulates with the plantar calcaneo-navicular ligament. All these facets are in continuity with each other, and are in front of the tarsal groove on the inferior surface of the talus. Occasionally a fourth narrow facet is found along the lateral and posterior part of the articular surface of the head of the talus, whereby it articulates with the calcaneo-navicular part of the bifurcate ligament.

The navicular bone presents a shallow, cup-shaped, articular cavity towards the head of the talus.

The articular surface of the sustentaculum tali is concave, and is usually marked off into two facets.

Two ligaments play an important part in binding together the calcaneus and the navicular, although these bones do not directly articulate; and further, these ligaments provide additional articular surfaces for the head of the talus. These are the two following:—

(a) The **ligamentum calcaneonaviculare plantare** (Figs. 325 and 326) is an extremely powerful fibro-cartilaginous band. It extends between the anterior margin of the sustentaculum tali and the plantar surface of the navicular. Certain of its upper fibres radiate upwards on the medial surface of the navicular, and

FIG. 325.—THE COMPOSITE ARTICULAR SOCKET FOR THE HEAD OF THE TALUS.

become continuous with the tibio-navicular portion of the deltoid ligament of the ankle-joint. The plantar aspect of this ligament is in contact with the tendon of the *tibialis posterior* muscle, through which the head of the talus receives great support. Superiorly it contributes an articular surface which forms a triangular portion of the floor of the composite socket in which the head of the talus is received.

(b) The calcaneo-navicular part of the bifurcate ligament (Fig. 325) lies deeply in the front part of the sinus tarsi, *i.e.* the interval between the talus and calcaneus. Its fibres are short, and extend from the dorsal surface of the front part of the

FIG. 326.—PLANTAR ASPECT OF TARSAI AND TARSO-METATARSAL JOINTS.

calcaneus, immediately to the lateral side of the sustentacular facet, forwards to the lateral side of the navicular bone. Frequently the ligament presents a surface which articulates with the head of the talus, and in these cases it forms a part of the composite socket.

The cavity of the talo-calcaneo-navicular joint is closed posteriorly by the interosseous talo-calcaneal ligament already described. On its medial and lateral inferior aspects it is closed by the calcaneo-navicular ligaments.

The superior and lateral aspects are covered by the *ligamentum talonaviculare dorsale*. This ligament is thin, and extends from the proximal non-articular area on the head of the talus to the dorsal surface of the navicular bone. It may be subdivided into *dorsal*, *lateral*, and *medial* talo-navicular bands (Fig. 324), which, with the calcaneo-navicular and interosseous talo-calcaneal ligaments, complete the capsular investment of the joint.

A distinct **synovial stratum** lines all parts of the capsule of the joint.

Articulatio Calcaneocuboidea.—This is situated between the anterior concavo-convex surface of the calcaneus and the posterior similar surface of the cuboid.

The **ligaments** which invest this joint constitute a **calcaneo-cuboid capsule**, whose parts are arranged in relation to the four non-articular sides of the cuboid bone, and are especially strong upon the plantar aspect, in relation to their great importance in resisting strains.

The **medial calcaneo-cuboid ligament** occupies part of the interval between the talus and calcaneus—the sinus tarsi. It is the *calcaneo-cuboid part* of the **lig. bifurcatum**, and is a V-shaped structure, of which the single end is attached to the calcaneus, and the double ends separate to reach contiguous areas on the navicular and cuboid respectively.

The **dorsal calcaneo-cuboid ligament** (Fig. 324) is a broad portion of the fibrous stratum of the capsule extending from the dorsal and lateral surfaces of the calcaneus to the dorsal surface of cuboid.

The **lateral calcaneo-cuboid ligament** is another but narrower part of the capsule which extends from the lateral aspect of the calcaneus to the lateral side of the cuboid, immediately behind the facet on the tuberosity.

The **inferior calcaneo-cuboid ligament** consists of two parts—a superficial and a deep. The superficial series of fibres, the **long plantar ligament** (Fig. 326), is attached to the plantar surface of the calcaneus in front of the processes of the tuber calcanei. It forms a long powerful structure which runs forwards to be fixed to the plantar surface of the cuboid ridge, but many of its fibres pass superficial to the tendon of the peronæus longus, and extend to the bases of the third, fourth, and fifth metatarsal bones.

The deep series of fibres, the **plantar calcaneo-cuboid ligament** (O.T. **short plantar ligament**) (Fig. 326), is distinctly separated from the long plantar ligament by a layer of areolar tissue. It forms a broad but short band of great strength, which is attached to the plantar surface of the distal end of the calcaneus, and extends to the plantar surface of the cuboid just behind the ridge. Both of these ligaments are of great importance in maintaining the longitudinal arch of the foot, and in this respect are only second to the plantar calcaneo-navicular ligament.

A **synovial stratum** lines the capsule.

Articulatio Tarsi Transversa (Choparti).—This is a term sometimes applied to the talo-navicular and calcaneo-cuboid joints. These articulations do not communicate with each other; and although there is an occasional direct articulation between the navicular and cuboid, it does not constitute an extension of the transverse tarsal joint, but is a prolongation from the series of cuneo-navicular and cuneo-cuboid articulations.

Nevertheless there is always a set of **ligaments** which bind the navicular and cuboid bones together, and these may be regarded as accessory to the various transverse tarsal joints.

The **dorsal cuboideo-navicular ligament** (Fig. 324) consists of short oblique fibres which attach the contiguous dorsal surfaces of the cuboid and navicular bones.

The **plantar cuboideo-navicular ligament** is transverse in direction, and extends between adjacent plantar areas of the cuboid and navicular bones.

The **interosseous cuboideo-navicular ligament** intervenes between contiguous surfaces of the same bones. When there is an extension of the cuneo-navicular joint backwards between the navicular and cuboid, it is situated in front of the last-mentioned ligament, and is called the **articulatio cuboideonavicularis**. Around this joint the preceding ligaments are grouped. Since, however, the joint is inconstant while the ligaments are always present, it is preferable to consider them as above indicated.

Articulatio Cuneonavicularis.—The cuneo-navicular articulation joint is situated between the navicular and the three cuneiform bones. The anterior surface of the navicular presents facets for each of the cuneiform bones, but its articular surface is not interrupted. These facets form a somewhat convex anterior surface

which fits into the shallow articular concavity presented by the proximal ends of the three cuneiform bones. This joint may be extended by the occasional cuboideo-navicular articulation already referred to.

The **fibrous stratum** of the articular capsule is composed of short strong bands which are distinctly visible on all sides except towards the cuboid bone, where the joint may communicate with the cuneo-cuboid and cuboideo-navicular joints. Anteriorly the joint communicates with the intercuneiform articulations. The dorsal parts of the capsule are short longitudinal bands termed **dorsal cuneo-navicular ligaments** (Figs. 323 and 324). These extend without interruption to the medial aspect of the joint. Inferiorly there are similar bands, known as **plantar cuneo-navicular ligaments**, also longitudinal in direction, but intimately associated with offsets from the tendon of the tibialis posterior muscle.

The **synovial stratum** which lines the fibrous stratum sends prolongations forwards on each side of the second cuneiform bone, and in addition it often communicates with the cuneo-cuboid joint cavity, and it always communicates with the cuboideo-navicular cavity when that joint exists.

Articulationes Intercuneiformeæ.—These are two in number, and exist between adjacent contiguous surfaces of the three cuneiform bones. These surfaces are partly articular and partly non-articular. The small size of the second cuneiform bone allows the first cuneiform as well as the third cuneiform to project forwards beyond it on both sides, and therefore the articular surfaces turned towards the second cuneiform are not entirely occupied by that bone. They form a recess towards the metatarsus, into which the base of the second metatarsal bone is thrust.

Ligamenta intercuneiformea dorsalia constitute fairly strong transverse bands which extend between adjacent dorsal surfaces and invest the joint cavities in this direction.

The **ligamenta intercuneiformea plantaria** are two strong bands which pass from the rough non-articular areas on opposite sides of the second cuneiform to the opposing surfaces of the first and third cuneiform bones. These ligaments shut in the joint cavities inferiorly, and also anteriorly in the case of the lateral of the two joints.

The **synovial stratum** is an extension of that which lines the cuneo-navicular joint; but while it is restricted to the lateral of the two joints, in the case of the medial one it is prolonged still farther forward to the tarso-metatarsal series of joints.

Articulatio Cuneocuboidea.—This occurs between the rounded or oval facets on the opposing surfaces of the cuboid and third cuneiform.

The **ligamentum cuneocuboideum dorsale** is a flat, somewhat transverse band which closes the joint on its dorsal aspect, and extends between the dorsal surfaces of the two bones.

The **ligamentum cuneocuboideum plantare** is difficult to determine. It is situated deep to the long plantar ligament, and extends between adjacent rough surfaces of the two bones.

The **ligamentum cuneocuboideum interosseum** is the strongest. It closes the joint cavity anteriorly, and is attached to the contiguous non-articular surfaces of the two bones.

The **synovial stratum** is frequently distinct, but at other times the joint cavity communicates with those of the cuneo-navicular and cuboideo-navicular articulations.

Synovial Strata of the Intertarsal Joints.—Four and sometimes five distinct and separate synovial strata may thus be enumerated in connexion with the tarsal articulations, viz.: (1) talo-calcaneal; (2) talo-calcaneo-navicular; (3) calcaneo-cuboid; (4) cuneo-navicular and its extensions; (5) occasionally cuneo-cuboid.

ARTICULATIONES TARSOMETATARSEÆ.

The **tarso-metatarsal joints** are found between certain articular facets on the cuboid and three cuneiform bones on the one hand, and others on the bases of the five metatarsal bones. These articulations are associated with three distinct synovial cavities—namely, a medial, lateral, and intermediate.

(1) The **medial tarso-metatarsal articulation** occurs between the distal convex reniform surface of the first cuneiform bone and the concavo-reniform surface on the proximal aspect of the base of the first metatarsal bone.

Ligaments which form the fibrous stratum of the **articular capsule** surround the articulation. In the capsule the **ligamenta tarsometatarsea dorsalia et plantaria** are its strongest parts, but it is not deficient either on the medial or on the lateral aspects.

A separate **synovial stratum** lines the fibrous stratum.

(2) The **intermediate tarso-metatarsal articulation** is an elaborate joint. It involves the three cuneiform bones and the bases of the second, third, and part of the fourth metatarsal bones.

The articulation presents the outline of an indented parapet both on its tarsal and its metatarsal aspects. Thus, on its tarsal side, the first and the third cuneiform bones project in front of the second cuneiform, so that the latter only presents a distal surface to the articulation; while the first cuneiform presents a portion of its lateral surface, and the third cuneiform presents both its distal and portions of its lateral and medial surfaces, since it projects in front of the cuboid bone. On its metatarsal side the base of the second metatarsal bone fits into the indentation between the third and first cuneiforms, to which it presents lateral and medial articular facets, but its proximal facet rests upon the distal facet of the second cuneiform. The base of the third metatarsal bone rests its proximal facet upon the third cuneiform. The fourth metatarsal base presents part of its medial facet to the lateral side of the third cuneiform. In this way the indentations alternate on the two sides of the articulation, and an extremely powerful interlocking of parts is provided, which places any marked independent movement of these metatarsal bones entirely out of the question.

The **ligamenta tarsometatarsea dorsalia** are broad, flat bands which represent the most distinct part of the fibrous stratum of an investing **articular capsule**. They pass from behind forwards, and while the second metatarsal bone receives three, *i.e.* one from each cuneiform, the third metatarsal only receives one—from the third cuneiform.

The **ligamenta tarsometatarsea plantaria** correspond with the foregoing in their general arrangement, but they are weaker. That for the second metatarsal is the strongest. Oblique bands extend from the first cuneiform bone to the second and third metatarsals.

The **ligamenta cuneometatarsea interossea** are three in number. The *medial* connects the lateral side of the first cuneiform with the medial side of the base of the second metatarsal bone. The *middle* connects the medial side of the third cuneiform with the lateral side of the base of the second metatarsal. The *lateral* connects the adjacent lateral sides of the third cuneiform and third metatarsal.

The **stratum synoviale**, which lines this articulation, sends a prolongation backwards between the first and second cuneiform bones, where it opens into the cuneo-navicular joint. It is likewise prolonged forwards upon both sides of each of the bases of the second and third metatarsal bones.

(3) The **lateral tarso-metatarsal articulation** is found between the proximal surfaces of the bases of the fourth and fifth metatarsal bones and the distal surface of the cuboid.

The fibrous stratum of the investing **articular capsule** may be resolved into the following ligaments:—

The **ligamenta tarsometatarsea dorsalia** resemble those already described. The base of the fourth metatarsal receives one from the third cuneiform and one from the cuboid. The base of the fifth metatarsal receives one from the cuboid.

The **ligamenta tarsometatarsea plantaria** are the weakest bands of the series, and consist of scattered fibres passing from the cuboid to the bases of the two metatarsals. Some fibres, which are almost transverse, extend from the third cuneiform to the fifth metatarsal, and additional fibres reach the fifth metatarsals from the long plantar ligament.

Occasionally the tarsal end of the **ligamentum cuneometatarseum interosseum laterale** is attached to the medial margin of the cuboid.

The **synovial stratum** is restricted to this articulation, and merely sends a prolongation forwards between the opposing articular surfaces of the fourth and fifth metatarsal bases.

ARTICULATIONES INTERMETATARSEÆ.

The **intermetatarsal articulations** are found between adjacent lateral aspects of the bases of the four lateral metatarsal bones. The articular facets are small, oval, or rounded surfaces which occupy only a limited portion of the flattened contiguous surfaces of the bones. Each joint is provided with an **articular capsule**, which, however, is not a complete investment, because the three joint cavities are in free communication on their proximal aspects with the tarso-metatarsal joint cavities—one with the lateral and two with the intermediate. The definite fibres of each fibrous stratum are situated chiefly in the transverse direction.

The **ligamenta basium dorsalia** are short bands which extend from one base to the other.

The **ligamenta basium plantaria** and the **ligamenta basium interossea** are similarly arranged, but the interosseous ligaments are the strongest and most important members of this series.

The **synovial stratum** of each capsule is an extension from the lateral and intermediate tarso-metatarsal joints.

Frequently a bursa is found between the bases of the first and second metatarsal bones. It produces an appearance of indistinct facetting upon these bones, and it may communicate with the first cuneo-metatarsal joint.

The **ligamentum metatarsale transversum (transverse metatarsal ligament)** lies upon, and is attached to, the non-articular plantar aspects of the heads of all the metatarsal bones. It differs from the corresponding ligament in the palm in the fact that it binds all the metatarsal bones together, whereas in the palm the thumb is left free. It is closely associated with the plantar fibrous plates of the metatarso-phalangeal joints, to the plantar surfaces of which it contributes prolongations.

ARTICULATIONES METATARSOPHALANGEÆ.

Metatarso-phalangeal Joints.—Each of these joints is a modified ball-and-socket in which a shallow cup upon the bases of the first phalanges receives the somewhat globular head of a metatarsal bone.

Each joint retains a modified **articular capsule** which invests the joint. Its only distinct bands of the fibrous stratum are the **ligamenta collateralia**. These are strong cord-like bands which are situated on the medial and lateral sides of each joint, where they extend between adjacent rough surfaces.

On the dorsal aspect, ligaments distinct from the dorsal expansion of the extensor tendons can hardly be said to exist. The plantar aspect of the capsule consists of a thick **fibrous plate** strengthened by transverse fibres to form the **plantar accessory ligament**, which in the case of the great toe presents developed within it two large sesamoid bones. In the other toes this plate remains fibrous throughout, and is grooved on its plantar aspect for the accommodation of the long flexor tendons. It will thus be seen that the metatarso-phalangeal joints are constructed upon a plan very similar to that of the corresponding joints in the hand.

A **synovial stratum** lines the capsule of each articulation; and the epiphyseal lines of the metatarsals and phalanges are extra-capsular.

ARTICULATIONES DIGITORUM PEDIS.

Interphalangeal Joints.—Each toe possesses two interphalangeal joints except the great toe, which has only one. Not infrequently in the little toe the distal joint is obliterated through ankylosis. All the joints of this series are uniaxial or hinge joints. The nature of the articular surfaces closely resembles the corresponding joints in the fingers.

Each joint possesses an **articular capsule** which is either very thin or limited to the synovial stratum on the dorsal aspect. The plantar surface of the capsule is strengthened by a **fibrous plate**. The **ligamenta collateralia** are well-defined bands similar to those already described in connexion with the metatarso-phalangeal joints.

A **synovial stratum** lines each capsule in the series. The epiphyseal lines are extra-capsular.

Mechanism of the Foot.—The bones of the foot are arranged in the form of a longitudinal and a transverse arch. The longitudinal arch is built on a very remarkable plan. Posteriorly the mass of the calcaneus constitutes a rigid and stable pier of support, while anteriorly, by increasing the number of component parts, the anterior pier acquires great flexibility and elasticity without sacrificing strength or stability. The summit of the arch is formed by the talus, which receives the weight of the body from the tibia, and the resilience of the arch is assured by the calcaneo-navicular, calcaneo-cuboid, and long plantar ligaments, together with the plantar aponeurosis, which act as powerful braces or tie-bands, preventing undue separation of the piers of the arch, and consequent flattening of the foot. The weight of the body is distributed over all the five digits, owing to the arrangement of the bones of the foot in two parallel columns, a **medial** and a **lateral**. The former, consisting of the talus, navicular, and the three cuneiforms, with the three medial metatarsal bones, distributes weight through the talo-navicular joint, while the latter (*i.e.* the lateral column), comprising the calcaneus, cuboid, and the two lateral metatarsal bones, acts in a similar manner through the talo-calcanean joint. The main line of immobility of this arch passes from the heel forwards through the middle toe, but its anterior section, which is slender, is supported on either side by two metatarsal bones, with their proximal tarsal associations, in all of which greater freedom of movement is found. The transverse arch is most marked at the level of tarso-metatarsal articulations. The intersection of these two arches at right angles to each other introduces an architectural feature of great importance in connexion with the support of heavy weights. These longitudinal and transverse arches of the foot are in effect “vaults” intersecting each other at right angles, and in relation to the area which is common to both “vaults” the body weight is superposed exactly as the dome of a cathedral is carried upon two intersecting vaults.

Movements at the Joints of the Tarsus, Metatarsus, and Phalanges.—Considered in detail, the amount of movement which takes place between any two of these bones is extremely small, and, so far as the tarsus and metatarsus are concerned, it is mostly of the nature of a gliding motion.

At the metatarso-phalangeal and interphalangeal joints movement is much more free, and is of the nature of **flexion** (bending of the toes towards the sole of the foot, *i.e.* plantar flexion) and **extension**. The latter movement when continued so as to raise the toes from the ground, and bend or approximate them towards the front of the leg, is termed **dorsiflexion**. Coincident with dorsiflexion there is always associated a certain amount of spreading of the toes, which is called **abduction**, and similarly with prolonged flexion there follows a diminution or narrowing of the transverse diameter of the anterior part of the foot by drawing the toes together—a movement termed **adduction**. In the foot the movements of abduction and adduction take place in regard to a plane which bisects the foot antero-posteriorly through the second toe, for this toe carries the first and second dorsal interosseous muscles.

Notwithstanding the small amount of possible movement in connexion with individual tarsal and metatarsal joints, yet the sum total of these movements is considerable as regards the entire foot. In this way the movements of **inversion** and **eversion** of the foot result. By inversion we mean the raising of the medial border of the foot so that the sole looks medially, while the toes are depressed towards the ground, and the lateral border of the foot remains downwards. This takes place chiefly at the talo-calcanean joint, but the transverse tarsal joints also participate.

Eversion is chiefly the opposite of inversion, and the return of the foot to the normal position of the erect attitude; but under certain conditions it may be carried further, so that the lateral border of the foot is raised from the ground, while the medial border is depressed. In both of these movements there is **rotation** between the talus and calcaneus about an oblique axis which passes from the medial side of the neck of the talus to the lateral and inferior part of the calcaneus.

Of course, all the movements of the foot are subordinated to its primary functions as an organ of support and progression. For these purposes its longitudinal and transverse arches are of extreme importance. The longitudinal arch resting on the calcaneus behind and the heads of

the metatarsal bones in front receives the weight of the body, as already explained, on the summit of the talus in the line of the third toe. Hence it is that the medial malleolus appears to be unduly prominent on the medial side of the ankle. The transverse arch buttresses the longitudinal one, and therefore, whether the body weight fall to the lateral or the medial side of the longitudinal arch, it is supported by a mechanism at once stable, flexible, and elastic, or resilient, and capable of reducing to a minimum all jars that may be received by the fore part of the foot. As the heel is raised in the act of walking, the weight is gradually transferred from the lateral to the medial side of the foot, until the foot finally leaves the ground with a propulsive movement, which results from flexion of the phalanges of the great toe. In this connexion it is worthy of note that the longitudinal line of greatest strength is on the medial side of the longitudinal arch, *i.e.* in relation to the great toe.

THE MUSCULAR SYSTEM.

MYOLOGY.

By A. M. PATERSON.

THE movements of the various parts and organs of the body are brought about by the agency of muscle-cells, which are characterised by a special histological structure and by the special function of contracting in length under the influence of a proper stimulus.

There are three classes of muscle-cells: (1) the **striated**, and usually voluntary muscle-cells, out of which the skeletal muscular system is constructed; (2) the **non-striated**, involuntary muscle-cells, occurring in the walls of vessels and hollow viscera, etc.; and (3) the **cardiac muscle-cells**, striated but involuntary, of which the substance of the heart is composed.

The following section deals solely with the skeletal muscles, the structure, arrangement, and mechanical action of which are based upon a common plan.

The cells of which the skeletal muscles are composed are long, narrow, and characterised by a peculiar striation, which is different from the striation of the muscle-cells of the heart; they also differ both in structure and function from the non-striated muscle-cells which occur in viscera and vessels.

A **typical skeletal muscle** consists of a fleshy mass enveloped in a membranous **aponeurosis** or **fascia**, and provided at its extremities or borders with membranous or tendinous attachments to bone, cartilage, or fascia.

Each muscle is made up of a number of **fasciculi** or bundles, arranged together in different muscles in different ways, so as to give rise to the particular form of the muscle in question. These fasciculi are clothed and connected together by a delicate connective tissue, the **perimysium externum**, continuous externally with the fascia enclosing the muscle.

Each muscular bundle or fasciculus is composed of a number of narrow, elongated **muscle-cells** or fibres, held together by a still more delicate connective tissue, the **perimysium internum**. This tissue is connected on the one hand with the **sarcolemma** or cell-wall of the muscle-cell, and on the other hand with the coarser tissue of the **perimysium externum** enclosing the muscular bundles.

By means of these connective tissue envelopes the muscle-cells, the essential agents of motor activity, are brought into firm and intimate relation with the osseous or other attachments of the muscle. Through the agency of **sarcolemma**, **perimysium internum**, **perimysium externum**, **fascia**, and **tendon**, the muscle-cell when it contracts can produce a precise and definite effect upon the weight to be moved.

Each muscle is supplied by one or more nerves, which, in their course through the muscle, separate into smaller and smaller branches, ultimately, by their terminal filaments (axons), forming special end-organs in relation to each muscle-cell.

While a muscle may thus be looked upon as an organ endowed with particular properties, and executing a definite movement in response to a stimulus by the simultaneous contraction of its constituent cells, the various muscles may further be considered in groups, associated together by mode of development, nerve-supply, and co-ordination of action. For example, we speak of the hamstring muscles of

the thigh, the muscles of the back, and the prevertebral muscles,—groups in which separate muscles are associated together by development, nerve-supply, and action. In their development the separate muscles arise from the subdivision of a larger stratum, as in the limbs, or from the fusion of segmental elements (myotomes), as in the case of the axial muscles. The peripheral nerves supplying skeletal muscles are distributed, through the plexuses or directly, so as to associate particular muscles morphologically and physiologically, and to secure a co-ordinated movement by the simultaneous contraction of several muscles.

FASCIÆ.

Beneath the skin there are two (or in some regions three) layers of tissue which require consideration in relation to the muscular system: the superficial fascia (panniculus adiposus), the deep fascia, and, in animals, the panniculus carnosus (rudimentary in man, and represented chiefly by the *platysma* in the neck).

Fascia Superficialis (Superficial Fascia).—The superficial fascia is a continuous sheet of areolar tissue which underlies the skin of the whole body. It is closely adherent to the cutis vera, and is sometimes termed **panniculus adiposus**, from the fact that, except beneath the skin of the eyelids, penis, and scrotum it is usually more or less impregnated with fat. The cutaneous vessels and nerves ramify in this fascia; and its deep surface, membranous in character, is in loose connexion with the subjacent deep fascia. It is in this layer that dropsical effusions chiefly occur.

Fascia Profunda (Deep Fascia).—Underneath the skin and superficial fascia is a fibrous membrane, bluish white in colour, devoid of fat, and in closest relation to skeleton, ligaments, and muscles. This is the deep fascia. It covers, invests, and in some cases forms the means of attachment of the various muscles. It has a special tendency to become attached to all subcutaneous bony prominences, and to be continuous with the connecting ligaments. It forms septal laminae, which separate groups of muscles and individual muscles; enclose glands and viscera; and form sheaths for vessels and nerves. Around joints it gives rise to bands which strengthen the capsule or limit the mobility of the joint, or, as in the region of the wrist and ankle, bind down the tendons passing over the joint. It not only ensheathes vessels and nerves, but is perforated by those which pass between superficial and deeper parts.

The term **aponeurosis** is used in relation to muscles. It is synonymous with deep fascia, either as an investing fascia, or as a membranous layer which (*e.g.* vertebral aponeurosis) performs at one and the same time the purpose of a deep fascia and the expanded membranous attachment of a muscle.

The **panniculus carnosus** is a thin muscular layer enveloping the trunk of animals with a hairy or furry coat. It is strongly developed in the hedgehog. In man it is represented mainly by the (rudimentary) *platysma*. It is placed between the superficial and the deep fascia.

Bursæ.—Where a tendon passes over a bony surface, or where the superficial fascia and skin cover a bony prominence, there is generally formed a mucous (synovial) sac, or bursa, containing fluid, for the purpose of lubricating the surface over which the tendon or fascia glides. Allied to these are the mucous or synovial sheaths which envelop the tendons passing over the wrist and the ankle joints.

Description of Muscles.—In studying the muscular system it is necessary to note the following characters in reference to each individual muscle: (1) The *shape* of the muscle—flat, cylindrical, triangular, rhomboidal, etc.; and the character of its extremities—membranous, tendinous, or fleshy. (2) The *attachments* of the muscle. The *origin* is the more fixed or central attachment: the *insertion* is the more movable or peripheral attachment. (3) The *relations* of the surfaces and borders of the muscle to bones, joints, muscles, and other important structures. (4) Its *vascular* and *nervous supply*; and (5) its *action*. It must be borne in mind that hardly any single muscle acts alone. Each muscle, as a rule, forms one

of a group acting more or less in harmony with, and antagonised by, other and opposite groups.

DESCRIPTION OF THE MUSCLES.

The skeletal muscles may be divided into two series: axial and appendicular. The **axial** muscles comprise the muscles of the trunk, head, and face, including the **panniculus carnosus** (platysma). These muscles are more or less segmental in arrangement, grouped around the axial skeleton. The **appendicular** muscles, the muscles of the limbs, are grouped around the appendicular skeleton. They are not segmental in arrangement, they are morphologically separate from the axial muscles, and they are arranged in definite strata in relation to the bones of the limbs.

APPENDICULAR MUSCLES.

THE UPPER LIMB.

FASCIÆ AND SUPERFICIAL MUSCLES OF THE BACK.

Fasciæ.

The **superficial fascia** of the back presents no peculiarity. It is usually of considerable thickness, and contains a quantity of fat.

The **deep fascia** closely invests the muscles. It is attached in the median plane of the back to the ligamentum nuchæ, supraspinous ligaments, and vertebral spines; laterally it is attached to the spine of the scapula and to the clavicle, and is continued over the deltoid region to the arm. In the neck it is attached above to the superior nuchal line of the occipital bone, and is continuous laterally with the deep cervical fascia. Below the level of the shoulder it is continuous, round the border of the latissimus dorsi muscle, with the fascia of the axilla and of the abdominal wall. In the back and loin it constitutes the **fascia lumbodorsalis** or aponeurosis of the latissimus dorsi. This layer conceals the sacrospinalis muscle, and is attached medially to the vertebral spines, and laterally to the angles of the ribs, and to the iliac crest.

The Superficial Muscles of the Back.

The muscles of the back are arranged in four series according to their attachments: (1) vertebro-scapular and vertebro-humeral; (2) vertebro-costal; (3) vertebro-cranial; and (4) vertebral. The first of this series consists of the posterior muscles connecting the superior extremity to the trunk, and comprises the first two layers of the muscles of the back—(1) trapezius and latissimus dorsi, and (2) levator scapulæ and rhomboidei (major and minor). The deeper (axial) muscles of the back are dealt with later (p. 437).

M. Trapezius.—The **trapezius** is a large triangular muscle occupying the upper part of the back. It arises from the superior nuchal line of the occipital bone in its medial third, from the external occipital protuberance (Fig. 396, p. 444), from the ligamentum nuchæ, from the spines of the seventh cervical and all the thoracic vertebræ, and the intervening supraspinous ligaments. The origin is by direct fleshy attachment, except in relation to the occipital bone, the lower part of the neck, and the lower thoracic vertebræ, in which places the origins are tendinous.

From their origin the muscular fibres converge towards the bones of the shoulder, to be inserted continuously from before backwards as follows: (1) The occipital and upper cervical fibres—into the posterior surface of the clavicle in its lateral third (Figs. 327, p. 366, and 329, p. 368); (2) the lower cervical and upper thoracic fibres—into the medial border of the acromion, and the upper border of the spine of the scapula; and (3) the lower thoracic fibres, by a

triangular flat tendon, beneath which a bursa is placed—into a rough tuberosity at the base of the spine of the scapula (Fig. 328, p. 367). The fibres inserted into the clavicle, acromion, and the upper border of the spine of the scapula spread over the adjacent subcutaneous surfaces of these bones for a variable distance. The occipital portion of the muscle may be in the form of a separate slip, or may be entirely absent.

The trapezius is superficial in its whole extent. Its upper lateral border forms the posterior limit of the posterior triangle of the neck. The inferior lateral border, passing over the upper edge of the latissimus dorsi and the vertebral margin of the scapula, forms a boundary of the so-called *triangle of auscultation*, completed below by the latissimus dorsi, and laterally by the vertebral margin of the scapula. This space is partly filled up by the rhomboideus major. The muscle overlaps the latissimus dorsi, and covers the levator scapulae, rhomboidei, and the deeper axial muscles of the back, along with the ascending and the descending branch of the transverse artery of the neck, the accessory nerve, and muscular branches from the cervical plexus.

Nerve-Supply.—The trapezius has a double nerve-supply: (1) from the terminal fibres of the accessory nerve, and (2) from the cervical plexus (C. 3. and 4.). These nerves communicate with the accessory nerve both in the posterior triangle of the neck and beneath the trapezius.

Action.—The main action of the trapezius is to draw the scapula backwards and upwards. The upper fibres of the muscle elevate the shoulder-girdle, while the lower fibres, pulling on the base of the spine of the scapula, depress the vertebral margin; the two movements result in a rotation of the scapula, by which the glenoid cavity is tilted upwards, as in the movement of raising the arm above the head in a forward direction.

M. Latissimus Dorsi.—The latissimus dorsi is a large triangular muscle occupying the lower part of the back. It has a triple origin. The greater part

FIG. 327.—MUSCLE-ATTACHMENTS TO THE RIGHT CLAVICLE (Upper Surface).

of the muscle arises—(1) from the posterior layer of the lumbo-dorsal fascia. This is a thick membrane which conceals the sacrospinalis muscle in the lower part of the back. Through it the latissimus dorsi gains attachment to the spines of the lower six thoracic vertebrae, the spines of the lumbar vertebrae, and the tendon of the sacrospinalis, with which the fascia blends below. It also arises laterally from the posterior part of the iliac crest.

From this origin the muscle is directed upwards and laterally, its fibres converging to the inferior angle of the scapula. In relation to its lateral and upper borders additional fibres arise. (2) *Along the lateral border* muscular slips arise from the lower three or four ribs, interdigitating with the slips of origin of the obliquus abdominis externus. (3) *As the superior border* of the muscle passes horizontally over the inferior angle of the scapula, an additional fleshy slip usually takes origin from this part of the bone to join the muscle on its deep surface (Fig. 329, p. 368).

Beyond the inferior angle of the scapula the latissimus dorsi, greatly narrowed, curves spirally round the teres major muscle, and forms the prominence of the posterior axillary fold. It ends in a ribbon-like tendon, which is closely adherent at first to the teres major, and is inserted into the floor of the intertubercular sulcus of the humerus, extending for about three inches distal to the distal and lateral part of the lesser tubercle (Fig. 336, p. 376). It is placed behind the axillary vessels and nerves, and in front of the insertion of the teres major, from which it is separated by a bursa.

In the back the latissimus dorsi is superficial, except in its upper part, which is concealed by the trapezius. It covers the lumbo-dorsal fascia, serratus

FIG. 328.—SUPERFICIAL MUSCLES OF THE BACK, AND VERTEBRO-SCAPULAR MUSCLES.

posterior inferior, the ribs, and inferior angle of the scapula, and at its borders two triangular spaces are formed; at the upper border is the so-called *triangle of auscultation*; at the lateral border is the *lumbar triangle of Petit*, a small space

bounded by the iliac crest, the latissimus dorsi, and the obliquus abdominis externus. This is sometimes the site of a lumbar hernia.

Nerve-Supply.—The muscle has a single nerve—the thoraco-dorsal nerve—which supplies it in its deep (axillary) surface. It is a branch from the posterior cord of the brachial plexus (C. (6.) 7. 8.).

Action.—The main action of the latissimus dorsi muscle is to depress and rotate the humerus medially, so lowering the arm as in swimming. Acting from the humerus it elevates the lower ribs, and is an extraordinary muscle of inspiration.

M. Levator Scapulæ.—The levator scapulæ is a strap-like muscle, arising by tendinous slips from the posterior tubercles of the transverse processes of the first three or four cervical vertebræ, between the attachments of the scalenus medius in front and the splenius cervicis behind.

It is directed downwards along the side of the neck, to be inserted into the vertebral margin of the scapula in its upper fourth, from the superior angle to the spine (Fig. 329).

It is concealed in its upper third by the sterno-mastoid muscle. In its middle third it occupies the floor of the posterior triangle. In its lower third it is again hidden from view by the trapezius. It conceals the splenius cervicis and iliocostalis cervicis.

Nerve-Supply.—The levator scapulæ has a double nerve-supply:—(1) from the dorsal scapular nerve from the brachial plexus (C. 5.), which either pierces or goes beneath the muscle, and (2) from the cervical plexus. Small branches from the anterior trunks of the third

FIG. 329.—MUSCLE-ATTACHMENTS TO THE RIGHT SCAPULA (Dorsal Surface).

and fourth cervical nerves enter the muscle on its superficial surface near its origin.

Action.—The levator scapulæ raises the superior angle and vertebral margin of the scapula, as in shrugging the shoulders.

M. Rhomboideus Minor.—The rhomboideus minor may be regarded as a separated slip of the rhomboideus major, with which it is often continuous. It arises from the *ligamentum nuchæ* and the spines of the seventh cervical and first thoracic vertebræ.

Passing obliquely downwards and laterally it is inserted into the vertebral margin of the scapula below the levator scapulæ muscle, and opposite to the base of the spine (Fig. 329).

M. Rhomboideus Major.—The rhomboideus major arises from the spinous processes of the thoracic vertebræ from the second to the fifth inclusive, and from the corresponding supraspinous ligaments.

Passing downwards and laterally it is inserted below the rhomboideus minor into the vertebral margin of the scapula, between the spine and the inferior angle (Fig. 329). The muscle is only inserted directly into the scapula by means of its inferior fibres. Its superior part is attached to a membranous band, which,

connected for the most part by loose areolar tissue to the vertebral margin of the scapula, is fixed to the bone at its extremities, above near the base of the spine, and below at the inferior angle.

The rhomboid muscles are concealed for the most part by the trapezius. The lower part of the rhomboideus major is superficial in the *triangle of auscultation*. The muscles cover the serratus posterior superior and vertebral aponeurosis.

Nerve-Supply.—The rhomboid muscles are supplied by the dorsal scapular nerve from the brachial plexus (C. 5.), which supplies branches in the deep surface of the muscles.

Action.—The rhomboid muscles elevate and draw backwards the vertebral margin of the scapula.

THE FASCIÆ AND MUSCLES OF THE PECTORAL REGION.

FASCIÆ.

The **superficial fascia** of the chest usually contains a quantity of fat, in which the mamma is embedded. The origin of the platysma muscle lies beneath its superior part.

The **deep fascia** is attached above to the clavicle, and in the median plane to the sternum. Below it is continuous with the fascia of the abdominal wall. It gives origin to the platysma and invests the pectoralis major. At the lateral border of the great pectoral muscle it is thickened, and forms the floor of the axillary space (**axillary fascia**), continued posteriorly on to the posterior fold of the axilla and laterally into connexion with the deep fascia of the arm.

Costo-Coracoid Membrane.—Beneath the pectoralis major a deeper stratum of fascia invests the pectoralis minor muscle. At the superior border of this muscle it forms the costo-coracoid membrane, which passes upwards to the inferior border of the subclavius muscle, where it splits into two layers, attached in front of and behind that muscle to the borders of the inferior surface of the clavicle. The membrane traced medially along the subclavius muscle is attached to the first costal cartilage; passing laterally along the upper border of the pectoralis minor it reaches the coracoid process. The part of the membrane extending directly between the first costal cartilage and the coracoid process is thickened and forms the **costo-coracoid ligament**. The costo-coracoid membrane is otherwise thin and of comparatively small importance. It is pierced by the cephalic vein, thoraco-acromial artery and vein, and branches of the lateral anterior thoracic nerve. By its deep surface it is connected to the sheath of the axillary vessels.

At the inferior border of the pectoralis minor there is a further extension of the deep fascia beneath the pectoralis major. It passes downwards to join the fascia forming the floor of the axilla, and is continued laterally into the fascia covering the biceps and coracobrachialis muscles.

MUSCLES OF THE PECTORAL REGION.

The anterior muscles connecting the upper limb to the axial skeleton comprise the pectoralis major, pectoralis minor, subclavius, serratus anterior, and sterno-cleido-mastoid. The last is described in a later section (p. 458).

M. Pectoralis Major.—The **pectoralis major** is a large fan-shaped muscle arising in three parts: (1) *a pars clavicularis* arising from the anterior surface of the clavicle in its medial half or two-thirds (Figs. 327, p. 366, and 331, p. 371); (2) *a pars sternocostalis*, the largest part of the muscle, arising from the anterior surface of the manubrium and body of the sternum by tendinous fibres decussating with those of the opposite muscle (Fig. 330, p. 370), and, more deeply, from the cartilages of the first six ribs; (3) *a pars abdominalis*, a small and separate slip, arising from the aponeurosis of the obliquus abdominis externus muscle. The abdominal slip, at first separate, soon merges with the sterno-costal portion, but a distinct interval usually remains between the two first-named parts of the muscle.

The fibres converge towards the proximal part of the arm, and are inseparably blended at a point half an inch from their insertion into the humerus. The muscle is inserted into (1) the lateral border of the sulcus intertubercularis of the humerus, extending proximally to the greater tubercle and blending laterally with the insertion of the deltoid, medially with the insertion of the latissimus dorsi (Fig. 336, p. 376); (2) from the proximal border of the insertion a membranous band extends proximally to the capsule of the shoulder-joint, enveloping at the same time the tendon of the biceps; and (3) from the distal border a band of fascia passes distally to join the fascia of the arm.

The arrangement of the fibres of the muscle at its insertion is peculiar. The muscle is twisted on itself, so that the lower (*sterno-costal*) fibres are directed upwards and laterally behind the upper (*clavicular*) part of the muscle; in consequence the clavicular part is attached to the humerus more distally than the sterno-costal portion, and is inserted also into the fascia of the arm. The twisting of the fibres is specially found in the inferior sterno-costal fibres of the muscle and the abdominal fibres. These curve upwards behind the superior sterno-costal fibres, and have the highest attachment to the shaft of the humerus, helping to form the fascial expansion which extends upwards over the biceps tendon to the capsule of the shoulder-joint. In this way a bilaminar tendon is produced united along its inferior border; consisting of a superficial lamina formed by the superior sterno-costal fibres, blending for the most part with the tendon of the clavicular portion; and a deep lamina, composed of the twisted lower sterno-costal and abdominal fibres. The disposition of the muscular fibres at their insertions is the reason for the application of the terms "*portio attollens*" to the clavicular portion, and "*portio deprimens*" to the sterno-costal and abdominal portions of the muscle.

FIG. 330.—MUSCLE-ATTACHMENTS TO THE FRONT OF THE STERNUM.

Placed superficially, the pectoralis major forms the anterior wall and anterior fold of the axilla. Its superior border is separated from the edge of the deltoid muscle by an interval in which lie the cephalic vein and deltoid branches of the a. thoracoacromialis. Its deep surface is in relation with the ribs and intercostal muscles, the costo-coracoid membrane and the structures piercing it, the pectoralis minor, the axillary vessels, and the nerves of the brachial plexus.

Nerve-Supply.—The pectoralis major has a double nerve-supply, from both anterior thoracic nerves. The lateral anterior thoracic nerve, derived from the lateral cord of the brachial

plexus (C. 5. 6. 7.), divides into two trunks. One pierces the costo-coracoid membrane, and supplies the clavicular part, and superior portion of the sterno-costal part of the muscle. The other branch communicates over the axillary artery with the medial anterior thoracic nerve, a derivative of the medial cord of the brachial plexus (C. 8. T. 1.). They then supply the pectoralis minor and, piercing that muscle, terminate in the lower part of the pectoralis major.

Action.—The pectoralis major draws the arm to the side. The clavicular fibres flex the shoulder-joint and raise the arm besides drawing it forwards. The sterno-costal and abdominal portions, on the other hand, depress the arm, while drawing it forwards.

Sternalis Muscle.—The sternalis is an occasional muscle placed, when present, parallel to the sternum upon the sterno-costal origin of the pectoralis major. It has attachments which are very variable both above and below, to the costal cartilages, sternum, rectus sheath, sternomastoid, and pectoralis major. Its **nerve-supply** is from one or both of the anterior thoracic nerves. In certain rare cases it has been said to be innervated by intercostal nerves. It is present in 44 cases out of 100, and it is slightly more frequent in the male than in the female. It has been regarded by different observers as (1) a vestige of the panniculus carnosus, (2) a homologue of the sterno-mastoid, or (3) a displaced slip of the pectoralis major.

Chondroepitrochlearis, Dorsoepitrochlearis, Axillary Arches, Costocoracoides.—One

or other of the above-named slips is occasionally present, crossing the floor of the axilla in the interval between the latissimus dorsi and the pectoralis major. They take origin from the costal cartilages, ribs, or borders of the pectoralis major (*chondroepitrochlearis*, *axillary arches*, *costo-coracoides*), or from the border of the latissimus dorsi (*dorsoepitrochlearis*, *axillary arches*, *costo-coracoides*). Their insertion is variable. The *chondroepitrochlearis* and *dorsoepitrochlearis* are inserted into the fascia of the arm, the medial intermuscular septum, or the medial epicondyle of the humerus. The *axillary arches* are inserted into the border of the pectoralis major, the fascia of the arm, or the coracobrachialis or biceps muscle. The *costocoracoides*, arising from the ribs or the aponeurosis of the obliquus externus, or detaching itself from the border of the pectoralis major or latissimus dorsi, is attached to the coracoid process, alone or along with one of the muscles attached to that bone. These variable slips of muscle are supplied by the medial anterior thoracic nerve, the medial cutaneous nerve of the arm, or the intercosto-brachial.

M. Pectoralis Minor.—The pectoralis minor is a narrow, flat, triangular muscle. It arises, under cover of the pectoralis major, from (1) the surfaces and superior borders of the third, fourth, and fifth ribs near their anterior ends, and (2) from the fascia covering the third and fourth intercostal spaces between these ribs. It may have an additional origin from the second rib (Fig. 414, p. 468); and that from the fifth rib is often absent.

Directed obliquely upwards and laterally, it is inserted by a short, flat tendon into the lateral half of the anterior border and upper surface of the coracoid process (Fig. 333, p. 372), and usually also into the conjoint origin of the biceps brachii and coracobrachialis.

It enters into the formation of the anterior wall of the axilla, and gives attachment along its superior border to the costo-coracoid membrane. It crosses the axillary vessels and the cords of the brachial plexus, and is pierced by branches of the anterior thoracic nerves.

Either in part or wholly the pectoralis minor may pass over the coracoid process of the scapula, separated from it by a bursa, to be inserted into the coraco-acromial ligament, or the acromion process; or piercing the coraco-acromial ligament, it may be attached to the capsule of the shoulder-joint (coraco-humeral ligament).

Pectoralis Minimus.—This is a slender slip, rarely present, which extends between the first costal cartilage and the coracoid process.

Nerve-Supply.—The pectoralis minor is innervated like the pectoralis major by both anterior thoracic nerves. The lower division of the lateral nerve (C. 5. 6. 7.) communicates with the medial anterior thoracic nerve (C. 8. T. 1.) over the axillary artery. Both nerves pierce and supply the pectoralis minor, and end in the pectoralis major.

Action.—The main use of the pectoralis minor is to draw the shoulder forwards. It is thus a chief assistant of the serratus anterior muscle.

M. Subclavius.—The subclavius muscle arises from the superior surface of the

FIG. 331.—MUSCLE-ATTACHMENTS TO THE RIGHT CLAVICLE (Inferior Surface).

first costal cartilage in front of the costo-clavicular ligament, and from the upper surface of the sternal end of the first rib (Fig. 414, p. 468).

It is inserted into a groove in the middle third of the inferior surface of the clavicle (Fig. 331).

The muscle is invested by the fascia which forms the costo-coracoid membrane, and is concealed by the clavicle and the clavicular origin of the pectoralis major.

Nerve-Supply.—The nerve to the subclavius is a fine branch of the brachial plexus (C. 5. 6.), which arises above the clavicle, and passes over the subclavian artery to reach the muscle.

Action.—It acts as a depressor of the clavicle; or, the shoulder girdle being fixed, it is capable of raising and fixing the first rib, in inspiration.

FIG. 332.—THE LEFT SERRATUS ANTERIOR MUSCLE.

The lateral surface of the muscle is partly superficial below the axillary space, on the side wall of the chest, where its slips of origin are seen inter-digitating with those of the obliquus externus abdominis. Higher up it forms the medial wall of the axilla, and is in contact with the pectoral muscles anteriorly and the subscapularis posteriorly. Its superior border appears in the floor of the posterior triangle, and over it the axillary artery and the cords of the brachial plexus pass in their course through the axilla. The inferior border is oblique, and is in contact with the latissimus dorsi muscle. The muscle may extend higher than usual, so as to be continuous in the neck with the levator scapulæ.

Nerve - Supply.—The serratus anterior muscle receives its nerve from the long thoracic nerve, a branch from the anterior trunks of the fifth, sixth, and seventh cervical nerves. After piercing the scalenus medius, the nerve enters the axilla, and supplies branches to the several digitations of the muscle on their superficial surface. The highest fibres of the muscle are supplied by the fifth, the lowest fibres by the seventh, and the intermediate part of the muscle by the sixth cervical nerve.

Action.—The primary action of the muscle is to draw the base of the scapula forwards. This causes

The **sternoclavicularis** is a small separate slip, rarely present, extending beneath the pectoralis major from the upper part of the sternum to the clavicle.

M. Serratus Anterior.—The **serratus anterior** (O.T. **serratus magnus**) is a large curved quadrilateral muscle occupying the side of the chest and medial wall of the axilla. It arises by fleshy slips from the lateral aspect of the upper eight and occasionally (as in the figure) from nine ribs. The first slip is a double one, arising from the first two ribs and the fascia covering the intervening space (Fig. 332).

The **insertion** of the muscle is threefold. (1) The first portion of the muscle (from the first and second ribs) is directed posteriorly to be inserted into the costal aspect of the superior angle of the scapula. (2) The next three slips of the muscle (from the second, third, and fourth ribs) are inserted into the vertebral margin of the scapula. (3) The last four slips (from the fifth, sixth, seventh, and eighth ribs) are directed obliquely upwards and posteriorly, to be inserted on the costal aspect of the inferior angle of the scapula (Fig. 333).

FIG. 333.—MUSCLE-ATTACHMENTS TO THE RIGHT SCAPULA (Anterior Aspect).

the whole shoulder to be brought forward by a movement at the sterno-clavicular joint. The movement of stretching forward the arm as in fencing is due to this action of the muscle. Further, by its relation to the inferior angle of the scapula, the serratus anterior causes (along with the trapezius) a rotation of the scapula, resulting in a tilting upwards of the glenoid cavity, and so facilitating the upward movement of the arm above the head. Acting from the shoulder on the ribs the serratus is a powerful muscle of inspiration.

Action of Muscles on the Sterno-Clavicular and Acromio-Clavicular Joints.—The muscles just considered (along with the sterno-cleido-mastoid and omo-hyoid muscles) act for the most part in the sterno-clavicular and acromio-clavicular joints.

A. Sterno-Clavicular Joint.—The movements at this articulation are vertical, horizontal and rotatory, and the muscles concerned may be tabulated as follows:—

Sterno-Clavicular Joint.

a. Movement in a Vertical Plane.		b. Movement in a Horizontal Plane.	
Elevation.	Depression.	Forwards.	Backwards.
Trapezius (superior fibres) Levator scapulæ Rhomboidæ Sterno-mastoid Omo-hyoid	Trapezius (inferior fibres) Subclavius Pectoralis minor Latissimus dorsi Pectoralis major (lower fibres)	Serratus anterior Pectoralis major Pectoralis minor	Trapezius Rhomboidæ Latissimus dorsi
c. Rotation—a combination of these muscles.			

B. Acromio-Clavicular Joint.—Movements at this joint are associated with **rotation** of the scapula. By the combined action of such muscles as the trapezius and serratus anterior (inferior fibres), the inferior angle of the scapula is drawn or thrust forwards, the body of the scapula is rotated, and the glenoid cavity is tilted upwards, so facilitating the upward movement of the arm above the horizontal level.

In **forced inspiration**, the sterno-mastoid, trapezius, levator scapulæ, rhomboidæ, subclavius, omo-hyoid, serratus anterior, pectoral muscles, and latissimus dorsi, acting together, raise and fix the shoulder girdle; while those of them which have costal attachments—subclavius, pectoral muscles, serratus anterior, and latissimus dorsi—simultaneously elevate the ribs and expand the thorax.

Lateral flexion and rotation of the vertebral column in the neck is effected partly by the action of the trapezius, levator scapulæ, and rhomboid muscles (with the shoulder fixed). The latissimus dorsi and pectoralis major act in climbing in a similar way, raising up the trunk towards the shoulder.

Action on the Upper Limb.—By reason of their insertion into the humerus the pectoralis major and latissimus dorsi muscles assist the movements of the upper limb. Acting together, the two muscles depress the shoulder, and draw the arm to the side of the body, at the same time rotating the humerus medially. The two parts of the pectoralis major have slightly different actions on the humerus. The clavicular part of the muscle (*portio attollens*) draws it medially and upwards; the sterno-costal part of the muscle (*portio deprimens*) draws it medially and downwards. The latissimus dorsi acting alone, besides rotating the limb, draws it medially and backwards, as in the act of swimming.

FASCIÆ AND MUSCLES OF THE SHOULDER.

The **deep fascia** covering the scapular muscles presents no feature of special importance. Attached to the clavicle, acromion, and scapular spine, it is thin over the deltoid muscle. Below the deltoid it is thicker; it encases and gives origin to the infraspinatus muscle, and is continuous with the fasciæ of the axilla and the back.

Muscles.

The **muscles** proper to the shoulder comprise the deltoid, supraspinatus, infraspinatus, teres minor, teres major, and subscapularis.

M. Deltoideus.—The deltoid, a coarsely fasciculated multipennate muscle, has an extensive origin from (1) the front of the clavicle in its lateral third (Figs. 327, p. 366, and 331, p. 371); (2) the lateral border of the acromion; (3) the inferior edge of the free border of the spine of the scapula (Figs. 329, p. 368, and 333, p. 372); and (4) from the deep fascia covering the infraspinatus muscle. Its origin embraces the insertion of the trapezius.

The fibres of the muscle converge to the lateral aspect of the shaft of the

humerus, to be inserted into a well-marked V-shaped impression above the radial groove (Fig. 336, p. 376). The insertion is partly united with the tendon of the pectoralis major.

The most anterior part of the deltoid muscle is formed of parallel fibres, not

FIG. 334.—LEFT SCAPULAR MUSCLES AND TRICEPS.

uncommonly separate from the rest of the muscle at their origin from the clavicle. These fibres may be continuous with the trapezius over the clavicle. The most posterior part arises by a fascial origin from the spine of the scapula and the fascia over the infraspinatus muscle. These portions are attached respectively to the front and back of the main tendon of insertion. The intermediate fibres are

multi-pennate, attached above and below to three or four septal tendons, which extend for a variable distance downwards and upwards from the origin and insertion of the muscle.

The deltoid is superficial in its whole extent, and forms the prominence of the shoulder. Its anterior border is separated from the pectoralis major by a narrow interval, in which the cephalic vein and deltoid branch of the thoraco-acromial artery are placed. The deep surface of the muscle, separated from the capsule of the shoulder-joint by a large bursa, is related to (1) the *coracoid process*, associated with which are the coraco-acromial ligament, and the attachments of the pectoralis minor, the coracobrachialis, and the short head of the biceps brachii; (2) the capsule of the *shoulder-joint* covering the *head of the humerus*, associated with which are the long head of the biceps, and the attachments of the subscapularis, supraspinatus, infraspinatus, and teres minor; and (3)

the proximal part of the lateral surface of the *shaft of the humerus*, associated with which are the posterior circumflex vessels of the humerus and the axillary nerve.

Nerve-Supply.—The deltoid muscle is supplied by the terminal branches of the axillary (O.T. circumflex) nerve from the fifth and sixth cervical nerves.

Action.—The main action of the deltoid, is to abduct the arm, and bring the humerus into

the horizontal position. In this movement it is aided by the supraspinatus and infraspinatus. The anterior (clavicular) portion of the muscle assists the pectoralis major in drawing the arm forwards, while the posterior portion draws it backwards.

M. Supraspinatus.—The supraspinatus arises by fleshy fibres from the supraspinous fossa (except near the neck of the bone) and from the deep fascia over it (Fig. 329, p. 368).

It is directed laterally under the trapezius muscle, the acromion and coraco-acromial ligament, to be inserted by a broad thick tendon into the most proximal facet on the larger tubercle of the humerus, and into the capsule of the shoulder-joint (Fig. 336, p. 376).

Nerve-Supply.—The muscle is supplied by the supra-scapular nerve (C. 5. 6.).

Action.—The supraspinatus assists the deltoid in abducting the arm from the side.

M. Infraspinatus.—The infraspinatus arises from the infra-spinous fossa of the scapula (excepting near the neck of the bone and the flat surface along the axillary margin) and from the thick fascia over it (Fig. 337, p. 376).

The fibres of the muscle converge to the neck of the scapula; and are inserted by tendon into the middle facet on the larger tubercle of the humerus, and into the capsule of the shoulder-joint (Fig. 336, p. 376). A bursa separates the muscle from the neck of the scapula, and in a minority of cases communicates with the synovial cavity of the shoulder-joint.

The supraspinatus and the upper part of the infraspinatus muscles are concealed by the trapezius, acromion, and deltoid. They cover the neck of the scapula, the transverse scapular artery, and supra-scapular nerve, and the capsule of the shoulder-joint.

Nerve-Supply.—Supra-scapular nerve.

Action.—The muscle assists the deltoid in abducting and drawing back the arm at the shoulder-joint.

M. Teres Minor.—The teres minor is a small muscle, arising by fleshy fibres from the proximal two-thirds of the flat surface on the dorsal aspect of the axillary margin of the scapula, and from fascial septa separating it from the infraspinatus and teres major muscles (Fig. 337, p. 376).

Lying alongside the lateral border of the infraspinatus, it is inserted under cover of the deltoid by a thick flat tendon into the most distal of the three facets on the

FIG. 335.—MUSCLES OF POSTERIOR WALL OF LEFT AXILLA AND FRONT OF ARM.

larger tubercle of the humerus and into the capsule of the shoulder-joint, and by fleshy fibres into the posterior aspect of the surgical neck and shaft of the humerus distal to the tubercle for about an inch (Fig. 341, p. 380).

It is separated from the *teres major* by the long or scapular head of the *triceps brachii*, and by the posterior circumflex vessels of the humerus and the axillary nerve. Its origin is pierced by the circumflex scapular artery. The muscle is invested by the deep fascia enclosing the *infraspinatus*, and is sometimes inseparable from that muscle.

Nerve-Supply.—The *teres minor* is supplied by a branch of the axillary nerve (C. 5. 6.). The nerve has a pseudoganglion, a fibrous swelling on it in its course to the muscle.

Action.—The muscle is a lateral rotator of the humerus.

M. Teres Major.—The *teres major* is much larger than the preceding muscle. It arises by fleshy fibres from the lower third of the flat surface on the dorsum of the scapula along its axillary

FIG. 336.—MUSCLE-ATTACHMENTS TO THE ANTERIOR ASPECT OF THE RIGHT HUMERUS.

FIG. 337.—MUSCLE-ATTACHMENTS TO THE RIGHT SCAPULA (Dorsal Surface).

margin (except for a small area at the inferior angle), and from fascial septa, which separate it on the one side from the subscapularis, and on the other from the *infraspinatus* and *teres minor* (Fig. 337).

The muscle is directed along the axillary margin of the scapula to the front of the shaft of the humerus, where it is inserted by a broad flat tendon into the medial border of the sulcus intertubercularis medial to the *latissimus dorsi* muscle (Fig. 337). Just before its insertion it is closely adherent to the tendon of the *latissimus dorsi*.

The *teres major* lies below the *subscapularis* muscle in the posterior wall of

the axilla. The latissimus dorsi muscle, sweeping round from the back, covers its axillary surface on its way to its insertion. The muscle forms the inferior boundary of a **triangular space** in the posterior wall of the axilla, of which the other boundaries are, above, the borders of the subscapularis and teres minor muscles, and laterally the surgical neck of the humerus. This space is subdivided by the long head of the triceps brachii, which passes behind the teres major muscle, into (a) a **quadrilateral space** above, for the passage of the axillary nerve and posterior circumflex artery of the humerus; and (b) a **smaller triangular space** below, for the circumflex scapulæ artery.

Nerve-Supply.—The teres major is supplied, along with part of the subscapularis muscle, by the lower subscapular nerve (C. 5. 6.).

Action.—A medial rotator of the humerus.

M. Subscapularis.—The subscapularis is a large triangular muscle occupying the costal surface of the scapula. It arises by fleshy fibres from the whole of the subscapular fossa and the groove along the axillary margin, excepting the surfaces at the angles of the bone (Fig. 333, p. 372). Springing from several ridges in the fossa are septa projecting into the substance of the muscle, which increase the extent of its attachment.

Converging to the head of the humerus, the muscular fibres are inserted by a broad, thick tendon into the smaller tubercle of the humerus and into the capsule of the shoulder-joint, and by fleshy fibres into the surgical neck and the shaft of the humerus distal to the tubercle for about an inch, under cover of the coracobrachialis and short head of the biceps (Fig. 336, p. 376).

This muscle forms the greater part of the posterior wall of the axilla. Its medial or anterior surface is in contact with the serratus anterior and the axillary vessels and nerves. It is separated from the neck of the scapula by a bursa, which is in direct communication with the synovial cavity of the shoulder-joint.

The **subscapularis minor** is an occasional muscle situated below the capsule of the shoulder-joint. It arises from the axillary border of the scapula below the subscapularis, and is inserted into the capsule of the joint or the proximal part of the shaft of the humerus.

Nerve-Supply.—There are two and often three nerves supplying the subscapularis, viz., the short subscapular (C. 5. 6.), which is often double; and the lower subscapular (C. 5. 6.), which, after supplying its lateral (lower) portion, ends in the teres major.

Actions.—The muscle aids in drawing the arm forward and medially rotating the humerus.

The principal action of the above group of muscles is on the shoulder-joint. They have also secondary actions in relation to movements of the trunk and limbs.

1. Movements at the Shoulder-Joint.

a. Abduction.	Adduction.	b. Flexion (Forwards).	Extension (Backwards).
Deltoid Supraspinatus	Teres major Teres minor Pectoralis major Latissimus dorsi Coracobrachialis Biceps (short head) Triceps brachii (long head) Weight of limb	Deltoid (anterior fibres) Subscapularis Pectoralis major Coracobrachialis Biceps brachii	Deltoid (posterior fibres) Teres major Infraspinatus Latissimus dorsi Triceps brachii

c. Rotation Laterally.	Rotation Medially.
Deltoid (posterior fibres) Infraspinatus Teres minor	Deltoid (anterior fibres) Teres major Pectoralis major Latissimus dorsi
d. Circumduction—combination of previous muscles.	

The various movements at the shoulder-joint are greatly aided by the muscles acting on the shoulder girdle. In raising the arm above the head, for instance, the humerus is brought to the horizontal position by the deltoid and supraspinatus, and the movement is continued by the

elevators of the shoulder girdle. Again, in forward and backward movements at the shoulder-joint, great assistance is derived from muscles acting directly on the shoulder girdle—pectoralis minor and serratus anterior; trapezius and rhomboidei.

2. **In relation to the trunk and limbs**, the shoulder muscles, by fixing the humerus, have auxiliary power on the one hand in movements of the trunk, such as forced inspiration; on the other hand, acting along with muscles fixing the elbow-joint, they stiffen the limb so as to permit of the more refined movements of the wrist and fingers.

FASCIÆ AND MUSCLES OF THE ARM.

FASCIÆ.

The **superficial fascia** presents no features of importance. There is a bursa beneath it over the olecranon, and occasionally another over the medial epicondyle of the humerus.

The **deep fascia** forms a strong tubular investment for the muscles on the anterior and posterior aspects of the humerus. It is continuous above with the deep fascia of the shoulder and axilla, and is further strengthened by fibres derived from the insertions of the pectoralis major, latissimus dorsi, and deltoid muscles. At the elbow it becomes continuous with the deep fascia of the forearm, and gains attachment to the epicondyles of the humerus and the olecranon of the ulna; it is strengthened also by important bands associated with the insertions of the biceps anteriorly and the triceps posteriorly, to which reference will be made in the account of these muscles.

About the middle of the arm on the medial side, the deep fascia is perforated for the passage of the basilic vein and the medial cutaneous nerve of the forearm.

The **intermuscular septa** are processes of the deep fascia attached to the epicondylar ridges of the humerus. The **medial** and stronger **septum** is placed between the brachialis muscle anteriorly and the medial head of the triceps posteriorly, and gives origin to both. It extends proximally to the insertion of the coracobrachialis (which is often continued into it), and the ulnar nerve and superior ulnar collateral vessels pass distally over its medial edge. The **lateral septum** is thinner. It separates the brachialis muscle and brachioradialis in front from the medial and lateral heads of the triceps behind, and gives origin to these muscles. It extends proximally to the insertion of the deltoid, and is pierced by the radial nerve and profunda brachii vessels.

MUSCLES OF THE ARM.

The muscles of the arm comprise the biceps, coracobrachialis, and brachialis on the anterior aspect, and the triceps brachii on the posterior aspect of the humerus. Except at its extremities, the biceps brachii is superficial, and forms a rounded fleshy mass on the anterior aspect of the arm. The coracobrachialis is visible on its medial side in the proximal half of the arm, particularly when the arm is raised. The brachialis is concealed by the biceps. The triceps brachii forms the thick mass of muscle covering the posterior surface of the humerus.

M. Coracobrachialis.—The **coracobrachialis** is a rudimentary muscle. It arises under cover of the deltoid from the tip of the coracoid process by fleshy fibres in common with the short head of the biceps, and also frequently from the tendon of insertion of the pectoralis minor muscle.

The fleshy belly is pierced by the musculo-cutaneous nerve, and ends in a flat tendon inserted into a faint linear impression about an inch in length on the middle of the medial border of the shaft of the humerus (Fig. 336, p. 376). It is often continued into the medial intermuscular septum.

The **coracobrachialis** is the remains of a *threefold muscle*, of which only two elements are usually present in man, but of which in anomalous cases all the parts may be more or less fully developed. The passage of the musculo-cutaneous nerve through the muscle is an indication of its natural separation into two parts, which represent the persistent middle and distal elements.

The commonest variety is one in which the more superficial (distal) part of the muscle extends more distally than usual, so as to be inserted into the medial intermuscular septum, or even into the medial epicondyle of the humerus. A third slip (*coracobrachialis superior* or *brevis*,

FIG. 338.—SUPERFICIAL MUSCLES ON THE ANTERIOR ASPECT OF THE RIGHT ARM AND FOREARM.

FIG. 339.—THE MUSCLES ON THE POSTERIOR SIDE OF THE LEFT ARM, FOREARM, AND HAND.

rotator humeri) may more rarely be present, forming a short muscle arising from the root of the coracoid process, and inserted into the medial side of the humerus just distal to the capsule of the shoulder-joint.

Nerve-Supply.—The nerve to the coracobrachialis comes from the 7th or 6th and 7th cervical nerves. Incorporated with the musculo-cutaneous, the nerve separates to supply the muscle before the latter nerve pierces it.

Action.—The muscle assists the biceps to raise the arm and draw it medially.

M. Biceps Brachii.—The **biceps brachii** arises by two tendinous *heads*. (1) The **short head** (*caput breve*) is attached in common with the coracobrachialis to

FIG. 340.—MUSCLE-ATTACHMENTS TO THE ANTERIOR ASPECT OF THE RIGHT HUMERUS.

FIG. 341.—MUSCLE-ATTACHMENTS TO THE POSTERIOR SURFACE OF THE RIGHT HUMERUS.

to the tip of the coracoid process of the scapula (Fig. 333, p. 372). Concealed by the deltoid and tendinous at first, this head forms a separate fleshy belly, which is united to the long head by an investment of the deep fascia. (2) The **long head** (*caput longum*) arises by a round tendon from the supraglenoid tuberosity at the root of the coracoid process and from the labrum glenoidale on either side. Its tendon passes through the cavity of the shoulder-joint, and emerging from the capsule beneath the transverse humeral ligament (invested by a prolongation of the synovial membrane), it occupies the intertubercular groove of the humerus covered by a fascial prolongation of the tendon of the pectoralis major. In the arm it forms a fleshy belly united to that derived from

the short head by an envelope of deep fascia (*intertubular mucous sheath*).

The **insertion** of the muscle is likewise twofold. (1) The two bellies become connected to a strong *tendon*, attached deeply in the hollow of the elbow to the rough dorsal portion of the tubercle of the radius (Figs. 335, p. 375, and 348, p. 389). A bursa separates the tendon from the volar portion of the tuberosity. (2) From the medial and anterior part of the tendon, and partly in continuity with the fleshy fibres of the muscle, a strong *membranous band* (the *lacertus fibrosus*) extends distally and medially over the hollow of the elbow to join the deep fascia covering the origins of the flexor and pronator muscles

of the forearm. Its proximal part is thickened and can be felt subcutaneously as a crescentic border.

In the arm the biceps conceals the brachialis muscle and the musculo-cutaneous nerve. Its medial border is the guide to the position of the brachial artery and median nerve.

The **biceps** is an extremely variable muscle. Its chief anomalies are due to an increase or diminution in the number of origins. A **third head of origin** is common (10 per cent), and usually arises from the humerus, between the insertions of the deltoid and coracobrachialis. Two or even three additional heads may be present at the same time. The long head of the muscle may be absent, or may take origin from the intertubercular groove. The muscle may have an additional insertion into the medial epicondyle of the humerus, or into the fascia of the forearm.

Nerve-Supply.—The biceps is supplied by the musculo-cutaneous nerve (C. 5. 6.).

Actions.—The actions of the biceps are complex, in that they affect three articulations—the shoulder, humero-radial, and radio-ulnar joint. The muscle raises and draws forward the humerus at the shoulder-joint, it flexes the elbow-joint, and it supinates the forearm. The combination of these actions results in a simple movement like that of raising the hand to the mouth.

M. Brachialis.—The **brachialis** (O.T. **brachialis anticus**) is a large muscle arising from the distal two-thirds of the anterior aspect of the shaft of the humerus and from the intermuscular septum on each side (Figs. 340 and 341, p. 380).

Clasping the insertion of the deltoid proximally, it ends distally in a strong tendon inserted deep in the hollow of the elbow into the anterior ligament of the elbow-joint, the distal surface of the coronoid process, and slightly into the volar surface of the shaft of the ulna immediately distal to this (Fig. 348, p. 389). The lateral part of the muscle arising from the lateral epicondylar ridge and lateral intermuscular septum forms a slip more or less separate, which may be partially fused with the brachioradialis muscle.

It is concealed for the most part by the biceps muscle in the arm. It forms the floor of the cubital fossa, and covers the anterior aspect of the elbow-joint.

Nerve-Supply.—It is supplied by the musculo-cutaneous nerve (C. 5. 6.); and also (in most instances) at its lateral border by a fine branch of the radial nerve (C. (5.) 6.).

Action.—This muscle is a flexor of the elbow-joint.

M. Triceps Brachii.—The **triceps brachii** is the only muscle on the posterior aspect of the arm. It arises by three heads: a lateral and a medial head, from the humerus, and a long or middle head, from the scapula. (1) The **long head** (**caput longum**) begins as a strong tendon attached to a rough triangular surface on the axillary border of the scapula just below the cavity (infra-glenoid tuberosity) (Figs. 333, p. 372, and 337, p. 376). This gives rise to a fleshy belly which, after passing between the teres major and teres minor muscles, occupies the middle of the back of the arm. (2) The **lateral head** is attached by fibres, partly tendinous and partly fleshy, to the curved lateral border of the humerus from the insertion of the teres minor proximally to the radial groove distally, and receives additional fibres from the posterior surface of the lateral intermuscular septum (Fig. 341, p. 380). Its fibres are directed distally and medially over the radial groove, concealing the radial (musculo-spiral) nerve, the profunda brachii artery, and the medial head of the muscle, to the tendon of insertion. (3) The **medial head** arises by fleshy fibres from an elongated triangular area on the posterior surface of the humerus, extending proximally to the level of the insertion of the teres major, and distally nearly to the margin of the olecranon fossa (Fig. 341, p. 380). It also arises on each side from the intermuscular septum,—from the whole length of the medial septum, and from the part of the lateral septum which is below the passage of the radial nerve.

The three heads of origin are inserted by a common tendon, broad and membranous, into an impression occupying the posterior part of the proximal end of the olecranon of the ulna (Fig. 355, p. 397), and into the deep fascia of the forearm on either side of it. The long and lateral heads join the borders of the tendon of insertion, and the medial head is attached to its deep surface. A small

thick-walled bursa separates the tendon of the triceps from the posterior ligament of the elbow-joint and the proximal end of the olecranon.

The **subanconæus** is a small muscle occasionally present, which consists of scattered fibres arising from the distal end of the humerus beneath the triceps, and inserted into the posterior ligament of the elbow-joint.

The muscle is superficial in almost its whole extent. The long (scapular) head is concealed at its origin by its relation to the teres muscles, between which it passes.

Nerve-Supply.—The several heads of the muscle are supplied separately by branches of the radial nerve. The lateral head receives fibres from C. (6.) 7. 8.; the long and medial head from C. 7. 8. The medial head has a double supply. One nerve enters its proximal part, another (ulnar collateral nerve of Krause) enters the distal part of the muscle.

Actions.—The triceps is the extensor muscle of the elbow-joint. The long head also acts as an adductor of the humerus at the shoulder-joint.

The chief action of these muscles (excepting the coracobrachialis) is on the elbow-joint, producing along with other muscles flexion and extension. The flexor muscles are much more powerful than the extensors.

Table of Muscles acting on the Elbow-Joint.

Flexors.	Extensors.
Biceps brachii	Triceps brachii
Brachialis	Anconæus
Brachioradialis	Extensors of wrist and fingers (in supination)
Pronator teres	
Flexors of wrist and fingers	
Extensors of wrist (in pronation)	

FASCIÆ AND MUSCLES OF THE FOREARM AND HAND.

Fasciæ.

The **superficial fascia** in the forearm presents no exceptional features. On the dorsum of the hand it is loose and thin; in the palm it is generally well furnished with fat, forming pads for the protection of the vessels and nerves. It is closely adherent to the palmar aponeurosis and to the skin, especially along the lines of flexure.

M. Palmaris Brevis.—The **palmaris brevis** is a quadrilateral subcutaneous muscle occupying the medial side of the hand under the superficial fascia. It arises from the medial border of the thick central portion of the palmar aponeurosis and from the volar surface of the transverse carpal ligament of the wrist, and is inserted into the skin of the medial border of the hand for a variable distance. It covers the ulnar artery and nerve, branches of which supply it. Its action is to wrinkle the skin of the medial border of the hand, and by raising up the skin and superficial fascia, to deepen the hollow of the hand.

The **deep fascia** of the forearm and hand is continuous above with the deep fascia of the arm. In the proximal part of the forearm it is strengthened by additional fibres around the elbow; in front by fibres from the lacertus fibrosus (semilunar fascia) of the biceps, behind by the fascial insertions of the triceps, and laterally by fibres derived from the humeral epicondyles in relation to the common tendons of origin of the flexor and extensor muscles of the forearm which in part take their origin from them. It is attached to the dorsal margin of the ulna, and affords increased attachment to the flexor and extensor carpi ulnaris and the flexor digitorum profundus muscles. Above the wrist the fascia is pierced anteriorly by the tendon of the palmaris longus, and by the ulnar artery and nerve. At the wrist it gains attachment to the bones of the forearm and carpus, is greatly strengthened by addition of transverse fibres, and constitutes the transverse carpal and dorsal carpal ligaments.

Ligamentum Carpi Transversum.—The transverse carpal ligament (O.T. anterior annular ligament) is a band about an inch and a half in depth, continuous proximally and distally with the deep fascia of the forearm and the palm of the

hand. It is attached laterally to the navicular and large multangular; medially to the pisiform and os hamatum; and it forms a membranous arch binding down in the hollow of the carpus the flexor tendons of the fingers, and the median nerve. It is divided into *two compartments*, the larger accommodating the tendons of the flexors of the digits and the median nerve, the smaller (placed laterally) containing the tendon of the flexor carpi radialis. There are *three synovial membranes* in these compartments: one for the flexor carpi radialis tendon, and two others, which often communicate together, enveloping the tendon of the flexor pollicis longus and the flexor tendons of the fingers respectively. The surface of the ligament is crossed by the palmar branches of the median and ulnar nerves; by the tendon of the palmaris longus muscle, which is attached to its surface; and by the ulnar artery and nerve, which are again bridged over and protected by a band of fibrous tissue, called the volar carpal ligament, which passes from the pisiform bone and the superficial fascia to the surface of the transverse carpal ligament. To the distal border of the ligament are attached the palmar aponeurosis in the centre, and the superficial muscles of the thumb and the muscles of the little finger on each side.

Ligamentum Carpi Dorsale.—

The dorsal carpal ligament (O.T. posterior annular ligament) is placed at a more proximal level than the transverse carpal ligament. It consists of an oblique band of fibres about an inch broad, continuous proximally and distally with the deep fascia of the forearm and hand. It is attached laterally to the lateral side of the distal end of the radius, and medially to the distal end of the ulna (styloid process), the carpus, and the ulnar collateral ligament of the wrist. It is crossed by veins, by the superficial ramus of the radial nerve, and by the dorsal branch of the ulnar nerve. *Six compartments* are formed beneath it by the attachment of septal bands to the distal ends of the radius and ulna. Each compartment is provided with a *synovial membrane*, and they serve to transmit the extensor tendons of the wrist and fingers in the following order from lateral to medial side:—

FIG. 342.—THE PALMAR APONEUROSIS.

(1) Abductor pollicis longus and extensor pollicis brevis, (2) Extensores carpi

radiales, longus and brevis, (3) Extensor pollicis longus, (4) Extensor digitorum communis and extensor indicis proprius, (5) Extensor digiti quinti proprius, (6) Extensor carpi ulnaris.

The thin deep fascia of the dorsum of the hand is lost over the expansions of the extensor tendons on the fingers. Between the metacarpal bones a strong layer of fascia covers and gives attachment to the interossei muscles.

Aponeurosis Palmaris.—The palmar aponeurosis is of considerable importance. In the centre of the palm it forms a thick triangular membrane, the apex

of which joins the distal edge of the transverse carpal ligament, and more superficially receives the insertion of the tendon of the palmaris longus muscle. The fascia separates below into four slips, one for each finger, connected together by transverse fibres, and forming beneath the webs of the fingers the superficial transverse metacarpal ligament (*fasciculi transversi*). Beyond this each slip separates into two parts, to be connected to the sides of the metacarpophalangeal joints and the first phalanx of the medial four digits. In the cleft between the two halves

FIG. 343.—SUPERFICIAL MUSCLES AND TENDONS IN THE PALM OF THE LEFT HAND.

of each slip the digital sheath is attached and extends distally on to the finger. The lateral borders of this triangular central portion of the palmar aponeurosis are continuous with thin layers of deep fascia, which cover and envelop the muscles of the thenar and hypothenar eminences. The medial border gives origin to the palmaris brevis muscle (p. 382).

The digital sheaths (*vaginæ mucosæ*) are tubular envelopes extending along the palmar aspect of the digits and enclosing the flexor tendons. Each consists of a fibrous sheath attached to the lateral borders of the phalanges and inter-phalangeal joints, and continuous proximally with the palmar aponeurosis. Opposite each inter-phalangeal articulation the digital sheath is loose and thin; opposite the first two phalanges (the first only in the case of the thumb) it becomes extremely thick, and gives rise to the *ligamenta vaginalia*, which serve to keep the tendons closely

applied to the bones during flexion of the fingers. Within each digital sheath are the flexor tendons, enveloped in a synovial membrane which envelops the tendon and lines the interior of the sheath. The synovial membranes of the digital sheaths extend a short distance proximally in the palm, and in some cases communicate with the large synovial membranes lining the flexor tendons beneath the transverse carpal ligament. There may be a separate distinct synovial membrane for each digit; but most commonly only the sheaths for the three middle digits have separate synovial membranes; those for the flexor pollicis longus and the flexor tendons of the little finger usually communicate with the synovial membranes placed beneath the transverse carpal ligament.

THE MUSCLES ON THE ANTERIOR AND MEDIAL ASPECTS OF THE FOREARM.

The muscles on the anterior and medial aspects of the forearm comprise the pronators and the flexors of the wrist and fingers. In the forearm they are arranged in three strata: (1) a superficial layer consisting of four muscles which radiate from the medial epicondyle of the humerus, from which they take origin by a common tendon. They are named, from radial to ulnar side, pronator teres, flexor carpi radialis, palmaris longus, and flexor carpi ulnaris. These muscles conceal the muscle which by itself constitutes (2) the intermediate stratum—the flexor digitorum sublimis, and this again conceals for the most part (3) the deep layer of muscles, including the flexor digitorum profundus covering the ulna, the flexor pollicis longus on the radius, and the pronator quadratus, which is more deeply placed than the previous muscles, and stretches across the forearm between the distal ends of the radius and ulna.

I. Superficial Muscles.

M. Pronator Teres.—The pronator teres is the shortest muscle of this group. It has a double origin: (1) a *superficial head* (*caput humerale*), the main origin, partly fleshy, partly tendinous, from the most distal part of the medial epicondylar ridge of the humerus and from the medial intermuscular septum, from the medial epicondyle of the humerus, from the fascia over it, and from an intermuscular septum between it and the flexor carpi radialis (Fig. 346, p. 387); (2) a *deep head* (*caput ulnare*), a slender tendinous slip from the medial side of the coronoid process of the ulna, which joins the superficial origin of the muscle on its deep surface (Fig. 348, p. 389). The median nerve separates the two heads from one another.

The muscle is directed distally and laterally to be inserted by tendon into an oval impression on the middle of the lateral surface of the shaft of the radius (Figs. 346, p. 387, and 348, p. 389). The fibres of the muscle are twisted on themselves, so that the most proximal humeral fibres form the most distal fibres of the tendon of insertion, and the most distal humeral fibres and those arising from the coronoid process are most proximal at the insertion.

The muscle forms the medial boundary of the hollow of the elbow. It is superficially placed, except near its insertion, where it is covered by the brachioradialis muscle and by the radial vessels and superficial branch of the radial nerve.

Nerve-Supply.—Median nerve (C. 6.).

Action.—The muscle is a flexor of the elbow-joint and a pronator of the forearm.

M. Flexor Carpi Radialis.—The flexor carpi radialis muscle takes its origin from the common tendon from the medial epicondyle of the humerus, from the fascia over it, and from the intermuscular septa on either side.

Its fleshy belly gives place to a strong round tendon in the distal half of the forearm, which, at the wrist, enters the hand in a special compartment beneath the transverse carpal ligament, and after occupying the groove on the large multangular bone, is inserted into the proximal ends of the second and third metacarpal

the forearm between the two heads of origin of the muscle), and the ulnar artery. The tendon serves as a guide to the artery in the distal half of the forearm.

FIG. 345.—THE SUPERFICIAL MUSCLES OF THE LEFT FOREARM.

FIG. 346.—DEEPER MUSCLES OF THE LEFT FOREARM.

Nerve-Supply.—Ulnar nerve (C. 8. T. 1.).

Actions.—The flexor carpi ulnaris is a flexor and adductor of the wrist, and an accessory flexor of the elbow-joint.

2. Intermediate Layer.

M. Flexor Digitorum Sublimis.—The *flexor digitorum sublimis* occupies a deeper plane than the four previous muscles. It has a threefold origin, from the humerus, radius, and ulna. (1) The chief or *humeral* head of origin is from the medial epicondyle of the humerus by the common tendon, from the *ulnar collateral* ligament of the elbow, and from adjacent intermuscular septa. (2) The *ulnar* head of origin is by a slender fasciculus from the medial border of the coronoid process of the ulna, proximal and medial to the origin of the pronator teres (Fig. 348, p. 389).

(3) The *radial* head of origin is from the proximal two-thirds of the volar margin of the radius by a thin fibromuscular attachment (Fig. 348, p. 389).

The muscle divides in the distal third of the forearm into four parts, each provided with a separate tendon which goes beneath the transverse carpal ligament, passes through the palm of the hand, and enters the corresponding digital sheath of the finger. At the wrist the four tendons are arranged in pairs, those for the middle and ring fingers in front, and those for the fore and little fingers behind, and are surrounded by a synovial sheath, along with the tendons of the *flexor digitorum profundus*, beneath the transverse carpal ligament. In the palm of the hand the tendons separate, and conceal the deep flexor tendons and lumbrical muscles.

Within the digital sheath each tendon is split into two parts by the tendon of the *flexor digitorum profundus*; after surrounding that tendon

FIG. 347.—THE TENDONS ATTACHED TO THE INDEX FINGER.

the two parts are partially re-united on its deep surface, and are inserted, after partial decussation, in two portions into the sides of the second phalanx.

The *vincula tendinum* form additional insertions of the muscle. They consist of delicate bands of connective tissue enveloped in synovial membrane, and are known as the *vincula longa* and *brevia*. The *vinculum breve* is a triangular band of fibres containing yellow elastic tissue (*ligamentum subflavum*), occupying the interval between the tendon and the digit for a short distance close to the insertion. It is attached to the front of the inter-phalangeal articulation and the head of the first phalanx. The *ligamentum longum* is a long narrow band extending from the back of the tendon to the proximal part of the palmar surface of the first phalanx.

Nerve-Supply.—Median nerve (C. 6.).

Actions.—The muscle is a flexor of the elbow, wrist, metacarpo-phalangeal and first (proximal) interphalangeal joints.

3. Deep Layer.

M. Flexor Digitorum Profundus.—The *flexor digitorum profundus* is a large muscle arising from the ulna, the interosseous membrane, and the deep fascia of the forearm, under cover of the *flexor digitorum sublimis* and the *flexor carpi ulnaris*. Its ulnar origin is from the volar and medial surfaces of the bone in its proximal two-thirds, extending proximally so as to include the medial side of the olecranon, and to embrace the insertion of the *brachialis* muscle into the coronoid

process. It arises laterally from the medial half of the interosseous membrane in its middle third (Figs. 348, p. 389, and 349, p. 390), and medially from the deep fascia of the forearm dorsal to the origin of the flexor carpi ulnaris.

The muscle forms a broad thick tendon which passes beneath the transverse carpal ligament, covered by the tendons of the flexor digitorum sublimis, and enveloped in the same synovial sac, and divides in the palm into four tendons for **insertion** into the terminal phalanges of the fingers. The tendon associated with the forefinger is usually separate from the rest of the tendons in its whole length.

Each tendon enters the digital sheath of the finger beneath the tendon of the flexor digitorum sublimis, which it pierces opposite the first phalanx, and is finally inserted into the base of the terminal phalanx. Like the tendons of the flexor sublimis, those of the deep flexor are provided with vincula, viz., *vincula brevia* attached to the capsule of the second interphalangeal articulation, and *vincula longa*, which are in this case connected to the tendons of the subjacent flexor digitorum sublimis.

Mm. Lumbricales. — The lumbricales are four small cylindrical muscles associated with the tendons of the flexor digitorum profundus in the palm of the hand. *The two lateral muscles* arise each by a single head from the radial sides of the tendons of the flexor digitorum profundus destined respectively for the fore and middle fingers. *The two medial muscles* arise, each by two heads, from the adjacent sides of the second and third, and third and fourth tendons.

From these origins the muscles are directed distally to the lateral side of each of the metacarpo-phalangeal joints, to be **inserted** into the capsules of these articulations, the lateral border of the first phalanx, and chiefly into the lateral side of the extensor tendon on the dorsum of the phalanx. The lumbricales vary considerably in number, and may be increased to six or diminished to two.

Nerve-Supply. — The flexor digitorum profundus is supplied in its lateral part by the volar interosseous branch of the median nerve (C. 7. 8. T. 1.); and in its medial part by the ulnar nerve (C. 8. T. 1.). The lateral two lumbricales are supplied by the median nerve (C. 6. 7.), and the medial two muscles by the ulnar nerve (C. 8. (T. 1.)).

Actions. — The flexor digitorum profundus is a powerful flexor of the wrist. It also flexes the fingers at the metacarpo-phalangeal joint, and acts in a similar way at both the interphalangeal joints.

The lumbrical muscles act as flexors of the fingers at the metacarpo-phalangeal joints, and

FIG. 348.—MUSCLE-ATTACHMENTS TO THE RIGHT RADIUS AND ULNA (Volar Aspects).

(by their attachment to the extensor tendons) as extensors of the fingers, acting on both interphalangeal joints.

M. Flexor Pollicis Longus.—The *flexor pollicis longus* arises beneath the *flexor digitorum sublimis* by fleshy fibres from the volar surface of the shaft of the radius in its middle two-fourths, and from a corresponding portion of the interosseous membrane. It has an additional origin occasionally from the medial border of the coronoid process of the ulna (Fig. 348, p. 389). Its radial origin is limited proximally by the oblique proximal part of the volar margin of the radius and the origin of the *flexor digitorum sublimis*, and distally by the insertion of the *pronator quadratus* muscle.

The muscle ends proximal to the wrist in a tendon, which passes over the *pronator quadratus* to the hand beneath the transverse carpal ligament, enveloped in a special synovial sheath.

In the palm the tendon is directed distally along the medial side of the thenar eminence, between the *flexor brevis* and adductor muscles of the thumb, to be inserted into the base of the terminal phalanx of the thumb on its palmar surface.

The muscle is placed deeply in the forearm, being concealed by the superficial layer of muscles and by the *flexor digitorum sublimis*.

Nerve-Supply.—Volar interosseous branch of the median (C. 7, 8, T. 1.).

Actions.—The muscle is a flexor of the wrist and thumb, acting in the latter movement on the metacarpal bone and both phalanges.

M. Pronator Quadratus.—The *pronator quadratus* is a quadrilateral fleshy muscle, occupying the distal fourth of the forearm. It is placed beneath the deep flexor tendons, and arises from the distal fourth of the volar margin and surface of the ulna (Fig. 348, p. 389).

It is directed transversely laterally to be inserted into the distal fourth of the volar surface of the radius, and into the narrow triangular area on its medial side in

FIG. 349.—THE DEEPEST MUSCLES ON THE VOLAR ASPECT OF THE LEFT FOREARM.

front of the attachment of the interosseous membrane (Fig. 348, p. 389).

The *pronator quadratus* is subject to considerable variations. It may even be absent; or it may have an origin from radius or ulna, or from both bones, and an insertion into the carpus.

The muscle is placed deeply in the distal part of the forearm, and is wholly concealed by the tendons of the muscles which descend beneath the transverse carpal ligament to the wrist and fingers. The radial artery and its accompanying veins pass over it at its insertion into the radius.

FIG. 350.—THE PALMAR MUSCLES (Right Side).

Nerve-Supply.—Volar interosseous branch of the median nerve (C. 7. 8. T. 1.).

Action.—The muscle acts along with the pronator teres in producing pronation of the forearm.

SHORT MUSCLES OF THE HAND.

The short muscles belonging to the hand, in addition to the palmaris brevis and the lumbrical muscles, already described, include the six muscles of the

thumb constituting the thenar eminence, the three muscles of the little finger constituting the hypothenar eminence, and the interossei muscles, which are deeply placed between the metacarpal bones.

Muscles of the Thumb.

The short muscles of the thumb are the abductor, opponens, and flexor brevis (with its deep portion, *interosseus primus volaris*), and the adductor muscle, subdivided into two heads—oblique and transverse.

M. Abductor Pollicis Brevis.—The **abductor pollicis brevis** (O.T. **abductor pollicis**) arises by fleshy fibres from the tubercle of the navicular, the ridge of the greater multangular, the volar surface of the transverse carpal ligament, and from

FIG. 351.—MUSCLE-ATTACHMENTS TO THE VOLAR ASPECT OF THE CARPUS AND METACARPUS.

tendinous slips derived from the insertions of the palmaris longus and abductor pollicis longus muscles (Fig. 350, p. 391). Strap-like in form, and superficial in position, it is inserted by a short tendon into the radial side of the first phalanx of the thumb at its proximal end, and into the capsule of the metacarpo-phalangeal joint.

Nerve-Supply.—Median nerve (C. 6. 7.).

Actions.—The muscle acts on the thumb at both the carpo-metacarpal and metacarpo-phalangeal joints. It abducts and draws forward the thumb.

M. Opponens Pollicis.—The **opponens pollicis**, partially concealed by the preceding muscle, arises by fleshy and tendinous fibres from the volar surface of the transverse carpal ligament and from the ridge on the greater multangular bone.

Extending distally and laterally it is inserted into the whole length of the lateral border and the radial half of the volar surface of the first metacarpal bone (Fig. 351, p. 392).

Nerve-Supply.—Median nerve (C. 6. 7.).

Action.—It acts solely on the first metacarpal bone, in the movement of opposition of the thumb.

M. Flexor Pollicis Brevis.—The *flexor pollicis brevis* consists of two parts.
a. The superficial part of the muscle, partly concealed by the abductor pollicis brevis, arises by fleshy and tendinous fibres from the distal border of the transverse carpal ligament, and sometimes from the ridge of the greater multangular.

It is inserted into the radial side of the base of the first phalanx of the thumb, a sesamoid bone being present in the tendon of insertion.

b. The deep part of the muscle (interosseus primus volaris) arises from the medial side of the base of the first metacarpal bone.

It is inserted into the medial side of the base of the first phalanx of the thumb along with the adductor pollicis.

This little muscle is deeply situated in the first interosseous space, in the interval between the adductor pollicis obliquus and the first dorsal interosseous muscle. It may be regarded as homologous with the volar interossei muscles, with which it is in series.

Nerve-Supply.—Median nerve (C. 6. 7.).

Actions.—It is a flexor of the thumb and assists also in the movement of opposition of the thumb to the fingers.

M. Adductor Pollicis.—The *adductor pollicis* is separated into two parts by the radial artery.

(1) The *oblique head* lies deeply in the palm, covered by the tendons of the long flexors of the thumb and fingers. It arises by fleshy fibres from the volar surfaces of the greater and lesser multangular and capitate bones, from the sheath of the tendon of the flexor carpi radialis, from the bases of the second, third, and fourth metacarpal bones, and from the volar ligaments connecting these bones together (Fig. 351, p. 392).

It is inserted by a tendon, in which a sesamoid bone is developed, into the medial side of the base of the first phalanx of the thumb. At its lateral border a slender slip separates from the rest of the muscle, and passing obliquely beneath the tendon of the flexor pollicis longus, is inserted into the lateral side of the base of the first phalanx along with the superficial part of the flexor pollicis brevis.

(2) The *transverse head*, lying deeply in the palm beneath the flexor tendons, arises by fleshy fibres from the medial ridge on the volar aspect of the shaft of the third metacarpal bone, in its distal two-thirds (Fig. 351, p. 392), and from the fascia covering the interosseous muscles in the second and third spaces.

Triangular in form, it is directed laterally, over the interossei muscles of the first two spaces, to be inserted by tendon into the medial side of the base of the first phalanx of the thumb along with the oblique head.

Nerve-Supply.—Deep branch of the ulnar nerve (C. 8. (T. 1.)).

Actions.—Adduction and opposition of the thumb.

Muscles of the Little Finger.

The short muscles of the little finger are the adductor, opponens, and flexor brevis digiti quinti.

M. Abductor Digiti Quinti.—The *abductor digiti quinti* is most superficial. It arises from the pisiform bone and from the tendon of the flexor carpi ulnaris and its ligamentous continuations (Fig. 351, p. 392).

It is inserted by tendon into the medial side of the base of the first phalanx of the little finger.

Nerve-Supply.—Deep branch of the ulnar nerve (C. 8. (T. 1.)).

Actions.—The muscle separates the little finger from the ring finger, and assists in flexion of the finger at the metacarpo-phalangeal joint.

M. Opponens Digiti Quinti.—The *opponens digiti quinti* arises beneath the

preceding muscle by tendinous fibres from the transverse carpal ligament and from the hamulus of the os hamatum.

It is inserted into the medial margin and medial half of the volar surface of the fifth metacarpal bone in its distal three-fourths (Fig. 351, p. 392).

FIG. 352.—THE VOLAR INTEROSSEOUS MUSCLES (Right Side).

V¹, first; V², second; and V³, third volar interosseous muscles.

Nerve-Supply.—Deep branch of the ulnar nerve (C. 8. (T. 1)).

Action.—The muscle acts only on the metacarpal bone, drawing it forward, so as to deepen the hollow of the hand.

M. Flexor Digiti Quinti Brevis.

—The flexor digiti quinti brevis may be absent or incorporated with either the opponens or abductor digiti quinti. It arises by tendinous fibres from the transverse carpal ligament and from the hamulus of the os hamatum (Fig. 351, p. 392).

It is inserted along with the abductor into the medial side of the first phalanx of the little finger.

Nerve-Supply.—The deep branch of the ulnar nerve (C. 8. (T. 1)).

Actions.—Flexion of the little finger at the carpo-metacarpal and metacarpophalangeal joints.

The Interosseous Muscles.

The interosseous muscles of the hand occupy the spaces between the metacarpal bones. They are arranged in two sets, volar and dorsal.

Mm. Interossei Volares.—The volar (O.T. palmar) interossei are three in

FIG. 353.—MUSCLE-ATTACHMENTS TO THE DORSAL ASPECT OF THE RIGHT METACARPUS.

number, occupying the three medial interosseous spaces. Each arises by a single head; the *first* from the medial side of the shaft of the second metacarpal bone; the *second* and *third* from the lateral sides of the shafts of the fourth and fifth metacarpal

bones respectively (Fig. 352, p. 394). Each ends in a tendon which is directed distally behind the deep transverse metacarpal ligament, to be inserted into the dorsal expansion of the extensor tendon, the capsule of the metacarpo-phalangeal articulation, and the side of the first phalanx of the finger; the *first* is inserted into the medial side of the second finger; the *second* and *third* into the lateral sides of the fourth and fifth fingers. The deep part of the flexor pollicis brevis (*interosseus primus volaris*) is to be regarded as the homologous muscle of the first interosseous space.

Mm. Interossei Dorsales.—The dorsal interossei are four in number. Each arises by two heads from the sides of the metacarpal bones bounding each interosseous space (Figs. 353, p. 394, and 354, p. 395).

Each forms a fleshy mass, ending in a membranous tendon which, passing distally behind the deep transverse metacarpal ligament, is inserted exactly like the volar muscles into the dorsal aspect of each of the four fingers. The insertion of the *first* dorsal interosseous muscle is into the lateral side of the index finger; the *second* muscle is attached to the lateral side of the middle finger; the *third*

FIG. 354.—DORSAL INTEROSSEOUS MUSCLES OF THE HAND (seen from the Volar Aspect).

muscle to the medial side of the same finger; and the *fourth* muscle to the medial side of the ring finger.

The interosseous muscles of the hand in some cases have a disposition similar to that of the corresponding muscles of the foot (p. 435).

Nerve-Supply.—The deep branch of the ulnar nerve (C. 8. (T. 1.)).

Actions.—The interossei muscles act in a similar way to, and along with, the lumbricales, flexing the fingers at the metacarpo-phalangeal joints, and extending them at the interphalangeal joints. In addition, the dorsal interossei serve to **abduct** the fingers into which they are inserted (fore, middle, and ring fingers) from the middle line of the middle finger; the **volar** muscles on the other hand are **adductors** of the fingers into which they are inserted (fore, ring, and little finger) towards the middle line of the middle finger.

THE MUSCLES ON THE DORSAL SURFACE OF THE FOREARM.

The group of muscles occupying the lateral side of the elbow and the dorsal surface of the forearm and hand include the supinator muscles of the forearm and the extensors of the wrist and digits. They are divisible into a **superficial** and a **deep layer**.

The **superficial layer** comprises seven muscles, which are in order, from the radial to the ulnar side of the forearm, the brachioradialis, the two radial extensors of the carpus, the extensor digitorum communis and extensor digiti quinti proprius, the extensor carpi ulnaris, and the anconæus.

The **deep muscles** are five in number: one, the supinator, extends between the proximal parts of the ulna and radius; the others are the special extensors of the thumb and forefinger, viz., the abductor pollicis longus, extensor pollicis longus and extensor pollicis brevis, and extensor indicis proprius. They cover the dorsal surface of the bones of the forearm and the interosseous membrane, and are almost wholly concealed by the superficial muscles. Only the abductor pollicis longus and the extensor pollicis brevis become superficial in the distal part of the forearm, emerging between the radial extensors of the carpus and the extensor digitorum communis.

Superficial Muscles.

M. Brachioradialis.—The brachioradialis arises by fleshy fibres from the anterior aspect of the proximal two-thirds of the lateral epicondylar ridge of the humerus, and from the anterior surface of the lateral intermuscular septum (Fig. 340, p. 380).

Occupying the lateral side of the hollow of the elbow, the muscle passes distally along the lateral border of the forearm, and ends about the middle in a narrow flat tendon which is inserted under cover of the tendons of the abductor pollicis longus and extensor pollicis brevis, by a transverse linear attachment, into the proximal limit of the groove for the above-named muscles on the lateral side of the distal extremity of the radius. Some of its fibres gain an attachment to the ridge on the volar margin of the groove, and others spread over the surface of the groove for a variable distance (Figs. 355, p. 397, and 348, p. 389).

Nerve-Supply.—The muscle is supplied by a branch of the radial nerve (C. 5. 6.) in the hollow of the elbow.

Actions.—The muscle is primarily a flexor of the elbow-joint. It is also a semi-pronator and semi-supinator of the forearm, bringing the limb from the supine or prone position, into a position in which the radius is uppermost. It thus assists both the pronator and supinator muscles.

M. Extensor Carpi Radialis Longus.—The extensor carpi radialis longus arises by fleshy fibres from the anterior aspect of the distal third of the lateral epicondylar ridge of the humerus, from the anterior surface of the lateral intermuscular septum, and from the common tendon of origin of succeeding muscles, attached to the lateral epicondyle (Figs. 356 and 357, p. 399).

It ends in a tendon in the distal half of the forearm, which passes beneath the dorsal carpal ligament, to be inserted into the dorsal surface of the base of the second metacarpal bone on its radial side (Fig. 353, p. 394).

The muscle is concealed in its proximal part by the brachioradialis, and its tendon in the distal half of the forearm is crossed obliquely by the abductor pollicis and by the extensor pollicis brevis.

Nerve-Supply.—The muscle is supplied by a branch of the radial nerve in the hollow of the elbow (C. (5.) 6. 7. 8.).

Actions.—The muscle is an extensor of the wrist, and also an accessory flexor of the elbow-joint.

M. Extensor Carpi Radialis Brevis.—The extensor carpi radialis brevis arises from the common tendon, from the *radial collateral* ligament of the elbow, from the fascia over it, and from intermuscular septa on either side.

It passes distally in the dorsal surface of the forearm and under the dorsal carpal ligament in close relation to the previous muscle, to be inserted by a tendon into the bases of the second and third metacarpal bones (Fig. 353, p. 394). A bursa is placed beneath the two radial extensor tendons close to their insertion.

It is practically concealed in the forearm by the extensor carpi radialis longus, and in the distal half is crossed obliquely by the abductor pollicis longus and the extensor pollicis brevis. The tendons of the two muscles are crossed on the dorsum of the wrist by the tendon of the extensor pollicis longus.

Nerve-Supply.—The muscle is supplied by the deep branch of the radial nerve.

Actions.—Like the long extensor, this muscle extends the hand at the wrist; and is a subsidiary flexor of the elbow-joint.

M. Extensor Digitorum Communis.—The *extensor digitorum communis* arises from the common tendon, from the lateral epicondyle of the humerus, from the fascia over it, and from intermuscular septa on either side. Extending along the dorsum of the forearm it ends proximal to the wrist in four tendons, of which the most lateral often has a separate fleshy belly. After passing beneath the dorsal carpal ligament in a compartment along with the *extensor indicis proprius*, the tendons separate on the dorsum of the hand, where the three most medial tendons are joined together by two obliquely placed bands. One passes distally and laterally, and connects together the third and second tendons; the other is a broader and shorter band, which passes also distally and laterally, and joins the fourth to the third tendon. In some cases a third band is present which passes distally and medially from the first to the second tendon; and frequently the tendon for the little finger is joined to the tendon for the ring finger, and separates from it only a short distance above the distal end of the metacarpal bone.

The tendons are inserted in the following manner:—On the finger each tendon spreads out so as to form a membranous expansion over the knuckle and on the dorsum of the first phalanx. The border of the tendon is indefinite over the metacarpo-phalangeal articulation, of which it forms the dorsal ligament. On the dorsum of the first phalanx the tendon receives at its sides the insertions of the interosseous and lumbrical muscles. At the distal end of the first phalanx it splits into ill-defined median and collateral slips, proceeding over the dorsum of the first inter-phalangeal articulation, of which they form the dorsal ligament. The median slip is inserted into the dorsum of the base of the second phalanx, while the two lateral pieces become united to form a membranous tendon on the dorsum of the second phalanx, which, after passing over the second inter-phalangeal articulation, is inserted into the base of the terminal phalanx.

The muscle is placed superficially in the forearm between the extensors of the carpus and the proper extensor of the little finger.

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).

Actions.—The muscle extends the elbow, wrist, and fingers. On account of the attachment together of the tendons to the third, fourth, and fifth fingers by accessory bands in the dorsum of the hand, these three fingers can only be fully extended together, while extension of the first finger

FIG. 355.—MUSCLE-ATTACHMENTS TO THE RIGHT RADIUS AND ULNA (Dorsal Aspect).

can take place separately. In extension of the inter-phalangeal joints, the muscle is aided by the interossei and lumbrical muscles.

M. Extensor Digiti Quinti Proprius.—The *extensor digiti quinti proprius* has an *origin* similar to and closely connected with that of the preceding muscle, from the common tendon, the fascia over it, and from intermuscular septa.

Passing along the dorsum of the forearm as a narrow fleshy slip, between the *extensor digitorum communis* and the *extensor carpi ulnaris*, it ends in a tendon which occupies a groove between the radius and ulna in a special compartment of the dorsal carpal ligament of the wrist. On the dorsum of the hand the tendon, usually split into two parts, lies on the medial side of the tendons of the *extensor digitorum communis*, and is finally *inserted* into the expansion of the *extensor tendon* on the dorsum of the first phalanx of the little finger.

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).

Actions.—The muscle extends the elbow, wrist, and little finger.

M. Extensor Carpi Ulnaris.—The *extensor carpi ulnaris* has a double origin : (1) from the common tendon from the lateral epicondyle of the humerus, from the fascia over it, and from the intermuscular septa; and (2) through the medium of the deep fascia, from the dorsal margin of the ulna in its middle two-fourths.

Lying in the forearm upon the dorsal surface of the ulna, it ends in a tendon which occupies a groove on the dorsal surface of the ulna in a special compartment of the dorsal ligament of the wrist, and is *inserted* into the medial side of the base of the fifth metacarpal bone (Fig. 353, p. 394).

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).

Actions.—The muscle is an extensor of the wrist, and at the same time, acting with the *flexor carpi ulnaris* it is a powerful adductor of the wrist. Its humeral attachment makes it also a subordinate extensor of the elbow-joint.

M. Anconæus.—The *anconæus* is a small triangular muscle arising by a separate tendon from the distal part of the dorsal surface of the lateral epicondyle of the humerus (Fig. 341, p. 380), and from the dorsal part of the capsule of the elbow-joint.

Spreading out over the dorsal surface of the elbow-joint and proximal part of the ulna, it is *inserted* by fleshy fibres into a triangular surface on the lateral aspect of the olecranon and dorsal surface of the ulna, as far distally as the oblique line (Fig. 355, p. 397). It is also *inserted* into the fascia which covers it.

The *epitrochleoanconæus* is an occasional small muscle arising from the dorsal surface of the medial epicondyle of the humerus, and *inserted* into the medial side of the olecranon. It covers the ulnar nerve in its passage to the forearm.

Nerve-Supply.—The muscle is supplied by the terminal branch of the nerve to the medial head of the triceps muscle from the radial (C. 7. 8.).

Actions.—The *anconæus* is an extensor of the elbow.

Deep Muscles.

M. Supinator.—The *supinator muscle* (O.T. *supinator radii brevis*) is the most proximal of the deeper muscles. It is almost wholly concealed by the superficial muscles, and has a complex *origin*,—(1) from the lateral epicondyle of the humerus; (2) from the radial collateral, and annular ligaments of the elbow-joint; (3) from the triangular surface on the shaft of the ulna just distal to the radial notch; and (4) from the fascia over it.

From this origin the muscle spreads laterally and distally, enveloping the proximal part of the radius, and is *inserted* into the volar and lateral surfaces of the bone, as far forwards as the tubercle of the radius, as far proximally as the neck, and as far distally as the oblique line and the insertion of the *pronator teres* (Figs. 348, p. 389, and 355, p. 397).

The muscle is divisible into *superficial* and *deep parts* with humeral and ulnar origins, between which the deep branch of the radial nerve passes in its course to the dorsal part of the forearm.

Nerve-Supply.—The supinator is supplied by a branch from the deep branch of the radial nerve, which arises from the nerve before the main trunk enters the muscle.

Action.—The muscle is an extensor of the elbow, and the main supinator of the forearm. In the latter action it is assisted by the biceps.

FIG. 356.—SUPERFICIAL MUSCLES ON THE DORSUM OF THE LEFT FOREARM.

FIG. 357.—DEEP MUSCLES ON THE DORSUM OF THE LEFT FOREARM.

M. Abductor Pollicis Longus.—The abductor pollicis longus (O.T. extensor ossis metacarpi pollicis) arises by fleshy fibres distal to the supinator muscle from the most proximal of the narrow impressions on the lateral half of the dorsal surface of the ulna; from the middle third of the dorsal surface of

the radius; and from the intervening portion of the interosseous membrane (Fig. 355, p. 397).

Becoming superficial in the distal part of the forearm along with the extensor pollicis brevis, between the extensors of the wrist and the common extensor of the fingers, its tendon passes with the latter muscle beneath the dorsal ligament of the wrist, to be inserted into the lateral side of the base of the first metacarpal bone (Fig. 356, p. 399). From the tendon close to its insertion a tendinous slip passes to the abductor pollicis brevis and the fascia over the thenar eminence, and another is frequently attached to the greater multangular bone.

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).

Actions.—The muscle abducts the metacarpal bone of the thumb, and assists in abduction and extension of the wrist.

M. Extensor Pollicis Brevis.—The *extensor pollicis brevis* (O.T. *extensor primi internodii pollicis*), an essentially human muscle, is a specialised portion of the previous muscle. It arises from a rhomboid impression on the dorsal surface of the radius, and from the interosseous membrane, distal to the abductor pollicis longus (Fig. 355, p. 397). It is closely adherent to that muscle, and accompanies it beneath the dorsal ligament of the wrist and over the radial artery to the thumb.

Its tendon is then continued along the dorsal surface of the first metacarpal bone, to be inserted into the dorsal surface of the base of the first phalanx of the thumb. Before reaching its insertion the tendon helps to form the capsule of the metacarpo-phalangeal joint.

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).

Actions.—The muscle extends the wrist and thumb (or the metacarpo-phalangeal joint), and assists in abduction of the wrist and thumb.

M. Extensor Pollicis Longus.—The *extensor pollicis longus* (O.T. *extensor secundi internodii pollicis*) arises from the lateral part of the dorsal surface of the ulna in its middle third, and from the interosseous membrane, distal to the abductor pollicis longus (Fig. 355, p. 397). Its tendon grooves the dorsal surface of the radius, and occupies a special compartment beneath the dorsal ligament of the wrist.

Extending obliquely across the dorsal surface of the hand, the tendon crosses the radial artery, and helps to form the capsule of the first metacarpo-phalangeal articulation, and is inserted into the dorsal surface of the base of the second phalanx of the thumb.

At the wrist the tendons of the muscles of the thumb, the abductor pollicis longus and extensor pollicis brevis laterally, and the extensor pollicis longus medially, bound a hollow (the “anatomical snuff-box”) best seen in extension and abduction of the thumb, which corresponds to the position of the radial artery as it winds round the wrist to reach the palm of the hand.

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).

Actions.—This muscle is an extensor and an abductor of the thumb, and of the wrist.

M. Extensor Indicis Proprius.—The *extensor indicis proprius* (O.T. *extensor indicis*) arises distal to the extensor pollicis longus from the most distal impression on the dorsal surface of the ulna, extending distally from the middle of the shaft to within two inches of its distal end, and sometimes also from the interosseous membrane (Fig. 355, p. 397). Its tendon passes through a compartment of the dorsal carpal ligament along with the tendons of the extensor digitorum communis.

On the dorsum of the hand the tendon lies on the medial side of the tendon of the common extensor destined for the forefinger, and is inserted into the forefinger, joining the membranous expansion of the tendon of the extensor digitorum communis on the dorsum of the first phalanx.

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).

Actions.—The muscle is an extensor of the wrist and forefinger.

Actions of the Muscles of the Forearm and Hand.

These muscles are concerned in the movements of the elbow, wrist, and digits.

In the majority of cases the muscles act upon more than one joint.

1. Action on the Elbow-Joint.—It has been shown already that flexion and extension of the elbow are assisted by certain of these muscles. The **flexor muscles** are the pronator teres, and the flexor muscles of the wrist and fingers. In the position of pronation, the movement of flexion is aided by the brachioradialis and extensor muscles of the wrist and fingers. The **extensors** are the supinator muscle and anconæus, and the extensor muscles of the wrist and fingers.

2. Pronation and supination of the hand are performed by special muscles, aided by muscles which act also upon other joints. The brachioradialis assists in flexion and pronation on the one hand, and in extension and supination on the other hand. In the supine position it assists pronation, and in the prone position it assists supination, in each case bringing the hand into the position intermediate between pronation and supination.

Pronation.	Supination.
Pronator teres Pronator quadratus Brachioradialis Flexor carpi radialis Weight of the limb	Supinator Biceps brachii Brachioradialis Extensors of thumb and fingers Weight of the limb

3. Action on the Wrist-Joint.—The movements at the wrist-joint are flexion and extension, abduction and adduction. Flexion and adduction are much more extensive movements than extension and abduction, on account of the form of the wrist-joint. The following muscles produce these movements:—

Flexion.	Extension.	Adduction.	Abduction.
Flexor carpi radialis Palmaris longus Flexor carpi ulnaris Long flexors of thumb and fingers	Extensors of the wrist Extensors of thumb and fingers	Flexor carpi ulnaris Extensor carpi ulnaris	Flexor carpi radialis Extensors of wrist Extensors of thumb

4. Movements of the Fingers.—Two separate series of movements occur in relation to the articulations of the fingers: flexion and extension (at the metacarpo-phalangeal and inter-phalangeal joints), and abduction and adduction (only at the metacarpo-phalangeal joints). The movements and the muscles concerned are given in the following tables:—

Flexion.	Extension.
Flexor digitorum sublimis Flexor digitorum profundus Lumbricales } <i>(acting on the metacarpo-phalangeal articulations)</i> Interossei } Flexor digiti quinti brevis	Extensor digitorum communis Extensor indicis proprius Extensor digiti quinti proprius Lumbricales } <i>(acting on the inter-phalangeal articulations)</i> Interossei }

Abduction.	Adduction.
Lumbricales Flexor brevis and Opponens, digiti quinti } <i>(from the medial side of the hand)</i> Dorsal interossei } <i>(from the middle line of the middle finger)</i>	Palmar interossei } <i>(to the middle line of the middle finger)</i>

Flexion is more powerful and complete than extension of the fingers. The flexor digitorum profundus alone acts on the terminal phalanges; the flexor sublimis and flexor profundus together flex the proximal inter-phalangeal joint; and flexion of the metacarpo-phalangeal articulation is effected by these muscles, assisted by the interossei, lumbricales, and flexor digiti quinti brevis. Extension of the phalanges is effected by the united action of the extensors of the digits, the interossei and lumbricales; extension of the fingers at the metacarpo-phalangeal joints is produced solely by the long extensor muscles. *Separate extension of the index finger* only is possible; the three inner fingers can only be flexed and extended together, on account of the connecting bands joining the extensor tendons together on the back of the hand.

5. Movements of the Thumb.—The movements of which the thumb is capable are flexion

and extension (occurring at the carpo-metacarpal, metacarpo-phalangeal, and inter-phalangeal joints); abduction and adduction, together with circumduction (occurring at the carpo-metacarpal joint).

The muscles and their respective actions are given in the following table:—

Flexion.	Extension.
Opponens pollicis { (carpo-metacarpal joint)	Abductor pollicis longus { (carpo-metacarpal joint)
Flexor brevis } (carpo-metacarpal and metacarpo-phalangeal joint)	Extensor pollicis brevis { (carpo-metacarpal and metacarpo-phalangeal joint)
Abductor brevis }	Extensor pollicis longus (all joints)
Flexor pollicis longus (all joints)	
Adduction.	Abduction.
Adductor of the thumb	Abductor pollicis brevis
Flexor pollicis brevis	Extensors of the thumb
Opponens pollicis	
First dorsal interosseous	
Circumduction—a combination of the above muscles.	

The characteristic features of the movements of the upper limb are their range and refinement. The hand, in addition to its intrinsic powers, can be moved through a wide range and in several planes by the muscles acting on the wrist and radio-ulnar joints; this range is increased by the fore and aft movements at the elbow-joint, and the extensive movements of which the shoulder and clavicular joints are capable. The result is that the hand can be brought into a position to cover and guard any portion of the body. The precision and refinement of movement is made possible by the co-ordinate movements of the various muscles acting upon the several joints, so that actions can be performed (as raising the food to the mouth) in which all the articulations of the limb are brought into play; while others (such as writing) are possible by movements at the joints of the wrist and fingers along with fixation of the elbow-joint.

THE LOWER LIMB.

FASCIÆ AND MUSCLES OF THE THIGH AND BUTTOCK.

FASCIÆ.

The **superficial fascia** of the thigh and buttock is continuous above with the fascia of the abdomen and back, medially with that of the perineum, and distally with that of the leg. It presents noticeable features in the buttock and groin.

In the **buttock** the superficial fascia is of considerable thickness, and is usually loaded with fat, whereby it assists in forming the contour of the buttock and the fold of the nates.

In the **groin** it is divisible into *two layers*: a **superficial fatty layer**, continuous with a similar layer on the anterior surface of the abdominal wall above, and over the perineum medially, and a **deeper membranous layer**, which is attached above to the medial half of the inguinal ligament, and to the deep fascia of the thigh just distal to the lateral half of that ligament. Medially it is attached to the pubic arch, and below the level of the femoral triangle it blends inseparably with the superficial fatty layer. The separation of these two layers of the superficial fascia is occasioned by the presence between them of the inguinal and superficial subinguinal lymph glands, the great saphenous vein and its tributaries, and some small arteries. The attachment of the deeper layer of the fascia to the pubic arch and the inguinal ligament cuts off the superficial tissues of the thigh from the perineum and the abdominal wall, and prevents the passage into the thigh of fluid collected in the perineum or beneath the fascia of the abdominal wall.

The **deep fascia** or **fascia lata** forms a tubular investment for the muscles and vessels of the thigh and buttock. It is firmly attached above to the iliac crest, the sacro-tuberous ligament, the ischium, the pubic arch, the pubic symphysis and crest, and the inguinal ligament. In the distal part of the thigh it forms the inter-muscular septa; and in relation to the knee, it is continuous with the deep fascia of the leg, gains attachment to the patella, the condyles of the tibia and the head of the fibula, and forms the collateral ligaments of the patella.

On the front of the thigh the deep fascia is thick and strong. It is pierced by numerous openings for vessels and nerves, the most important of which is the **fossa ovalis** (O.T. **saphenous opening**) for the passage of the great saphenous vein. A femoral

FIG. 358.—SUPERFICIAL ANATOMY OF THE LEFT GROIN.

hernia passes through this opening to reach the groin and anterior abdominal wall. It is an oval opening of variable size situated just distal to the medial half of the inguinal ligament, and immediately anterior to the femoral vessels. It is covered by the superficial fascia, and by a special layer of fascia, the **fascia cribrosa**, a thin perforated lamina attached to the margins of the opening. The lateral edge of the opening (*margo falciformis*) is formed by the margin of the *iliac portion* of the fascia lata, which is attached above to the iliac crest and the inguinal ligament; the medial edge is formed by the *fascia pectinea* which is continued proximally behind the femoral sheath, over the adductor longus and pectineus muscles to the ilio-pectineal line and the capsule of the hip-joint. These two layers of the fascia lata are continuous at the distal concave margin of the fossa ovalis, forming its **inferior cornu**. As they pass proximally towards the pelvis they occupy different

planes, the iliac portion being in front of the sheath of the femoral vessels, while the pectineal fascia is behind it. The **superior cornu** of the fossa ovalis, placed in front of the sheath, is derived solely from the iliac portion of the fascia lata. It forms a strong triangular band of fascia known as the **falciform margin**, attached above to the medial half of the inguinal ligament. It has an important share in directing the course of a femoral hernia upwards on to the abdominal wall.

On the medial side of the thigh the fascia lata is thin where it covers the adductor muscles. At the knee it is associated with the tendons of the vasti muscles, and forms the **collateral ligaments of the patella**, attached to the borders of the patella and to the condyles of the tibia. On the lateral side of the thigh it

FIG. 359.—THE DISSECTION OF THE LEFT INGUINAL CANAL.

forms the **tractus iliotibialis**—a broad thick layer of fascia which is attached above to the iliac crest, and receives the insertions of the tensor fasciæ latæ, and part of the glutæus maximus muscles; its distal attachment is to the capsule of the knee-joint and the lateral condyle of the tibia. A strong band of fascia continued proximally from the ilio-tibial tract beneath the tensor fasciæ latæ muscle joins the tendon of origin of the rectus femoris and the capsule of the hip-joint.

On either side of the thigh above the knee an intermuscular septum is formed. The **lateral intermuscular septum** extends medially from the ilio-tibial tract to the lateral epicondylar line and linea aspera of the femur, and gives attachment to the vastus lateralis and vastus intermedius anteriorly, and the short head of the biceps posteriorly. The **medial intermuscular septum** in the distal third of the thigh is associated with, and to a large extent represented by, the tendon of insertion of the adductor magnus muscle. It is also related to the fascia which envelops the

adductor muscles, and forms the sheaths for the sartorius and gracilis muscles. In the middle third of the thigh the fascia under the sartorius is greatly thickened by transverse fibres and binds together the vastus medialis and adductor longus and adductor magnus muscles. This layer of fascia roofs over the femoral vessels in their course through Hunter's *adductor canal*.

The *fascia lata of the buttock* is thick anteriorly where it covers and gives origin to the glutæus medius, thinner posteriorly over the glutæus maximus, at the upper border of which it splits to enclose the muscle. It is thickened over the greater trochanter, where it forms the insertion of the greater part of the latter muscle.

On the posterior surface of the thigh and over the popliteal fossa the fascia is strengthened by transverse fibres derived from the hamstring muscles. The popliteal fascia forming the roof of the popliteal fossa is specially thick, and is usually pierced by the small saphenous vein.

Femoral Sheath.—This is a conical membranous investment, derived from the fascial lining of the abdominal cavity, the fascia transversalis in front and the fascia iliaca behind, prolonged along the femoral vessels in their passage behind the inguinal ligament into the femoral triangle. The sheath is about an inch and a half in length, and is divided into three compartments—a lateral space for the artery, an intermediate space for the vein, and a medial channel containing lymph vessels and fat, and named the *femoral canal*. This canal is the passage through which a femoral hernia enters the thigh. Its proximal limit is the *femoral ring* bounded anteriorly by the inguinal ligament, posteriorly by the origin of the pectineus muscle from the pubis, medially by the *ligamentum lacunare* (*Gimbernati*), and laterally by the femoral vein. In front of it the fascia transversalis forming the sheath is thickened to form the *deep femoral arch*. The part of the inguinal ligament in front of the ring is called the *superficial femoral arch*. The inferior epigastric artery separates the ring from the abdominal inguinal ring. The canal ordinarily contains fat which is continuous above with the extra-peritoneal tissue. The ring is filled by a plug of fat or a lymph gland, constituting the *femoral septum*.

The femoral canal ends behind the fossa ovalis, covered by the fascia cribrosa, while the falciform margin crosses over it and conceals its proximal portion. The course of a femoral hernia is determined by this band. The hernia descends through the femoral ring, pushing the femoral septum before it; after passing through the femoral canal, it is directed forwards through the fossa ovalis. The anterior part of the hernia being pressed upon and retarded by the femoral arches, and by the falciform margin, the posterior part pushes onwards, hooks round the falciform margin, and is directed upwards over the inguinal ligament. The coverings of a femoral hernia, in addition to peritoneum and extra-peritoneal tissue (femoral septum), are femoral sheath, fascia cribrosa, superficial fascia, and skin.

MUSCLES OF THE THIGH AND BUTTOCK.

The muscles of the thigh and buttock are divisible into four main groups by their situation, action, and nerve-supply. On the *anterior surface* of the thigh are the quadriceps femoris, the sartorius, ilio-psoas, and pectineus muscles; on the *medial side* of the thigh are the adductor muscles; in the region of the *buttock* are the glutæi and rotators of the hip-joint; and on the *posterior aspect* of the thigh are the hamstring muscles.

THE MUSCLES ON THE ANTERIOR ASPECT OF THE THIGH.

The chief muscle on the anterior aspect of the thigh is the quadriceps femoris, which occupies the space between the tensor fasciæ latæ and ilio-tibial tract laterally, and the sartorius medially. The sartorius crosses the thigh obliquely; it separates the quadriceps femoris from the adductor muscles; it forms in the proximal third of the thigh the lateral boundary of the femoral triangle, and in

FIG. 360.—THE MUSCLES OF THE ANTERIOR ASPECT OF THE RIGHT THIGH.

the middle third of the thigh, the roof of Hunter's adductor canal. The ilio-psoas, passing into the thigh beneath the inguinal ligament, assists along with the pectineus and adductor muscles in forming the floor of the femoral triangle.

M. Sartorius.—The sartorius, a long strap-like muscle, arises from the superior anterior spine of the ilium and half of the notch below it (Fig. 360).

It passes distally in the thigh to the medial side of the knee, where it is inserted by aponeurotic fibres into the medial surface of the shaft of the tibia just distal to the medial condyle, and by its borders into fascial expansions which join the capsule and the tibial collateral ligament of the knee-joint, and the fascia lata of the leg (Fig. 363, p. 408).

The sartorius is superficial in its whole extent. Its proximal third forms the lateral boundary of the femoral triangle; its middle third forms the roof of the adductor canal; and its distal third, in contact with the medial side of the knee, is separated from the tendon of the gracilis muscle by the saphenous nerve and the saphenous branch of the arteria genu suprema. A bursa lies beneath the tendon at its insertion.

Nerve-Supply.—The sartorius is supplied by two sets of nerves associated with the two intermediate cutaneous branches of the femoral nerve (L. 2. 3.).

Actions.—The sartorius, "the tailor's muscle," is a flexor of the hip and knee. It also everts the thigh and assists in medial rotation of the knee-joint.

M. Quadriceps Femoris.—The quadriceps femoris is composed of four muscles—the rectus femoris, vastus lateralis, vastus intermedius, and vastus medialis.

The rectus femoris is superficial except at its origin, which is covered by the glutæi, sartorius, and tensor fasciæ latæ muscles. The vasti lie on either side of the rectus muscle, the vastus lateralis being partially concealed

by the tensor fasciæ latæ and ilio-tibial tract, the vastus medialis by the sartorius

muscle. The vastus intermedius envelops the femur, and is concealed by the other muscles.

M. Rectus Femoris.—The rectus femoris has a double tendinous origin. (1) The *straight head* arises from the inferior anterior spine of the ilium (Fig. 366, p. 412); (2) the *reflected head* springs from a rough groove on the dorsum ilii just above the highest part of the acetabulum (Fig. 366, p. 412). A bursa lies beneath this head of origin. The two heads, bound together and connected to the capsule of the hip-joint by a band of fascia derived from the deep surface of the tensor fasciæ latæ (ilio-tibial tract), give rise to a single tendon which extends for some distance on the anterior surface of the muscle, and from which the muscular fibres arise. The muscular fibres springing from this tendon, and also from a median septal tendon, present a bipennate arrangement, and end below in a broad tendon which passes proximally for some distance along the posterior surface of the muscle. This tendon gradually narrows towards the knee, and spreading out again, is inserted into the proximal border of the patella. It receives laterally parts of the insertions of the lateral and medial vasti muscles, and on its deep surface is joined by the insertion of the vastus intermedius. A bursa, which communicates with the synovial membrane of the knee-joint, lies beneath its tendon in front of the distal end of the shaft of the femur.

FIG. 361.—MUSCLE-ATTACHMENTS TO THE ANTERIOR SURFACE OF THE PROXIMAL PART OF THE LEFT FEMUR.

FIG. 362.—TRANSVERSE SECTION OF THE THIGH (HUNTER'S ADDUCTOR CANAL).

M. Vastus Lateralis.—The vastus lateralis has an origin, partly fleshy, partly membranous, from (1) the capsule of the hip-joint, (2) the tubercle of the femur, (3) a concave surface on the anterior surface of the shaft of the bone medial to the

greater trochanter, (4) the distal border of the greater trochanter, (5) the lateral margin of the gluteal tuberosity of the femur and the tendon of the glutæus maximus, (6) the proximal half of the linea aspera, and (7) the fascia lata and lateral intermuscular septum (Fig. 360, p. 406).

It forms a thick, broad muscle directed distally and forwards, and is inserted by a broad membranous tendon into (1) the lateral border of the tendon of the rectus femoris, (2) the proximal and lateral border of the patella, and (3) the capsule of the knee-joint and the fibular collateral ligament of the patella. A bursa intervenes between it and the membranous insertion of the glutæus maximus.

M. Vastus Medialis.—The vastus medialis is larger than the vastus lateralis and has a more extensive origin, from (1) the distal two-thirds or more of the spiral

line, the linea aspera, and the proximal two-thirds of the line leading from the linea aspera to the medial condyle of the femur; (2) the membranous expansion of the fascia lata which lies beneath the sartorius and forms the roof of the adductor canal; and (3) the medial intermuscular septum and the tendon of the adductor magnus (Figs. 359, p. 404, and 365, p. 410).

From its origin the muscle is directed distally and laterally towards the knee; it is inserted by a strong aponeurotic tendon into (1) the medial border of the rectus tendon; (2) into the proximal and medial border of the patella; and (3) the capsule of the knee-joint and the collateral ligament of the patella. The muscle conceals the medial side of the shaft of the femur and the vastus intermedius, with which it is closely incorporated in its distal two-thirds.

M. Vastus Intermedius.—The vastus intermedius muscle (O.T. crureus) arises by fleshy fibres from (1) the proximal two-thirds of the shaft of the femur on the anterior and lateral surfaces—but not the medial surface; (2) the distal half of the lateral lip

FIG. 363.—MUSCLE-ATTACHMENTS TO THE MEDIAL SIDE OF THE PROXIMAL PART OF THE RIGHT TIBIA.

of the linea aspera and the proximal part of the line leading therefrom to the lateral condyle; and (3) a corresponding portion of the lateral intermuscular septum (Fig. 359, p. 404).

For the most part deeply placed, the muscle is directed distally to an insertion into the deep surface of the tendons of the rectus and vasti muscles by means of fibres which join a membranous expansion on its surface. It is closely adherent to the vastus lateralis muscle in the middle third of the thigh; it is inseparable from the vastus medialis below the proximal third. In the distal third of the thigh it conceals the articularis genu muscle, a bursa, and the proximal prolongation of the synovial membrane of the knee-joint.

M. Articularis Genu.—The articularis genu (O.T. subcrureus) muscle consists of a number of separate bundles of muscular fibres arising beneath the vastus intermedius from the distal fourth of the anterior surface of the femur, and inserted into the synovial membrane of the knee-joint.

The four elements composing the quadriceps femoris muscle have been traced in their convergence to the patella. Their ultimate insertion is into the tubercle of the tibia (Fig. 363), by means of the ligamentum patellæ, and the vasti

skeleton; and another element, the **iliacus**, extending between the hip bone and the femur. The muscles chiefly occupy the posterior wall of the abdomen and pelvis major, their insertions only appearing in the thigh below the inguinal ligament, in the lateral part of the genueral triangle.

M. Psoas Major.—The **psoas major** is a large piriform muscle, which has an extensive **origin** by fleshy fibres from the vertebral column in the lumbar region. It arises from (1) the intervertebral fibro-cartilages above each lumbar vertebra, and the adjacent margins of the vertebræ—from the inferior border of the 12th thoracic to the superior border of the 5th lumbar vertebra; (2) it arises also from four aponeurotic arches which pass over the sides of the bodies of the first four lumbar vertebræ; and (3) it has an additional origin posteriorly from the transverse processes of all the lumbar vertebræ. The fibres form a fusiform muscle directed inwards over the superior aperture of the pelvis and beneath the inguinal ligament, ending in a tendon which is **inserted** into the apex of the lesser trochanter of the femur (Fig. 365). A bursa, which may be continuous with the synovial cavity of the hip-joint, separates the tendon from the pubis and the capsule of the hip-joint.

FIG. 365.—MUSCLE-ATTACHMENTS TO THE POSTERIOR ASPECT OF THE PROXIMAL PART OF THE LEFT FEMUR.

by fleshy fibres, mainly from a horseshoe-shaped origin around the margin of the iliac fossa; it has additional origins also from the ala of the sacrum, the anterior sacro-iliac, lumbo-sacral, and ilio-lumbar ligaments, and outside the pelvis, from the proximal part of the capsule of the hip-joint (ilio-femoral ligament). It is a fan-shaped muscle, its fibres passing distally over the hip-joint towards the lesser trochanter of the femur.

Lying lateral to the psoas muscle, it passes through the femoral triangle, and is **inserted** by fleshy fibres (1) into the lateral side of the tendon of the psoas major; (2) into the concave anterior and upper surfaces of the lesser trochanter; and (3) into the shaft of the femur distal to the lesser trochanter for about an inch (Fig. 365); and (4) by its most lateral fibres into the capsule of the hip-joint. These fibres are often separate, forming the **iliacus minor**, or **iliocapsularis**.

Nerve-Supply.—The **psoas major** is supplied directly by branches from the anterior rami of the second and third lumbar nerves with additional branches in some cases from the first and fourth.

M. Psoas Minor.—The **psoas minor** (*O.T. parvus*) is often absent (40 per cent). It arises from the intervertebral fibro-cartilage between the last thoracic and first lumbar vertebræ, and from the contiguous margins of these vertebræ. The muscle is closely apposed to the anterior surface of the psoas major.

It forms a slender fleshy belly, and is **inserted** by a narrow tendon into the middle of the linea terminalis and the ilio-pectineal eminence, its margins blending with the fascia covering the psoas major.

M. Iliacus.—The **iliacus** muscle arises in the pelvis major

The **psoas minor** receives a nerve from the first or second lumbar nerve. The **iliacus** is supplied by branches from the femoral nerve (L. 2. 3. 4.) within the abdomen.

Actions.—The psoas minor assists the psoas major in flexing forwards and laterally the vertebral column.

Besides this action the psoas major acts with the iliacus muscle as a flexor of the hip. With the thighs fixed the two muscles can draw the trunk downwards.

M. Pectineus.—The **pectineus** muscle arises by fleshy fibres from (1) the sharp anterior portion of the linea terminalis of the pubis, and the triangular surface of the pubic bone in front of this (Fig. 366, p. 412), (2) the femoral surface of the ligamentum lacunare, and (3) the pectineal portion of the fascia lata which covers it.

Forming a broad muscular band, occupying the floor of the femoral triangle, medial to the ilio-psoas, it is **inserted** by a thin flat tendon about two inches in length into the proximal half of the pectineal line, leading from the back of the lesser trochanter of the femur towards the linea aspera; its distal attachment being placed in front of the insertion of the adductor brevis muscle (Fig. 365, p. 410). The muscle may be occasionally divided into medial and lateral parts, the former innervated by the obturator, the latter by the femoral nerve.

Nerve-Supply.—The pectineus is always supplied by a branch of the femoral nerve (L. 2. 3.) which passes medially behind the femoral vessels to enter its lateral border. It receives in some instances an additional nerve from the obturator, or when that is present, the accessory obturator nerve.

Actions.—The muscle is mainly an adductor of the hip-joint. It is also a flexor of the hip.

THE MUSCLES ON THE MEDIAL SIDE OF THE THIGH.

The muscles on the medial side of the thigh include the adductors of the femur—the adductor longus, adductor brevis, and adductor magnus; the gracilis, and the obturator externus.

The gracilis is superficially placed along the medial side of the thigh. The adductor muscles, occupying the space between the hip bone and the femur, are placed on different planes, the adductor longus being in the same plane as the pectineus and lying superficially in the femoral triangle; the adductor brevis, on a deeper level, is in contact with the obturator externus, and along with it is largely concealed by the pectineus and adductor longus; the adductor magnus, the largest and deepest of these muscles, is in contact with the other adductors and the sartorius anteriorly, while its posterior surface is in relation to the hamstring muscles on the back of the thigh.

M. Gracilis.—The **gracilis muscle** is a long flat band placed on the medial side of the thigh and knee. It arises by a tendon from the lower half of the edge of the symphysis pubis, and for a similar distance along the border of the pubic arch (Fig. 366, p. 412).

Its flattened belly passes distally on the medial side of the thigh to the knee, to end in a tendon, placed between the sartorius and semitendinosus, which expands to be **inserted** into the medial surface of the shaft of the tibia just distal to the medial condyle, behind the sartorius, and proximal to and in front of the semitendinosus (Fig. 376, p. 420). It is separated from the sartorius tendon by a bursa, and beneath its tendon is another bursa common to it and the semitendinosus. It is superficial in its whole extent.

Nerve-Supply.—Obturator nerve (L. 2. 3.).

Actions.—The gracilis has a threefold action. It adducts the hips, and it flexes and rotates medially the knee.

M. Adductor Longus.—The **adductor longus** is a triangular muscle occupying the femoral triangle and the floor of Hunter's adductor canal. It arises from the anterior surface of the body of the pubis in the angle between the crest and symphysis (Fig. 366, p. 412).

Extending distally and laterally, it is **inserted** into the middle two-fourths of the medial lip of the linea aspera in front of the adductor magnus.

Nerve-Supply.—Obturator nerve (L. 2. 3.).

Actions.—The muscle adducts and assists in flexing the thigh.

M. Adductor Brevis.—The **adductor brevis** is a large muscle which arises from an elongated oval surface on the front of the body and upper part of the inferior ramus of the pubic bone, surrounded by the other muscles of this group (Fig. 366).

Directed distally and laterally the muscle expands, to be inserted by a short aponeurotic tendon, behind the insertion of the pectineus, into the distal two-thirds of the line leading from the lesser trochanter of the femur to the linea aspera, and to the proximal fourth of the linea aspera itself (Fig. 365, p. 410).

Nerve-Supply.—Obturator nerve (L. 2. 3. 4.).

Actions.—The muscle adducts and flexes the thigh.

FIG. 366.—MUSCLE-ATTACHMENTS TO THE OUTER SURFACE OF THE RIGHT PUBIS AND ISCHIUM.

M. Adductor Magnus.—The **adductor magnus**, the largest of the adductor group, is a roughly triangular muscle arising mainly by fleshy fibres by a curved origin from the lower part of the lateral border and a large portion of the adjoining inferior surface of the sciatic tuberosity, from the edge of the inferior ramus of the ischium, and from the anterior surface of the inferior ramus of the pubic bone, its most anterior fibres arising between the obturator externus and adductor brevis (Fig. 366). Its upper fibres are directed horizontally and laterally from the pubic bone towards the proximal part of the femur; the lowest fibres are directed distally from the sciatic tuberosity to the medial condyle of the femur; while the intermediate fibres radiate obliquely laterally and downwards.

The muscle is inserted by tendinous fibres (1) into the space distal to the insertion of the quadratus femoris, proximal to the linea aspera; (2) into the

whole length of the *linea aspera*; (3) into the medial epicondylar line of the femur; (4) into the adductor tubercle on the medial condyle of the femur; and (5) into the medial intermuscular septum (Fig. 365, p. 410). The part of the muscle attached to the space proximal to the *linea aspera* is often separated from the rest as the **adductor minimus**. The attachment of the muscle to the epicondylar ridge is interrupted for the passage of the femoral vessels into the popliteal fossa. The attachment to the medial condyle is by means of a strong tendon which receives the fibres arising from the ischium (the part of the muscle associated with the hamstring group). This tendon is closely connected with the *tibial collateral ligament* of the knee-joint.

The muscle is covered anteriorly by the other adductors and by the sartorius muscle. The profunda femoris artery separates it from the adductor longus muscle

FIG. 367.—SCHEME OF THE COURSE AND DISTRIBUTION OF THE RIGHT OBTURATOR NERVE.

while the femoral artery is in contact with the muscle as it pursues its course through the adductor canal. The posterior surface of the muscle is in relation with the hamstring muscles.

Nerve-Supply.—The adductor magnus is a double muscle, and has a double nerve-supply. The medial part of the muscle extending between the tuber ischiadicum and the medial condyle of the femur, associated with the hamstring group of muscles, derives its nerve from the nerve to the hamstring muscles, from the tibial nerve (L. 4. 5. S. 1.). This enters the muscle on its posterior surface.

The adductor portion of the muscle is supplied on its anterior surface by the deep branch of the obturator nerve (L. 3. 4.).

Actions.—The adductor magnus is an adductor and extensor of the thigh.

M. Obturator Externus.—The **obturator externus** is placed deeply under cover of the previous muscles. It is a fan-shaped muscle lying horizontally in the angle between the hip bone and the neck of the femur.

It arises from the surfaces of the pubic bone and ischium, which form the inferior half of the margin of the obturator foramen, and from the corresponding

portion of the superficial surface of the obturator membrane (Figs. 366, p. 412, and 367, p. 413).

Its fibres converge towards the greater trochanter, and end in a stout tendon which, after passing distal to and posterior to the hip-joint, is inserted into the trochanteric fossa of the greater trochanter of the femur (Figs. 365, p. 410, and 373, p. 417).

FIG 368.—DEEP MUSCLES ON THE POSTERIOR ASPECT OF THE RIGHT THIGH.

Nerve-Supply.—The deep part of the obturator nerve (L. 3, 4).

Actions.—This muscle is mainly a lateral rotator of the thigh; it also flexes and adducts it.

Trigonum Femorale.—

The femoral triangle (O.T. Scarpa's triangle) is a large triangular space on the front of the thigh in its proximal third, which contains the femoral vessels in the proximal part of their course and the femoral nerve. It is bounded above by the inguinal ligament, laterally by the sartorius,

and medially by the medial border of the adductor longus muscle. Its floor is formed laterally by the ilio-psoas, and medially by the pectineus, adductor longus, and a small part of the adductor brevis.

Canalis Adductorius Hunteri.—

The adductor canal (O.T. Hunter's canal) occupies the middle third of the medial side of the thigh, and contains the femoral vessels in the distal part of their course. It is bounded superficially by the sartorius, under which is a dense fascia derived from the fascia lata, binding together the vastus medialis, which forms the lateral wall of the canal, and the adductors, longus and magnus, which form the medial wall or floor of the canal. Besides the femoral vessels and their sheath, the canal contains the saphenous nerve.

THE MUSCLES OF THE BUTTOCK.

This group includes the three glutæi muscles, the tensor fasciæ latæ, piriformis, obturator internus and gemelli, and quadratus femoris.

The glutæus maximus and tensor fasciæ latæ muscles are in the same plane, invested by envelopes of the fascia lata. The glutæus medius, partially covered by the glutæus maximus, conceals the glutæus minimus; while the piriformis, obturator internus, gemelli, and quadratus femoris intervene between the glutæus maximus and the posterior surface of the hip-joint.

M. Glutæus Maximus.—The *glutæus maximus* is a large quadrilateral muscle, with a crescentic origin arising from (1) a portion of the area on the dorsum ilii above the posterior gluteal line (Fig. 369); (2) the tendon of the sacro-spinalis muscle; (3) the dorsal surface of the sacrum and coccyx (Fig. 395, p. 443); and (4) the posterior surface of the sacro-tuberous ligament. The fibres which form its superior and lateral border take origin directly from the fascia lata which envelops the muscle.

The muscle forms a large fleshy mass, whose fibres are directed obliquely over the buttock, invested by the fascia lata, and are inserted by short tendinous fibres, partly into the fascia lata over the greater trochanter of the femur (joining the ilio-tibial tract), and partly into the gluteal tuberosity (Fig. 370, p. 416). The fascia lata receives the insertion of the whole of the superficial fibres of the muscle and the superior half of the deep fibres. The inferior half of the deep portion of

FIG. 369.—MUSCLE-ATTACHMENTS TO THE RIGHT DORSUM ILII AND TUBER ISCHIADICUM.

the muscle is inserted for the most part into the gluteal tuberosity; but the most inferior fibres of all are inserted into fascia lata, and are thereby connected with the lateral intermuscular septum and the origin of the short head of the biceps.

The *glutæus maximus* is the coarsest and heaviest muscle in the body. By its weight it helps to form the fold of the nates. It is superficial in its whole extent. The *glutæus medius* is visible at its superior border, covered by the fascia lata; at its lower border the hamstring muscles and sciatic nerve appear on their way to the thigh. Three bursæ are beneath it: one (not always present) over the sciatic tuberosity, a second over the lateral side of the greater trochanter, and a third over the vastus lateralis. The fibres of the *glutæus maximus* arising from the coccyx may form a separate muscle (*agitator caudæ*).

Nerve-Supply.—Inferior gluteal nerve, from the sacral plexus (L. 5. S. 1. 2.).

Actions.—The *glutæus maximus* is mainly an extensor of the thigh, and has a powerful action in straightening the lower limb, as in climbing or running. Its lower fibres also adduct the thigh and rotate it laterally.

M. Tensor Fasciæ Latæ.—The *tensor fasciæ latæ* arises from the iliac crest

FIG. 370.—MUSCLE-ATTACHMENTS TO THE POSTERIOR ASPECT OF THE PROXIMAL PART OF THE LEFT FEMUR.

verging to the greater trochanter, to be inserted by a strong, short tendon into the postero-superior angle of the greater trochanter, and into a well-marked diagonal line on its lateral surface (Fig. 370, and Fig. 372, p. 417). A bursa is placed beneath the tendon at its insertion.

The muscle is partly superficial, partly concealed by the glutæus maximus. It covers the glutæus minimus, and the superior gluteal nerve and the deep branches of the superior gluteal artery.

Nerve-Supply.—The superior gluteal nerve from the sacral plexus (L. 4. 5. S. 1.).

Actions.—This muscle is a powerful abductor and medial rotator of the thigh.

M. Glutæus Minimus.—The glutæus minimus arises, under cover of the glutæus

and the dorsum ilii just lateral to the superior anterior spine, and from the fascia covering its lateral surface (Fig. 369, p. 415).

Invested like the glutæus maximus by the fascia lata, it is inserted distal to the level of the greater trochanter of the femur into the fascia, which forms the ilio-tibial tract (p. 404). The muscle is placed along the anterior borders of the glutæus medius and glutæus minimus.

Nerve-Supply.—The superior gluteal nerve from the sacral plexus (L. 4. 5. S. 1.) ends in this muscle after passing between the glutæus medius and glutæus minimus.

Actions.—It assists in the abduction and rotation of the thigh; and along with the glutæus maximus, by its insertion into the ilio-tibial tract, it helps to support the knee-joint in the extended position.

M. Glutæus Medius.—The glutæus medius arises from (1) the dorsum ilii, between the iliac crest and posterior gluteal line above and the anterior gluteal line below (Fig. 369, p. 415), and (2) the strong fascia lata covering its surface anteriorly.

It is a fan-shaped muscle, its fibres con-

FIG. 371.—THE RIGHT GLUTÆUS MAXIMUS MUSCLE.

medius, by fleshy fibres from the dorsum ilii between the anterior and inferior gluteal lines (Fig. 369, p. 415).

This muscle is fan-shaped and its fibres converge to the antero-superior angle of the greater trochanter, to be inserted into the anterior surface of the trochanter, and sometimes also into the front part of the superior border of the greater trochanter (Figs. 361, p. 407, and 373). It is also inserted into the capsule of the hip-joint. A bursa is placed beneath the tendon in front of the greater trochanter.

Nerve-Supply.—The superior gluteal nerve from the sacral plexus (L. 4. 5. S. 1.).

Actions.—The muscle is primarily an abductor of the thigh. Its anterior fibres in addition produce medial rotation and its posterior fibres lateral rotation of the limb.

M. Piriformis.—

The **piriformis** is one of the few muscles connecting the lower limb to the axial skeleton. It arises (1) within the pelvis from the roots of the vertebral arches of the second, third, and fourth sacral vertebrae, and from the adjacent part of the bone lateral to the anterior sacral foramina. Passing out through the greater sciatic foramen, it receives an origin from (2) the upper margin of the greater sciatic notch of the ilium, and (3) the pelvic surface of the sacro-tuberous ligament.

FIG. 373.—MUSCLE-ATTACHMENTS TO THE PROXIMAL ASPECT OF THE GREATER TROCHANTER OF THE LEFT FEMUR.

posterior wall of the pelvis. In the buttock it is covered by the gluteus maximus, and lies behind the capsule of the hip-joint, between the gluteus medius and superior gemellus.

Nerve-Supply.—Branches direct from the anterior rami of the first and second sacral nerves.

FIG. 372.—THE MUSCLES AND NERVES OF THE RIGHT BUTTOCK.

The gluteus maximus is reflected; and the gluteus medius is cut in part to show the gluteus minimus.

In the buttock it forms a rounded tendon, which is inserted into a facet on the superior border and medial aspect of the greater trochanter of the femur (Figs. 370, p. 416, and 373).

The piriformis, at its origin, lines the

Actions.—The muscle is an abductor and lateral rotator of the hip.

M. Obturator Internus.—The *obturator internus* arises on the pelvic aspect of the hip bone, from (1) the whole of the margin of the obturator foramen (except the obturator notch); (2) the surface of the obturator membrane; (3) the whole of the pelvic surface of the hip bone behind and above the obturator foramen; and (4) the parietal pelvic fascia covering it medially.

It is a fan-shaped muscle, and its fibres converging to the lesser sciatic foramen, give rise to several tendons united together, which hook round the margin of the foramen (a bursa intervening), and after passing over the posterior surface of the hip-joint, are inserted into a facet on the medial surface of the greater trochanter of the femur above the trochanteric fossa (Figs. 370, p. 416, and 373, p. 417).

In the pelvis the muscle occupies the lateral wall, covered by the parietal pelvic fascia, which separates it from the pelvic cavity above and the ischio-rectal fossa below. In the buttock the tendon is embraced by the gemelli muscles which are attached to its superior and inferior margins.

The *gemelli muscles* form accessory portions of the obturator internus.

M. Gemellus Superior.—The *superior gemellus* arises from the gluteal surface of the ischial spine (Fig. 369, p. 415).

It is inserted into the upper margin and superficial surface of the tendon of the obturator internus muscle.

M. Gemellus Inferior.—The *gemellus inferior* arises from the superior part of the gluteal surface of the ischial tuberosity (Fig. 369, p. 415).

It is inserted into the inferior margin and superficial aspect of the tendon of the obturator internus.

Nerve-Supply.—The obturator internus and superior gemellus receive branches from a special nerve, the *nerve to the obturator internus* from the anterior aspect of the sacral plexus (S. 1. 2. 3.). The inferior gemellus is supplied by the nerve to the quadratus femoris, a branch derived also from the anterior aspect of the sacral plexus (L. 4. 5. S. 1.).

Actions.—The obturator internus and gemelli are abductors and lateral rotators of the hip.

M. Quadratus Femoris.—The *quadratus femoris* arises from the lateral margin of the tuber ischiadicum (Figs. 366, p. 412, and 369, p. 415). It is inserted into the quadrate tubercle and quadrate line of the femur (Fig. 370, p. 416).

The muscle is concealed by the glutæus maximus and the hamstring muscles. Its deep surface is in contact with the obturator externus muscle and the lesser trochanter of the femur, a bursa intervening. The muscle is not infrequently fused with the adductor magnus.

Nerve-Supply.—A special nerve from the sacral plexus (L. 4. 5. S. 1.) which enters its deep (anterior) surface.

Actions.—The muscle is an adductor and lateral rotator of the thigh.

THE MUSCLES ON THE POSTERIOR ASPECT OF THE THIGH.

The Hamstring Muscles.

The muscles comprised in this series include the biceps, semitendinosus, and semimembranosus. A part of the adductor magnus, already described, also belongs morphologically to this group. They occupy the buttock and posterior aspect of the thigh, and diverge at the knee to bound the popliteal fossa. The origins of the muscles are concealed by the glutæus maximus. In the back of the thigh, enveloped by the fascia lata, they are placed behind the adductor magnus—the semitendinosus and semimembranosus medially, the biceps laterally. The former two muscles help to form the medial boundary of the popliteal fossa, of which the biceps is a lateral boundary.

M. Biceps Femoris.—The *biceps femoris* has a double origin. (1) *Its long head* arises by means of a tendon, in common with the semitendinosus, from the inferior and medial facet upon the sciatic tuberosity (Figs. 366, p. 412, and 369, p. 415) and from the sacro-tuberous ligament. This head, united for a

distance of two or three inches with the semitendinosus, forms a separate fleshy mass, which extends to the distal third of the thigh, to end in a tendon joined by the short head of the muscle. (2) The *short head* arises separately from (1) the whole length of the lateral lip of the linea aspera and the proximal two-thirds of the lateral epicondylar line of the femur, and (2) the lateral intermuscular septum. The proximal limit of its origin is sometimes blended with the insertion of the lowest fibres of the glutæus maximus.

The fibres of the short head, directed distally, join the tendon of the long head, and the muscle is inserted (1) into the head of the fibula by a strong tendon, which is split into two parts by the *fibular collateral* ligament of the knee-joint; (2) by a slip attached to the lateral condyle of the tibia; and (3) along its posterior border by a fascial expansion which connects the tendon with the popliteal fascia.

FIG. 374.—MUSCLE-ATTACHMENTS TO THE RIGHT DORSUM ILII AND TUBER ISCHIADICUM.

There is a bursa between the tendon and the *fibular collateral* ligament of the knee-joint.

The short head may be absent: there may be an additional origin from the ischium or femur; and the long head may send a slip to the gastrocnemius or tendo calcaneus (Achillis) (*tensor fasciæ suralis*).

M. Semitendinosus.—The *semitendinosus* arises, in common with the long head of the biceps, from the inferior and medial facet upon the ischial tuberosity (Fig. 374, p. 419). Separating from the common tendon two or three inches from its origin, the muscle forms a long, narrow band which becomes tendinous in the middle third of the thigh.

Passing over the medial side of the knee it spreads out and becomes membranous and is inserted (1) into the medial side of the shaft of the tibia just distal to the medial condyle, distal to the gracilis and behind the sartorius (Fig. 376, p. 420), and (2) into the deep fascia of the leg. A bursa separates it from the sartorius superficially, and another, common to it and the gracilis, lies deep to its insertion. The belly of the muscle is marked by an oblique septal tendinous intersection about its middle.

Nerve-Supply.—The semitendinosus is supplied by two branches from the nerve to the hamstring muscles (L. 5. S. 1. 2.)

Actions.—A flexor and medial rotator of the knee, and an extensor of the hip.

M. Semimembranosus.—The **semimembranosus** arises by a tendon from the superior and lateral facet on the ischial tuberosity (Figs. 366, p. 412, and 374, p. 419). In the proximal third of the thigh the tendon gives place to a rounded fleshy belly, which lies beneath the ischial origin of the biceps and semitendinosus muscles.

Becoming tendinous at the back of the knee, it is inserted into the horizontal groove on the postero-medial aspect of the medial condyle of the tibia (Figs. 376, below, and 384, p. 428). A bursa lies deep to the tendon at its insertion. It has three *additional membranous insertions*: (1) a fascial band extends distally and medially to join the posterior border of the *tibial collateral ligament* of the knee-joint; (2) another fascial band extends distally

FIG. 375.—THE MUSCLES ON THE POSTERIOR ASPECT OF THE RIGHT THIGH.

FIG. 376.—MUSCLE-ATTACHMENTS TO THE MEDIAL SURFACE OF THE PROXIMAL PART OF THE RIGHT TIBIA.

and laterally, forms the fascia covering the popliteus muscle (*popliteus fascia*), and is attached to the oblique line of the tibia; and (3) a third strong band extends proximally and laterally to the back of the lateral condyle of the femur, forming the oblique popliteal ligament of the knee-joint.

The membranous origin of the muscle is concealed by the orifices of the semitendinosus and long head of the biceps. The insertion covers the origin of the inner head of the gastrocnemius.

Nerve-Supply.—It is innervated by the nerve to the hamstring muscles (L. 5. S. 1. 2.).

Actions.—A flexor and medial rotator of the knee, as well as an extensor of the hip.

Actions of the Muscles of the Thigh and Buttock.

Most of the above muscles act on the pelvis and on the hip- and knee-joints. The psoas major muscle in addition assists in the movements of the vertebral column (p. 411).

1. Movements at the Hip-Joint.—The movements of the thigh at the hip-joint are flexion and extension, adduction and abduction, medial and lateral rotation. The following table gives the muscles producing these movements:—

a. Flexion and Extension.	
Sartorius	Glutæus maximus
Iliacus	„ medius
Psoas major	„ minimus
Rectus femoris	Biceps femoris
Pectineus	Semitendinosus
Adductor longus	Semimembranosus
Gracilis	Adductor magnus
Obturator externus	

b. Adduction and Abduction.	
Pectineus	Tensor fasciæ latæ
Adductor longus	Glutæus medius
„ brevis	„ minimus
„ magnus	Obturator externus
Gracilis	Piriformis
Quadratus femoris	Obturator internus
Glutæus maximus	Gemelli
(lower fibres)	Sartorius
	Glutæus maximus
	(upper fibres)
	during flexion

c. Medial Rotation and Lateral Rotation.	
Tensor fasciæ latæ	Obturator externus
Glutæus medius (anterior fibres)	Glutæus maximus (lower fibres)
„ minimus „ „	Quadratus femoris
	Glutæus medius } (posterior fibres)
	„ minimus } (posterior fibres)
	Piriformis
	Obturator internus
	Gemelli
	Sartorius
	Ilio-psoas
	Pectineus
	Adductor longus
	„ brevis
	„ magnus
	Biceps femoris
	during extension

2. Movements of the Pelvis on the Thigh.—It is to be noted that the several movements tabulated above refer to the movements of the femur at the hip-joint. The contraction of the same groups of muscles produces similar movements of the pelvis on the femur, exemplified in the various changes in the attitude of the pelvis in relation to the thigh and the vertebral column, which occur in locomotion.

3. Movements at the Knee-Joint.—The movements at the knee-joint are mainly flexion and extension. Flexion is much more powerful than extension. There is also a limited amount of rotation of the tibia. The movements are produced by certain of the muscles described above, associated with certain of the muscles of the leg.

<i>a. Flexion and Extension.</i>		<i>b. Rotation medially and Rotation laterally.</i>	
Sartorius	Quadriceps femoris	Sartorius	Biceps femoris
Gracilis		Gracilis	
Semitendinosus		Semitendinosus	
Semimembranosus		Semimembranosus

Gastrocnemius			
Plantaris			
Popliteus			

THE FASCIÆ AND MUSCLES OF THE LEG AND FOOT.

FASCIÆ.

The **superficial fascia** of the leg and foot presents no special features except in the sole, where it is greatly thickened by pads of fat, particularly under the tubercles of the calcaneus, and under the balls of the toes.

The **deep fascia** has numerous important attachments about the knee. Posteriorly it forms the *popliteal fascia*, and is joined by expansions from the tendons of the sartorius, gracilis, semitendinosus, and biceps femoris muscles. In front of the knee it is attached to the patella, the ligamentum patellæ, and the tubercle of the tibia; laterally it is connected to the condyles of the tibia and the head of the fibula, and forms the **collateral patellar ligaments**—broad fascial bands which pass obliquely from the sides of the patella to the condyles of the tibia, and are joined by fibres of the vasti muscles. Passing into the leg, the fascia blends over the medial surface of the tibia with the periosteum of the bone. It extends round the lateral side of the leg from the anterior crest to the medial border of the tibia, binding together and giving origin to the muscles, and gaining an attachment to the distal part of the shaft of the fibula. **Two septa** pass from its deep surface; one septum (anterior peroneal septum), attached to the anterior crest of the fibula, encloses the (superficial peroneal) nerve, and separates the extensor from the peronæi muscles. The other septum (posterior peroneal septum) is attached to the lateral crest of the fibula, and separates the peronæi from the flexor muscles. From the last-named septum another extends across the back of the leg, forms a partition between the superficial and deep flexor muscles, and encloses the posterior tibial vessels and the tibial nerve. It gives rise to subordinate septa attached to the vertical line of the tibia and the medial crest of the fibula, which separate the tibialis posterior from the flexors of the toes on either side.

At the ankle the deep fascia is strengthened by additional transverse fibres, which give rise to thickened bands named the ligamentum laciniatum, lig. transversum cruris, lig. cruciatum cruris and the retinaculum of the peroneal muscles. They were formerly known as the annular ligaments.

The **ligamentum laciniatum** (O.T. internal annular ligament) stretches between the medial malleolus and the tuberosity of the calcaneus. While it is continuous at its proximal border with the general investment of the deep fascia, it is chiefly formed by the septal layer covering the deep muscles on the back of the leg. It sometimes gives insertion to the plantaris muscle. It is continuous distally with the plantar aponeurosis, and gives origin to the abductor hallucis muscle. It is pierced by the calcanean vessels and nerve. Along with the posterior tibial vessels and the tibial nerve, the tendons of the tibialis posterior, flexor digitorum longus, and flexor hallucis longus, pass beneath it, each enclosed in a separate synovial sheath.

The **superior peroneal retinaculum** (O.T. lateral annular ligament) is a thickened band of the deep fascia stretching between the lateral malleolus and the calcaneus. It binds down the tendons of the peronæi, which occupy a space beneath the ligament, lined by a single synovial membrane; while the inferior

peroneal retinaculum binds them down separately on the lateral surfaces of the calcaneus.

The *ligamentum transversum cruris* (O.T. anterior annular ligament, upper band), broad and undefined at its proximal and distal borders, stretches across the front of the ankle between the two malleoli. This band binds down to the distal end of the tibia the tendons of the *tibialis anterior* and *extensor muscles* of the toes. One synovial sheath is found beneath it, surrounding the tendon of the *tibialis anterior*.

Ligamentum Cruciatum Cruris.—On the dorsum of the foot, where the general covering of deep fascia is much thinner, a special well-defined band, named the *ligamentum cruciatum cruris* (O.T. anterior annular ligament, lower band), stretches over the extensor tendons. It has an attachment laterally to the lateral border of the dorsal surface of the calcaneus. It divides into two bands as it passes medially over the dorsum of the foot—a *proximal part*, which joins the *lig. transversum cruris* and is attached to the medial malleolus, and a *distal part*, which passes across the dorsum of the foot, and joins the fascia of the sole at its medial border.

Beneath this ligament are three special compartments with separate synovial sacs, one for the *tibialis anterior* tendon, a second for that of the *extensor hallucis longus*, and a third for the *extensor digitorum longus* and *peronæus tertius* tendons. There are occasionally other additional bands of the deep fascia passing like the straps of a sandal across the dorsum of the foot.

FIG. 377.—FRONTAL SECTION THROUGH THE LEFT ANKLE-JOINT, TALUS, AND CALCANEUS.

The *plantar aponeurosis* is of great importance. In the centre of the sole it forms a thick triangular band, attached posteriorly to the tuberosity of the calcaneus. It spreads out anteriorly and separates into *five slips*, which are directed forwards to the bases of the toes. These slips as they separate are joined together by ill-defined bands of transverse fibres, which constitute the *superficial transverse metatarsal ligament* (*fasciculi transversi aponeurosis plantæ*). The slip for each toe joins the tissue of the web of the toe and is continuous with the digital sheath. It splits to form a band of fibres directed forwards on each side of the toe to be attached to the sides of the metatarso-phalangeal articulation and the base of the first phalanx.

This central portion of the plantar aponeurosis assists in preserving the arch of the foot, by drawing the toes and the calcaneus together.

On each side it is continuous with a much thinner layer which covers the lateral and medial muscles of the sole, and joins the fascia of the dorsum of the foot at each border. It also gives rise to intermuscular septa, which pass deeply on each side of the *flexor digitorum brevis*, enclosing that muscle in a separate sheath, and giving investments on either side to the *abductor* muscles of the great and little toes. At the lateral border of the foot the *calcaneo-metatarsal ligament*, a thickened band of the fascia, connects the tuberosity of the calcaneus with the base of the fifth metatarsal bone.

The digital sheaths, though smaller, are the same in arrangement as those of the fingers (p. 389). Vaginal ligaments are present in relation to the first and second phalanges.

THE MUSCLES OF THE LEG AND FOOT.

The muscles of the leg and foot are divisible into three series: (1) the extensor muscles on the front of the leg and dorsum of the foot; (2) the peronæi on the lateral aspect of the leg; and (3) the flexor muscles on the back of the leg and in the sole of the foot.

FIG. 378.—THE LEFT PLANTAR FASCIA.

The Muscles on the Front of the Leg and Dorsum of the Foot.

The muscles on the front of the leg and dorsum of the foot include two groups: (1) on the front of the leg, the tibialis anterior, long extensors of the toes and peronæus tertius; and (2) on the dorsum of the foot, the extensor digitorum brevis, and extensor hallucis brevis.

On the front of the leg the tibialis anterior and the extensor digitorum longus and peronæus tertius are superficially placed, and conceal the extensor hallucis longus muscle. On the dorsum of the foot the extensor digitorum brevis muscle lies beneath the tendons of the long extensor of the toes.

M. Tibialis Anterior.—The tibialis anterior arises from the lateral condyle and the proximal two-thirds of the lateral surface of the shaft of the tibia, from the interosseous membrane from the fascia over it, and from an intermuscular septum laterally. The muscle ends in a strong tendon which passes over the dorsum of the foot, to be inserted into a facet on the medial surface of the first cuneiform and the medial side of the base of the first metatarsal bone (Fig. 379, p. 425). Its tendon occupies special compartments beneath both ligamentum transversum and lig. cruciatum cruris, enclosed in a separate, single, synovial sac.

The **tibio-fascialis anterior** is a separated portion of the muscle occasionally present, inserted into the fascia on the dorsum of the foot.

Nerve-Supply.—Deep peroneal nerve (L. 4. 5. S. 1.).

Actions.—The muscle is a dorsi-flexor of the ankle, and (in combination with the tibialis posterior) it invests the foot.

M. Extensor Digitorum Longus.—The **extensor digitorum longus** arises by fleshy fibres from the lateral side of the lateral condyle of the tibia, from the proximal two-thirds or more of the anterior part of the medial surface of the shaft of the fibula, from the fascia over it, and from intermuscular septa on either side.

It gives rise to a tendon which passes beneath the ligamentum transversum and cruciatum, and in front of the ankle subdivides into four tendons, inserted into the four lateral toes, exactly in the same way as the corresponding tendons in the hand (see p. 397). They form membranous expansions on the dorsum of the first phalanx, joined by the tendons of the **extensor digitorum brevis**, **lumbricales**,

FIG. 379.—MUSCLE-ATTACHMENTS TO LEFT TARSUS AND METATARSUS (Plantar Aspect).

and **interossei**, each of which separates into one central and two collateral slips, attached respectively to the middle and terminal phalanges. The tendon occupies a separate compartment along with the **peronæus tertius** beneath the ligamentum cruciatum cruris, invested by a special synovial membrane.

Nerve-Supply.—Deep peroneal nerve (L. 4. 5. S. 1.).

Actions.—A dorsi-flexor of the ankle and an extensor of the four lateral toes.

M. Peronæus Tertius.—The **peronæus tertius** is a separated portion of the **extensor digitorum longus**. It is an essentially human muscle. It arises (inseparably from the **extensor digitorum longus**) from the anterior part of the medial surface of the fibula, and from the inter-muscular septum lateral to it.

The tendon of the muscle is inserted into the dorsal aspect of the base of the fifth metatarsal bone.

Nerve-Supply.—Deep peroneal nerve (L. 4. 5. S. 1.).

Actions.—The muscle dorsi-flexes the ankle and raises the lateral border of the foot (as in skating or dancing).

M. Extensor Hallucis Longus.—The **extensor hallucis longus** arises from the anterior part of the medial surface of the fibula in its middle three-fifths, medial to the origin of the extensor digitorum longus, and for a corresponding extent from the interosseous membrane. Its tendon passes over the dorsum of the foot, to be inserted into the base of the terminal phalanx of the great toe.

The **extensor primi internodii longus** and **extensor ossis metatarsi hallucis** are occasional separate slips of this muscle inserted into the proximal phalanx and the metatarsal bone.

Nerve-Supply.—Deep peroneal nerve (L. 4. 5. S. 1.).

Actions.—This muscle dorsi-flexes the ankle, and extends the great toe.

M. Extensor Digitorum Brevis.—The **extensor digitorum brevis** arises on the dorsum of the foot from a special impression on the dorsal surface of the calcaneus, and from the deep surface of the ligamentum cruciatum cruris.

It usually gives rise to four fleshy bellies, from which narrow tendons are directed forwards and medially, to be inserted into the four medial toes. The three lateral tendons join those of the long extensor muscle to form the membranous expansions on the dorsum of the toes. The *most medial tendon* (**extensor hallucis brevis**) is inserted separately into the base of the first phalanx of the great toe.

Nerve-Supply.—Deep peroneal nerve (L. 4. 5. S. 1.).

Actions.—Extension of the four inner toes.

The Muscles on the Lateral Side of the Leg.

These muscles comprise the **peronæi**,—**longus** and **brevis**. They are placed on the lateral side of the leg between the **extensor digitorum longus** in front, and the **soleus** and **flexor hallucis longus** behind, enclosed in a special compartment of the deep fascia.

M. Peronæus Longus.—The **peronæus longus** arises from the head and the proximal two-thirds of the lateral surface of the shaft

FIG. 380.—MUSCLES OF THE FRONT OF THE RIGHT LEG AND DORSUM OF THE RIGHT FOOT.

of the fibula, from intermuscular septa on either side, and from the fascia over it.

It forms a stout tendon, which, lying superficial to the **peronæus brevis**, hooks round the lateral malleolus beneath the peroneal retinaculum, crosses the lateral side of the calcaneus, and passing through a groove on the cuboid bone, is directed across the sole of the foot to be inserted into the lateral sides of the first cuneiform and the

base of the first metatarsal bones (Fig. 379, p. 425). As it enters the sole of the foot a *fibro-cartilage* is formed in the tendon, which plays over a smooth tubercle on the cuboid bone, a bursa intervening. In its passage across the foot the tendon is enclosed in a sheath derived from the long plantar (long calcaneo-cuboid) ligaments and the tibialis posterior tendon.

Nerve-Supply.—Superficial peroneal nerve (L. 4. 5. S. 1.).

Actions.—An extensor of the ankle; this muscle also everts the foot. It strengthens the arch of the foot by its passage across the sole to its insertion.

FIG. 381.—THE INSERTIONS OF THE TIBIALIS POSTERIOR AND PERONÆUS LONGUS IN THE SOLE OF THE LEFT FOOT.

M. Peronæus Brevis.—The *peronæus brevis* arises by fleshy fibres from the distal two-thirds of the lateral surface of the shaft of the fibula, and from an intermuscular septum along its anterior border.

Its tendon grooves the back of the lateral malleolus and the lateral side of the calcaneus, invested by a synovial sheath common to it and the *peronæus longus*, and is inserted into the tuberosity and dorsal surface of the base of the fifth metatarsal bone.

The *peronæus longus* and *brevis* may be fused together, or additional slips may be present, as *peronæus accessorius*, *peronæus digiti quinti*, *peronæocalcaneus externus*, and *peronæocuboides*.

Nerve-Supply.—Superficial peroneal nerve (L. 4. 5. S. 1.).

Actions.—An extensor of the ankle and an evertor of the foot.

FIG. 382.—THE RIGHT SOLEUS MUSCLE.

The Muscles on the Posterior Aspect of the Leg.

The muscles on the back of the leg are divisible into two groups, superficial and deep.

The **superficial group** comprises the gastrocnemius and soleus (constituting together the **triceps suræ**) and the plantaris. They form the prominence of the calf of the leg. The gastrocnemius is superficial except at its origin, where the two bellies forming the boundaries of the popliteal fossa are overlapped by the tendons of the hamstring muscles. The soleus muscle is partially concealed by the gastrocnemius and plantaris, and becomes superficial in the distal part of the leg on each side of the common tendon (**tendo calcaneus**).

M. Gastrocnemius.

—The **gastrocnemius** arises by *two heads*, medial and lateral, by means of strong tendons which are prolonged over the surface of the muscle. The **lateral head** arises from an impression on the proximal and posterior part of the lateral surface of the lateral condyle of the femur, and from the distal end of the lateral epicondylar line; while the **medial head** arises from a prominent rough mark on the popliteal surface of the femur proximal to the medial epicondyle and posterior to the adductor tubercle. Each head has an additional origin from the back of the capsule of the knee-joint. A bursa lies beneath each tendon of origin.

Each fleshy belly

of the muscle is **inserted** separately into a broad membranous tendon, prolonged proximally on its deep surface for some distance. The medial head is the larger.

The **tendo calcaneus** is formed by the union of the two membranous insertions

FIG. 383.—THE DEEP MUSCLES ON THE BACK OF THE RIGHT LEG.

FIG. 384.—MUSCLE-ATTACHMENTS TO THE POSTERIOR SURFACE OF THE RIGHT TIBIA.

of the bellies of the gastrocnemius. Prolonged upwards beneath the separate bellies, the tendon forms a broad membranous band connecting together the distal parts of the two bellies.

Narrowing gradually, and becoming thicker in the distal half of the leg, the tendon is finally inserted into the posterior aspect of the calcaneus. A bursa lies beneath the tendon at its insertion. The tendo calcaneus also affords insertion to the soleus and (sometimes) the plantaris muscles.

Nerve-Supply.—Each head of the muscle is innervated by a branch from the tibial nerve (S. 1. 2.).

Actions.—The muscle is a powerful flexor of the knee and extensor of the ankle.

M. Plantaris.—The plantaris arises by fleshy fibres from the lateral epicondylar line of the femur for about an inch at its distal end, from the adjacent part of the popliteal surface of the femur, and from the oblique ligament of the knee-joint.

It forms a narrow fleshy slip which ends in a tendon extending distally in the back of the leg, to be inserted into the medial side of the tuberosity of the calcaneus, or the tendo calcaneus, or the ligamentum laciniatum. The tendon of the muscle is capable of considerable lateral extension.

The plantaris lies between the lateral head of the gastrocnemius and the soleus. In the distal half of the leg its tendon lies along the medial border of the tendo calcaneus. The muscle is not always present.

Nerve-Supply.—Tibial nerve (L. 4. 5. S. 1.).

Actions.—The muscle is an accessory flexor of the knee and extensor of the ankle.

M. Soleus.—The soleus has a triple origin from (1) the posterior surface of the head and the shaft of the fibula in its proximal third; (2) a fibrous arch (arcus tendineus m. solei) stretching over the popliteal vessels and tibial nerve between the tibia and fibula; and (3) the oblique line and middle third of the medial border of the tibia (Fig. 384, p. 428).

From this origin the proximal muscular fibres are directed distally to join a tendon placed on the superficial aspect of the muscle, which is inserted into the tendo calcaneus; the most distal fibres are inserted directly into the tendo calcaneus to within one or two inches of the calcaneus.

Nerve-Supply.—Two nerves supply this muscle. One from the tibial nerve in the popliteal space enters its superficial surface (S. 1. 2.); the other from the tibial nerve in the back of the leg supplies the deep surface of the muscle (L. 5. S. 1. 2.).

Actions.—The soleus is a powerful extensor of the ankle.

The deep muscles of the back of the leg comprise the popliteus, flexor digitorum longus, flexor hallucis longus, and tibialis posterior.

The popliteus muscle is deeply placed behind the knee-joint in the floor of the popliteal fossa, and is covered by the popliteal vessels and tibial nerve. The flexor digitorum longus lies behind the tibia, the flexor hallucis longus behind the fibula, and the tibialis posterior lying between them is related to the interosseous membrane and both bones of the leg. All these muscles are concealed by the superficial group, and are bound down to the bones of the leg by layers of the deep fascia.

M. Popliteus.—The popliteus arises by a stout tendon from a rough impression in front of a groove on the lateral aspect of the lateral epicondyle of the femur. The tendon passes between the lateral meniscus and the capsule of the knee-joint, and pierces the oblique ligament, from which it takes an additional fleshy origin. A bursa is placed beneath the tendon, which usually communicates with the synovial cavity of the knee-joint.

The muscle is inserted by fleshy fibres (1) into a triangular surface on the back of the tibia above the oblique line (Fig. 384, p. 428), and (2) into the fascia over it (the popliteus fascia, derived from the tendon of the semimembranosus muscle).

The popliteus minor is a small occasional muscle attached to the popliteal surface of the femur and the posterior ligament of the knee-joint.

Nerve-Supply.—The popliteus is supplied by a branch of the tibial nerve (L. 4. 5. S. 1.), which winds round the distal border of the muscle and enters it in its deep surface.

Actions.—A medial rotator and flexor of the knee.

M. Flexor Digitorum Longus.—The flexor digitorum longus occupies both the back of the leg and the sole of the foot. Its origin is by fleshy fibres from the posterior surface of the shaft of the tibia in its middle three-fifths, distal to the oblique line, medial to the vertical line and the origin of the tibialis posterior, from the fascia over it, and from an intermuscular septum on each side (Fig. 384, p. 428).

Its tendon, after crossing obliquely over the tendon of the tibialis posterior, passes beneath the ligamentum laciniatum, invested in a special synovial sheath, and enters the sole of the foot. There it crosses superficially the tendon of the flexor hallucis longus, and finally divides into four subordinate tendons, which are inserted into the four lateral toes in precisely the same manner as the flexor digitorum profundus is inserted in the hand (p. 389). Each tendon enters the digital sheath of the toe, perforates the tendon of the flexor digitorum brevis, and is inserted into the base of the terminal phalanx. Vincula accessoria (longa and brevia) are present as in the hand.

The tendon of the flexor hallucis longus sends a fibrous band to the tendon of the flexor digitorum longus as it crosses it in the sole of the foot, which usually passes to the tendons destined for the second and third toes. Associated with this muscle in the sole of the foot are the lumbricales and quadratus plantæ muscles.

Mm. Lumbricales.—The lumbricales are four small muscles arising in association with the tendons of the flexor digitorum longus in the sole. The *first muscle* arises by a single origin from the tibial side of the tendon of the flexor digitorum longus for the second toe; the *other three* arise by two heads from the adjacent sides of all four tendons.

Each muscle is inserted into the dorsal expansion of the extensor tendon, the metatarso-phalangeal capsule, and the base of the first

phalanx, precisely as in the case of the lumbrical muscles of the hand. Each muscle passes forwards on the tibial side of the corresponding toe, superficial to the transverse metatarsal ligament.

Nerve-Supply.—The flexor digitorum longus is supplied by the tibial nerve (L 5. S. 1.). The first lumbrical is supplied by the medial plantar nerve (L 4. 5. S. 1.); the other three, by the lateral plantar nerve (S. 1. 2.).

Actions.—The flexor digitorum longus extends the ankles and flexes the four outer toes.

FIG. 385.—THE MUSCLES OF THE RIGHT FOOT (Second Layer).

The lumbrical muscles have a similar action to those of the hand; they flex the metatarsophalangeal, and extend the interphalangeal joints of the four lateral toes.

M. Quadratus Plantæ.—The *quadratus plantæ* (O.T. *accessorius*) arises by two heads: (1) the lateral tendinous head springs from the lateral border of the plantar surface of the calcaneus and from the lateral border of the long plantar ligament; (2) the medial head, which is fleshy, arises from the concave medial surface of the calcaneus in its whole extent, and from the medial border of the long plantar ligament (Fig. 379, p. 425). The long plantar ligament separates the two origins.

The two heads unite to form a flattened band, which is inserted into the dorsal aspect of the tendons of the flexor digitorum longus, and usually into those destined for the second, third, and fourth toes.

In the sole of the foot the tendons of the flexor digitorum longus, along with the lumbricales and quadratus plantæ, and the flexor hallucis longus muscles, constitute the second layer of muscles, lying between the abductors of the great and little toes and the flexor digitorum brevis superficially, and the flexor brevis and adductor of the great toe more deeply.

Nerve-Supply.—Lateral plantar nerve (S. 1. 2.).

Actions.—The muscle is an accessory flexor of the toes, assisting the long flexor of the toes. It tends to draw the tendons into which it is inserted into the middle of the sole of the foot.

M. Flexor Hallucis Longus.—The *flexor hallucis longus* arises on the back of the leg, between the tibialis posterior and the peronæi muscles, from the distal two-thirds of the posterior surface of the shaft of the fibula, from the fascia over it, and from intermuscular septa on either side.

Its tendon passes beneath the ligamentum laciniatum enclosed in a special synovial sheath, and after grooving the posterior surface of the distal end of the tibia, the talus, and the plantar surface of the sustentaculum tali of the calcaneus, it is directed forwards in the sole of the foot, to be inserted into the base of the terminal phalanx of the great toe.

In the foot it crosses over the deep aspect of the tendon of the flexor digitorum longus, and gives to it a strong fibrous slip, which is prolonged into the tendons for the second and third toes.

Nerve-Supply.—Tibial nerve (L. 5. S. 1. 2.).

Actions.—The muscle is one of the most important in the leg and foot. It is an extensor of the ankle and a flexor of the great toe. By its position in relation to the tarsus and inferior calcaneo-navicular ligament, it has an important share in maintaining and supporting the arch of the foot.

M. Tibialis Posterior.—The *tibialis posterior* has a fourfold fleshy origin in the leg. It arises (1) from the proximal four-fifths of the medial surface of the shaft of the fibula between the medial crest and the interosseous crest; (2) from the distal part of the lateral condyle, and from the proximal two-thirds of the shaft of the tibia distal to the oblique line and between the vertical line and the interosseous border (Fig. 384, p. 428); (3) from the interosseous membrane; and (4) from the fascia over it and the septa on either side. The muscle gives rise to a strong tendon which passes beneath the ligamentum laciniatum, invested by a special synovial sheath, and grooves the back of the medial malleolus, on its way to the medial border of the foot.

After crossing over the plantar calcaneo-navicular ligament between the sustentaculum tali and the navicular bone, the tendon spreads out and is inserted by three bands into (1) the tubercle of the navicular bone and the plantar surfaces of the first and second cuneiform bones, (2) the plantar aspects of the bases of the second, third, fourth, and sometimes the fifth metatarsal bones, the second and third cuneiform bones, and the groove on the cuboid, and (3) into the medial border of the sustentaculum tali of the calcaneus (Fig. 379, p. 425).

The *peronæo-calcaneus* muscle, when present, arises from the fibula, and is inserted into the calcaneus.

Nerve-Supply.—Tibial nerve (L. 5. S. 1.).

Actions.—The muscle extends the ankle and inverts the foot.

The Muscles in the Sole of the Foot.

The muscles in the sole of the foot are divisible into four layers placed beneath the plantar aponeurosis.

The *first layer* includes the abductor hallucis, flexor digitorum brevis, and abductor digiti quinti. The *second layer* consists of the lumbricales and quadratus plantæ, together with the tendons of the flexor hallucis longus and flexor digitorum longus. The *third layer* comprises the flexor hallucis brevis, adductor hallucis, and

FIG. 386.—MUSCLE-ATTACHMENTS TO LEFT TARSUS AND METATARSUS (Plantar Aspect).

flexor digiti quinti brevis. The *fourth layer* consists of the interossei (plantar and dorsal), placed between the metatarsal bones: and the tendons of insertion of the tibialis posterior and peronæus longus.

FIRST LAYER.

M. Abductor Hallucis.—The **abductor hallucis** has a double **origin**: (1) by a short tendon from the medial side of the medial process of the tuberosity of the calcaneus (Fig. 386), and (2) by fleshy fibres from the ligamentum laciniatum, the plantar aponeurosis which covers it, and the intermuscular septum between it and the flexor digitorum brevis.

Lying superficially along the medial border of the sole, its tendon is **inserted**,

along with part of the flexor hallucis brevis, into the medial side of the base of the first phalanx of the great toe.

Nerve-Supply.—Medial plantar nerve (L. 4. 5. S. 1.).

Actions.—A flexor and abductor of the great toe.

M. Flexor Digitorum Brevis.—The flexor digitorum brevis has likewise a double origin: (1) from the anterior part of the medial process of the tuberosity of the calcaneus (Fig. 386, p. 432), and (2) from the thick central part of the plantar aponeurosis which covers it, and from the intermuscular septa on either side.

Passing forwards, it gives rise to four slender tendons, which are inserted into the second phalanges of the four lateral toes, after having been perforated by the long flexor tendons, just as in the case of the tendons of the flexor digitorum sublimis of the hand (p. 389).

Nerve-Supply.—Medial plantar nerve (L. 4. 5. S. 1.).

Actions.—The muscle is a flexor of the toes, acting on the metatarsophalangeal and first inter-phalangeal articulations of the four lateral toes.

M. Abductor Digiti Quinti.

—The abductor digiti quinti also has a double origin: (1) by fleshy and tendinous fibres from the anterior part of both processes of the tuberosity of the calcaneus, partly concealed by the flexor digitorum brevis (Fig. 386, p. 432), and (2) by fleshy fibres from the lateral portion of the plantar aponeurosis and the calcaneo-metatarsal ligament, and from the intermuscular septum between it and the flexor digitorum brevis.

Its tendon lies along the fifth metatarsal bone, and is inserted into the lateral side of the posterior end of the first phalanx of the little toe. The most lateral fibres usually obtain an additional insertion into the lateral side of the plantar surface of the fifth metatarsal bone.

Nerve-Supply.—Lateral plantar nerve (S. 1. 2.).

Actions.—Flexion and abduction of the little toe.

FIG. 387.—SUPERFICIAL MUSCLES OF THE RIGHT FOOT.

SECOND LAYER.

The tendons of the long flexors of the toes, the lumbricales and quadratus plantæ muscles, constituting the second layer of muscles, have already been described

(p. 430). Lying deep to the abductor hallucis and the flexor digitorum brevis, they occupy the hollow of the tarsus and the space between the first and fifth metatarsal bones; their deep surfaces are in contact with the adductor of the great toe and the interossei muscles.

THIRD LAYER.

M. Flexor Hallucis Brevis.—The flexor hallucis brevis arises by tendinous fibres from (1) the medial part of the plantar surface of the cuboid bone (Fig. 386, p. 432), and (2) the tendon of the tibialis posterior. Directed forwards over the first metatarsal bone, the muscle separates into two parts, between which is the tendon of the flexor hallucis longus.

Each portion gives rise to a tendon which is inserted into the corresponding side of the base of the first phalanx of the great toe; in each tendon, under the metatarso-phalangeal articulation, a sesamoid bone is developed. The medial tendon is united with the insertion of the abductor, the lateral tendon with the insertions of the adductor muscle of the great toe.

Nerve-Supply.—Medial plantar nerve (L. 4. 5. S. 1.).

Actions.—A flexor of the metatarso-phalangeal joint of the great toe.

M. Adductor Hallucis.—The adductor hallucis consists of two parts. The oblique head of the muscle arises (1) from the sheath of the peronæus longus, and (2) from the plantar surfaces of the bases of the second, third, and fourth metatarsal bones (Fig. 386, p. 432). Occupying the hollow of the foot, on a deeper plane than the long flexor tendons and lumbricales, and on the lateral side of the flexor hallucis brevis, it is directed obliquely medially and forwards, to be inserted on the lateral side of the base of the first phalanx of the great toe between and along with the flexor brevis

FIG. 388.—DEEP MUSCLES OF THE SOLE OF THE FOOT.

and the transverse head of the adductor hallucis.

The transverse head arises from (1) the capsules of the lateral four metatarso-phalangeal articulations and (2) the transverse metatarsal ligament.

Directed transversely medially under cover of the flexor tendons and lumbricales, the muscle is inserted, along with the oblique head, into the lateral side of the base of the first phalanx of the great toe.

Nerve-Supply.—Lateral plantar nerve (S. 1. 2.).

Actions.—Flexion and adduction of the great toe towards the middle line of the foot.

M. Flexor Digiti Quinti Brevis.—The flexor digiti quinti brevis arises from (1) the sheath of the peronæus longus and (2) the base of the fifth metatarsal bone (Fig. 386, p. 432).

Partially concealed by the abductor digiti quinti, the muscle passes along the fifth metatarsal bone, to be inserted, in common with that muscle, into the lateral side of the base of the first phalanx of the little toe.

Nerve-Supply.—Lateral plantar nerve (S. 1. 2.).

Actions.—Flexion of the little toe.

FOURTH LAYER.

Mm. Interossei.—The interossei muscles of the foot resemble those of the hand except in one respect. In the hand the line of action of the muscles is the middle line of the middle finger. In the foot the *second toe* is the digit round which the muscles are grouped, and their attachments and their actions differ accordingly.

There are four dorsal and three plantar muscles, which occupy together the four interosseous spaces, and project into the hollow of the foot.

The four dorsal muscles, one in each interosseous space, arise by two heads each from the shafts of the metatarsal bones.

Each gives rise to a tendon, which, after passing dorsal to the transverse metatarsal ligament, is inserted on the dorsum of the foot, into the side of the first phalanx, the metatarso-phalangeal capsule, and the dorsal expansion of the extensor tendon. The *first* and *second* muscles are inserted respectively into the medial and lateral sides of the proximal end of the first phalanx of the second toe. The *third* and *fourth* muscles are inserted into the lateral sides of the third and fourth toes.

The three plantar muscles occupy the three lateral interosseous spaces. Each arises by a single head from the medial side of the third, fourth, and fifth metatarsal bones respectively.

Each ends in a tendon which passes dorsal to the transverse metatarsal ligament, and is inserted, in the same manner as the dorsal muscles, into the medial sides of the third, fourth, and fifth toes.

Nerve-Supply.—Lateral plantar nerve (S. 1. 2.).

Actions.—The muscles are flexors of the metatarso-phalangeal joints, and extensors of the inter-phalangeal joints of the four lateral toes. The dorsal interossei *abduct* the toes into which they are inserted from the middle line of the second toe. The plantar interossei *adduct* the three lateral toes towards the second toe.

Actions of the Muscles of the Leg and Foot.

The muscles of the leg and foot act chiefly in the movements of the ankle-joint (assisted by movements of the intertarsal joints); of the metatarso-phalangeal joints (assisted by movements of the tarso-metatarsal and inter-metatarsal joints); and of the inter-phalangeal joints.

I. Tibio-Fibular Articulations.—The proximal tibio-fibular articulation is only capable of

FIG. 389.—INTEROSSEOUS MUSCLES OF THE RIGHT FOOT.

slight gliding movement, occasioned by the action of the biceps and popliteus and the muscles arising from the tibia.

II. Movements at the Ankle-Joint.—The movements at the ankle-joint are movements of flexion and extension of the foot on the leg, along with inversion and eversion (only during extension). These movements are produced at the ankle, aided by movements in the intertarsal joints, and are occasioned by the following muscles:—

<i>a. Flexion.</i>	<i>Extension.</i>	<i>b. Inversion.</i>	<i>Eversion.</i>
Tibialis anterior Extensor digitorum longus Extensor hallucis longus Peronæus tertius	Gastrocnemius Plantaris Soleus Tibialis posterior Peronæus longus Peronæus brevis Flexor digitorum longus Flexor hallucis longus	Tibialis anterior Tibialis posterior	Peronæus tertius Peronæus longus Peronæus brevis

III. Movements of the Toes.—*A. At the Metatarso-Phalangeal Joints* (assisted by movements at the tarso-metatarsal and inter-metatarsal joints).—These movements are flexion and extension, abduction and adduction (in a line corresponding to the axis of the second toe).

<i>a. Flexion.</i>	<i>Extension.</i>
Flexor digitorum longus Quadratus plantæ Lumbricales Flexor hallucis longus Flexor hallucis brevis Flexor digitorum brevis Flexor digiti quinti brevis Interossei	Extensor digitorum longus Extensor digitorum brevis Extensor hallucis longus Extensor hallucis brevis

<i>b. Abduction.</i>	<i>Adduction.</i>
<i>(From and to the middle line of the second toe.)</i>	
Abductor hallucis Dorsal interossei Abductor digiti quinti	Adductor hallucis Plantar interossei

B. At the inter-phalangeal joints the movements are limited to flexion and extension.

<i>Flexion.</i>	<i>Extension.</i>
Flexor digitorum brevis (<i>acting on the first joint</i>) Flexor digitorum longus (<i>acting on both joints</i>) Flexor hallucis longus (<i>acting on the hallux</i>)	Extensor digitorum longus Extensor digitorum brevis Interossei Lumbricales Extensor hallucis longus

Movements of the Lower Limb generally.

The characteristic features of the lower limb are stability and strength, and its muscles and joints are both subservient to the functions of transmission of weight and of locomotion. In the standing position the centre of gravity of the trunk falls between the heads of the femora, and is located about the middle of the body of the last lumbar vertebra. It is transmitted from the sacrum through the posterior sacro-iliac ligaments to the hip bone, and through the bones of the lower limb to the arch of the foot, where the talus distributes it backwards through the calcaneus to the heel, and forwards through the tarsus and metatarsus to the balls of the toes.

Locomotion.—The three chief means of progression are walking, running, and leaping. In walking, the body and its centre of gravity are inclined forwards, the trunk oscillates from side to side as it is supported alternately by each foot, the arms swing alternately with the corresponding leg, and one foot is always on the ground. The act of progression is performed by the leg, aided in two ways by gravity. The movements of the leg occur in the following way. At the beginning of a step, one leg, so to speak, “shoves off”; the heel is raised and the limb is extended. By the action of the muscles flexing the hip and knee-joints, and extending the ankle-joint and toes, this limb is raised from the ground sufficiently to clear it, and passes forwards by the action of gravity, aided by the force given to the movement by the extensor muscles. After passing the

line of the centre of gravity the flexion of the joints ceases, the muscles relax, and the limb gradually returns to the ground. The other limb then passes through the same cycle, the weight of the body now resting on the limb which is in contact with the ground. As the foot reaches the ground it, as it were, rolls over it; the heel touches it first, then the sole, and lastly, as the foot leaves the ground again, only the toes. In *running*, the previous events are all exaggerated. The time of the event is diminished, while the force and distance are increased. Both feet are off the ground at one time; the action of flexors and extensors alternately is much more powerful, so that on the one hand the knees are drawn upwards to a greater extent in the forward movement, and not the whole foot, but only the toes reach the ground in the extension of the limb. The attempt is made to bring the foot to the ground in front of the line of the centre of gravity. At the same time the trunk is sloped forwards much more than in walking. In *leaping*, the actions of the limbs are still more exaggerated. The movements of flexion of the limb are still more marked, and the foot reaches the ground still farther in front of the line of the centre of gravity.

AXIAL MUSCLES.

THE FASCIÆ AND MUSCLES OF THE BACK.

THE FASCIÆ OF THE BACK.

The general fascial investments of the back have been described along with the superficial muscles associated with the shoulder-girdle (p. 365). The latissimus dorsi muscle has been described as arising in large part from the posterior layer of the lumbo-dorsal fascia. This is a strong fibrous lamina which conceals the sacro-

spinalis muscle. In the loin it extends from the spines of the lumbar vertebræ outwards to the interval between the last rib and the iliac crest, where it joins the middle layer. Below the loin the posterior layer of the lumbo-dorsal fascia is attached to the iliac crest, and more medially blends with the subjacent tendinous origin of the sacrospinalis. The layer can be followed upwards over the sacrospinalis in the region of the thorax, where it is attached laterally to the ribs and is continuous with the intercostal aponeuroses. In the lower part of the thorax it is replaced by the muscular slips of the serratus posterior inferior; in the upper part of the thorax it passes beneath the serratus posterior superior and blends with the deep cervical fascia.

Fascia Lumbodorsalis.—The lumbo-dorsal fascia consists of three fascial strata, called respectively the posterior layer, just described; the middle, and the anterior layers. They unite at the lateral margin of the sacrospinalis muscle to

FIG. 390.—TRANSVERSE SECTION THROUGH THE ABDOMEN, OPPOSITE THE SECOND LUMBAR VERTEBRA.

form a narrow ligamentous band which connects the last rib to the iliac crest between the muscles of the back on the one hand and those of the abdominal wall on the other. The **middle layer** is a fascia which stretches laterally from the ends of the transverse processes of the lumbar vertebræ, between the sacrospinalis behind and the quadratus lumborum muscle in front. The **anterior layer** is attached to the

lumbar vertebræ near the bases of their transverse processes. It covers the anterior surface of the quadratus lumborum muscle, and separates it from the psoas major. The **psoas fascia** is continuous at the lateral border of the psoas major muscle with the anterior layer of the lumbo-dorsal fascia. At the lateral borders of the quadratus lumborum and sacrospinalis muscles the three layers blend together, and give partial origin to the obliquus internus and transversus abdominis muscles.

FIG. 391.—SCHEMATIC REPRESENTATION OF THE PARTS OF THE LEFT SACROSPINALIS MUSCLE.

THE MUSCLES OF THE BACK.

The muscles of the back are arranged in four series according to their attachments: (1) vertebro-scapular and vertebro-humeral, (2) vertebro-costal, (3) vertebro-cranial, and (4) vertebral. They are in irregular strata, the most superficial muscles having the most widely spread attachments.

The first series of muscles of the back, connecting the axial skeleton to the upper limb, have already been described. They are arranged in two layers: (1) trapezius and latissimus dorsi superficially; (2) levator scapulæ, and rhomboidei, beneath the trapezius (p. 368).

The remaining muscles are almost entirely axial, and may be divided into four groups: (1) serrati posteriores, superior and inferior; splenius capitis and splenius cervicis; (2) sacrospinalis and semispinalis capitis; (3) semispinalis dorsi and cervicis (transverso-spinales); and (4) the small deep muscles (rotatores, interspinales, intertransversarii, and suboccipital muscles). They extend from the sacrum to the head, forming a cylindrical column in the loin, filling up the

vertebral groove in the thorax, and giving rise to the muscular mass at the back of the neck.

First Group.

M. Serratus Posterior Superior.—The serratus posterior superior has a membranous origin from the ligamentum nuchæ and the spines of the last cervical

and upper three or four thoracic vertebræ. It is directed obliquely downwards and laterally, to be **inserted** by separate slips into the second, third, fourth, and fifth ribs. The muscle is concealed by the vertebro-scapular muscles, and crosses obliquely over the splenius, sacrospinalis and semispinalis capitis. It lies superficial to the lumbo-dorsal fascia.

Nerve-Supply.—Posterior rami of upper thoracic nerves.

Actions.—It is an accessory muscle of inspiration and an extensor of the vertebral column. Acting on the vertebral column, from the costal attachment, it assists in lateral movement of the column.

M. Serratus Posterior Inferior.—The **serratus posterior inferior** has a membranous **origin** through the medium of the lumbo-dorsal fascia from the last two thoracic and first two lumbar spinous processes.

It forms four muscular bands which pass almost horizontally to an **insertion** into the last four ribs. The muscular slips overlap one another from below upwards. The muscle is on the same plane as the posterior layer of the lumbo-dorsal fascia, and is concealed by the latissimus dorsi.

Nerve-Supply.—Posterior rami of the lower thoracic nerves.

Actions.—The muscle is an extensor of the vertebral column and an accessory muscle of inspiration, raising, everting, and fixing the lower four ribs.

M. Splenius.—The **splenius muscle** is a broad, flattened band which occupies the back of the neck and the upper part of the thoracic region. It arises from the ligamentum nuchæ (from the level of the fourth cervical vertebra downwards) and from the spinous processes of the last cervical and higher (four to six) thoracic vertebræ.

Its fibres extend upwards and laterally into the neck, separating in their course into an upper and a lower part. The upper part forms the **splenius capitis**, which is **inserted** into the mastoid process and the lateral part of the superior nuchal line of the occipital bone (Fig. 396, p. 444). The lower part forms the **splenius cervicis**, which is **inserted** into the posterior tubercles of the transverse processes of the upper three or four cervical vertebræ, behind the origin of the levator scapulæ.

The muscle is partially concealed by the trapezius and sterno-mastoid, and appears between them in the floor of the posterior triangle of the neck (**splenius capitis**). It is covered by the rhomboid muscles, levator scapulæ, and serratus posterior superior.

Nerve-Supply.—Posterior rami of cervical and upper thoracic nerves.

Actions.—The **splenius cervicis** extends the spine, and assists in lateral movement and rotation. The **splenius capitis** helps in the movements of raising the head, and also of lateral flexion and rotation.

Second Group.

M. Sacrospinalis.—The **sacrospinalis** (O.T. **erector spinæ**) possesses vertebral, vertebro-cranial, and vertebro-costal attachments. It consists of an elongated mass composed of separated slips extending from the sacrum to the skull. Simple at its origin, it becomes more and more complex as it is traced upwards towards the head.

It arises (1) by fleshy fibres from the iliac crest; (2) from the posterior sacro-iliac ligament; and (3) by tendinous fibres continuous with the former from the iliac crest, the dorsum of the sacrum, and the spines of the upper sacral and all the lumbar vertebræ. Its fibres extend upwards through the loin, enclosed between the posterior and middle layers of the lumbo-dorsal fascia, and separate into two columns—a **lateral portion** derived from the lateral fleshy origin, the **iliocostalis**, and a **medial portion** comprising the remaining larger part of the muscle, the **longissimus**.

M. Iliocostalis.—The **iliocostalis lumborum** is **inserted** by six slender slips into the lower six ribs.

Medial to the insertion of each of these slips is the origin of the **iliocostalis dorsi** (O.T. **accessorius**), which, arising from the lower six ribs medial to the

iliocostalis lumborum, is inserted in line with it by similar slips into the upper six ribs.

The iliocostalis cervicis (O.T. *cervicalis ascendens*) arises in the same way by six slips from the upper six ribs, medial to the insertions of the previous muscle. It forms a narrow band, which, extending into the neck, is inserted into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebræ, behind the scalenus posterior. *The iliocostales, lumborum, dorsi, and cervicis form together a continuous muscular column, and constitute the most lateral group of the component elements of the sacrospinalis.*

M. Longissimus.—The longissimus is the largest element in the sacrospinalis muscle. The longissimus dorsi forms the middle column of the muscle. It is continued up into the neck as the longissimus cervicis and longissimus capitis. Mostly tendinous on the surface at its origin, it becomes fleshy in the upper part of the loin. It is thickest in the loin, and becomes thinner as it passes upwards in

FIG. 392.—SCHEME OF MUSCULAR-ATTACHMENTS TO THE TRANSVERSE AND ARTICULAR PROCESSES OF THE CERVICAL VERTEBRÆ.

the back between the column formed by the iliocostalis and its upward continuations laterally, and the spinalis dorsi medially.

It is inserted by two series of slips, medial and lateral, laterally into nearly all the ribs, and medially into the transverse processes of the thoracic and the accessory processes of the upper lumbar vertebræ. It is prolonged upwards into the neck by its association with the common origin of the longissimus cervicis and the longissimus capitis.

The longissimus cervicis (*transversalis cervicis*) has an origin from the transverse processes of the upper six thoracic vertebræ, medial to the insertions of the longissimus dorsi.

Extending upwards into the neck, it is inserted into the posterior tubercles of the transverse processes of the second, third, fourth, fifth, and sixth cervical vertebræ. It is concealed in the neck by the iliocostalis cervicis and splenius cervicis muscles.

The longissimus capitis (*trachelo-mastoid*) arises, partly by an origin common to it and the previous muscle, from the transverse processes of the upper six thoracic vertebræ, and partly by an additional origin from the articular processes of the lower four cervical vertebræ.

Separating from the longissimus cervicis, the muscle ascends through the neck as a narrow band which is inserted into the mastoid process beneath the splenius

FIG. 393.—THE DEEP MUSCLES OF THE BACK.

capitis muscle. In the neck the muscle is placed between the splenius capitis and semispinalis capitis.

M. Spinalis Dorsi.—The spinalis dorsi forms the medial column of the sacrospinalis. It occupies the thoracic region, and arises by tendinous fibres from the lower two thoracic and upper two lumbar spinous processes, and also directly from the tendon of the longissimus dorsi.

It is a narrow muscle which, lying close to the thoracic spinous processes medial to the longissimus dorsi, is inserted into the upper (four to eight) thoracic spines. It is not prolonged into the neck.

The semispinalis capitis (O.T. *complexus*) closely resembles in position and attachments the longissimus capitis.

It takes origin from the transverse processes of the upper six thoracic and the articular processes of the lower four cervical vertebræ, medial to the longissimus cervicis and longissimus capitis. It has an additional origin also from the spinous process of the last cervical vertebra.

It forms a broad muscular sheet which extends upwards in the neck, to be inserted into the medial impression between the superior and inferior nuchal lines of the occipital bone (Fig. 396, p. 444). The medial portion of the muscle is separate, and forms the *biventer cervicis*, consisting of two fleshy bellies with an intervening tendon, placed vertically in contact with the ligamentum nuchæ. The muscle is covered mainly by the splenius and longissimus capitis muscles. It conceals the semispinalis cervicis and the muscles of the suboccipital triangle.

Nerve-Supply.—Posterior rami of spinal nerves.

Actions.—The several parts of the sacrospinalis muscle have a complex action, on the vertebral column, head, ribs, and pelvis. The muscle serves as an extensor of the vertebral column, and assists in lateral movement and rotation. The longissimus capitis and semispinalis capitis assist in extension, lateral movement and rotation of the head. The iliocostales and longissimus are accessory muscles of inspiration. The whole muscle helps in extension and lateral movement of the pelvis in the act of walking.

Third Group.

This group comprises the semispinales (dorsi and cervicis) and multifidus. They occupy the vertebral furrow under cover of the sacrospinalis and semispinalis capitis muscles. They are only incompletely separate from one another. The semispinales, dorsi and cervicis, form a superficial stratum, the multifidus being more deeply placed. The more superficial muscles have the longer fibres; the fibres of the multifidus pass over fewer vertebræ. Both muscles extend obliquely upwards from transverse to spinous processes.

M. Semispinalis.—The semispinalis muscle extends from the loin to the second cervical vertebra. Its fibres are artificially separated into an inferior part, the semispinalis dorsi, and a superior part, the semispinalis cervicis.

The semispinalis dorsi arises from the transverse processes of the lower six thoracic vertebræ.

It is inserted into the spinous processes of the last two cervical and first four thoracic vertebræ.

The semispinalis cervicis arises from the transverse processes of the upper six thoracic, and the articular processes of the lower four cervical vertebræ.

It is inserted into the spines of the cervical vertebræ from the second to the fifth.

M. Multifidus.—The multifidus (O.T. *multifidus spinæ*) differs from the previous muscle in extending from the sacrum to the second cervical vertebra, and in the shortness of its fasciculi, which pass over fewer vertebræ to reach their insertion.

It arises from the sacrum, from the posterior sacro-iliac ligament (Fig. 395, p. 443), from the mamillary processes of the lumbar vertebræ, from the transverse processes of the thoracic vertebræ, and from the articular processes of the lower four cervical vertebræ.

It is inserted into the spines of the vertebræ up to and including the second cervical.

FIG. 394.—THE SUBOCCIPITAL TRIANGLE OF THE LEFT SIDE.

Lying in contact with the vertebral laminae, the muscle is covered in the neck and back by the semispinalis, and in the loin by the sacrospinalis muscle.

FIG. 395.—MUSCLE-ATTACHMENTS TO THE SACRUM (Dorsal Aspect).

Nerve-Supply.—Posterior rami of the spinal nerves.

Actions.—These muscles are concerned in extension, lateral movement and rotation of the spine.

Fourth Group.

This group includes several sets of small muscles, which are vertebro-cranial or intervertebral in their attachments.

The muscles bounding the **suboccipital triangle** are four in number—obliqui capitis, inferior and superior, and recti capitis posteriores, major and minor.

These muscles are concealed by the semispinalis capitis and splenius capitis; they enclose a triangular space (the suboccipital triangle) in which the vertebral artery, the posterior ramus of the suboccipital nerve, and the posterior arch of the atlas are contained.

FIG. 396.—MUSCLE-ATTACHMENTS TO THE OCCIPITAL BONE.

The **obliquus capitis inferior** arises from the spine of the epistropheus, and is inserted into the transverse process of the atlas.

Nerve-Supply.—Posterior ramus of the first cervical (suboccipital) nerve.

Actions.—Extension, lateral flexion and rotation of the atlas in the axis.

M. Obliquus Capitis Superior.—The **obliquus capitis superior** arises from the transverse process of the atlas, and is inserted into the occipital bone beneath and lateral to the semispinalis capitis and above the inferior nuchal line (Fig. 396).

Nerve-Supply.—Posterior ramus of the first cervical (suboccipital) nerve.

Actions.—Elevation, lateral movement and rotation of the head on the atlas.

M. Rectus Capitis Posterior Major.—The **rectus capitis posterior major** arises from the spine of the second cervical vertebra, and is inserted into the occipital bone beneath the obliquus capitis superior and semispinalis capitis and below the inferior nuchal line (Fig. 396).

Nerve-Supply.—Posterior ramus of the first cervical (suboccipital) nerve.

Actions.—Elevation, lateral movement and rotation of the head.

M. Rectus Capitis Posterior Minor.—The **rectus capitis posterior minor** arises beneath the previous muscle from the posterior tubercle of the atlas, and is

inserted into the occipital bone below the inferior nuchal line medial to and beneath the rectus capitis posterior major (Fig. 396, p. 444).

Nerve-Supply.—Posterior ramus of the first cervical (suboccipital) nerve.

Actions.—Elevation, lateral movement and rotation of the head.

Mm. Rotatores.—The **rotatores** are eleven pairs of small muscles occupying the vertebral groove in the thoracic region, beneath the semispinalis dorsi, of which they form the deepest fibres. Each consists of a small slip arising from the transverse process and inserted into the lamina of the vertebra directly above.

Nerve-Supply.—Posterior rami of the thoracic nerves.

Actions.—Extension and rotation of the vertebral column.

Mm. Interspinales.—The **interspinales** are bands of muscular fibres connecting together the spinous processes of the vertebræ.

Nerve-Supply.—Posterior rami of the spinal nerves.

Action.—Extension of the vertebral column.

Mm. Intertransversarii.—The **intertransversarii** are slender slips extending between the transverse processes. They are double in the neck, the anterior branches of the spinal nerves passing between them. In the loin the inter-transverse muscles are usually double, but they are often absent, or are replaced by membrane.

Nerve-Supply.—Anterior rami of the spinal nerves.

Actions.—Lateral movement and rotation of the vertebral column.

Mm. Rectus Capitis Lateralis.—The **rectus capitis lateralis**, extending from the transverse process of the atlas to the jugular process of the occipital bone (Fig. 396, p. 444), is homologous with the posterior of the two inter-transverse muscles.

Nerve-Supply.—Anterior ramus of the first cervical (suboccipital) nerve.

Action.—Lateral movement and rotation of the head. The action of these muscles is extremely complex. Not only do they act on the vertebral column, ribs, head, and pelvis, in conjunction with other muscles, but some of them act also in relation to the movements of the limbs as well. In this section will be given an analysis of their movements in relation to the vertebral column, head, and pelvis. The movements of the limbs and of the ribs (respiration) are dealt with in other sections. The chief muscles are engaged in preserving the erect position, and in the movements of the trunk they are assisted in large measure by muscles whose chief actions are referred to elsewhere.

1. Movements of the Vertebral Column.—The movements of the vertebral column are flexion, extension, and lateral movement or rotation. These movements occur in all regions—neck, thorax, and loin; flexion and extension and lateral movement are most limited in the region of the thorax; while rotation is most limited in the region of the loin.

a. Flexion.	Extension.
Longus colli	Serrati posteriores
Longus capitis	Splenius capitis

Movements of the Pelvis.—The movements of the pelvis (as in locomotion) are partly caused by certain of the muscles of the back. Those muscles, which are attached to the vertebral column or the ribs on the one hand, and to the hip bone on the other, produce the movements (flexion, extension, and lateral movement) of the whole pelvis. In addition, the muscles passing between the hip bone and femur, in certain positions of the lower limb, assist in these movements.

THE FASCIÆ AND MUSCLES OF THE HEAD AND NECK.

FASCIÆ.

The superficial fascia of the head and neck possesses certain features of special interest. Over the scalp it is closely adherent to the skin and subjacent galea aponeurotica and contains the superficial vessels and nerves. Beneath the skin of the eyelids it is loose and thin and contains no fat. Over the face and at the side of the neck it is separated from the deep fascia by the facial muscles and the platysma. Between the buccinator and the masseter it is continuous with a pad of fat (*corpus adiposum buccæ*) occupying the interval between these muscles.

The **deep fascia** of the head and neck presents many remarkable characters. *Over the scalp* it is represented by the **galea aponeurotica** (O.T. **epicranial aponeurosis**), the tendon of the epicraneus muscle. This is a tough membrane, tightly stretched over the calvaria, from which it is separated by loose areolar tissue. It is attached posteriorly, partly through the agency of the occipitalis muscle, to the superior nuchal line of the occipital bone; anteriorly it joins the frontalis muscle and the orbicularis oculi, and has no bony attachment; laterally it is attached to the temporal line and the mastoid process. Below the temporal line it is continuous with the **temporal fascia**, a stout layer of fascia attached to the temporal line and zygomatic arch, which covers and gives origin to the temporal muscle. This fascia separates into two layers above the zygomatic arch, to enclose a quantity of fat along with branches of the temporal and zygomatico-orbital arteries. *On the face* the fascia is practically non-existent anteriorly in relation to the facial muscles. Posteriorly it forms the thin **parotideo-masseteric fascia**, and is much thicker in relation to the parotid gland, for which it forms a capsule.

In the neck the deep fascia invests the muscles, and forms fascial coverings for the pharynx, trachea, oesophagus, glands, and large vessels. It encloses the **sterno-mastoid muscle**, and can be traced backwards over the posterior triangle to the trapezius and deeper muscles, which it surrounds; it can be traced forwards over the anterior triangle to the median plane of the neck, where it forms a continuous membrane. *Above the sternum* the fascia, after enclosing the sterno-mastoid muscles, is attached in the form of two layers to the front and back of the jugular notch. The layer enclosing the infra-hyoid muscles passes across the median plane of the neck anterior to the trachea, and is attached above to the hyoid bone, below to the sternum, clavicle, and first rib. A third layer of fascia passes medially anterior to the trachea, enclosing the thyroid gland. Beneath the sterno-mastoid the fascia helps to form the **carotid sheath**, which is completed by septal processes stretching medially across the neck in relation to the infra-hyoid muscles, trachea,

oesophagus, and pharynx, and the prævertebral muscles. The trachea, oesophagus, and pharynx are likewise encapsuled in cervical fascia, a septal layer passing across the median plane of the neck between the trachea and oesophagus. Lastly, a strong **prævertebral fascia** passes across the neck anterior to the prævertebral muscles, and posterior to the oesophagus and pharynx.

The cervical fascia is attached above to the **bones of the skull**: superficially to the superior nuchal line of the occipital bone, the mastoid process, the zygoma (over the parotid gland), and the inferior border of the mandible; more deeply to the styloid and vaginal processes of the temporal bone, the great wing of the sphenoid and the basilar part of the occipital bone. This deeper attachment (*prævertebral fascia*) is posterior to the parotid gland and pharynx, and is associated with the formation of three ligaments: **stylo-mandibular ligament**, **spheno-mandibular ligament**, and **pterygo-spinous ligament**. The fascia is attached below, through its muscular connexions, to the sternum, first rib, clavicle, and scapula. By means of its connexion with the trachea and the common carotid artery it is carried down behind the first rib into the superior mediastinum, and so becomes continuous with the pericardium. By means of its connexion with the subclavian vessels and brachial nerves it is carried down to the axilla, as the axillary sheath, which becomes connected with the costo-coracoid membrane.

THE MUSCLES OF THE HEAD.

The muscles of the head are divisible into three separate groups: the superficial muscles, muscles of the orbit, and muscles of mastication.

Superficial Muscles.

The superficial muscles comprise a large group, including the muscles of the scalp and face, and the platysma in the neck.

The **platysma** is a thin quadrilateral sheet extending from chest to face over the side of the neck, between the superficial and deep fasciæ. It arises from the deep fascia of the pectoral region and the clavicle.

It is directed upwards and forwards, and is partly **inserted** (by its intermediate fibres) into the inferior border of the mandible, becoming connected with the quadratus labii inferioris and triangularis muscles (Fig. 398, p. 449). The more anterior fibres pass across the median plane of the neck and decussate for a variable distance below the chin with those of the opposite side. The posterior fibres sweep over the angle of the jaw and become continuous with the risorius muscle. The platysma is the rudiment of the cervical portion of the **panniculus carnosus** of lower animals, in which it has a much more intimate connexion with the muscles of the face than is usually the case in man.

Nerve-Supply.—Cervical branch of the facial nerve.

Actions.—It depresses the mandible and laterally flexes the head. It also throws into folds the skin of the side of the neck.

The Muscles of the Scalp.

The muscles of the scalp comprise the epicranium muscle and the muscles of the auricle.

M. Epicranium.—The **epicranium** (O.T. **occipitofrontalis**) is a muscle with two bellies and an intervening tendon (the galea aponeurotica) which stretches uninterruptedly across the median plane of the cranium. The **posterior belly** (**occipitalis**) arises as a broad flat band from the lateral two-thirds of the superior nuchal line of the occipital bone. The **anterior belly** (**frontalis**) has no bony attachments; arising from the galea aponeurotica about the level of the coronal suture, it passes downwards to the supra-orbital arch, where it blends with the orbicularis oculi and corrugator supercilii muscles. It extends across the full width of the forehead, and blends in the median plane with the muscle of the opposite side.

The *galea aponeurotica* (O.T. *epicranial aponeurosis*), extending between the two fleshy bellies, is a continuous membrane which glides over the calvaria, and has attachments laterally to the temporal ridge, and behind, between the posterior bellies, to the superior nuchal lines of the occipital bone. It has no osseous attachment anteriorly.

Nerve-Supply.—The *occipitalis* is supplied by the posterior auricular branch of the facial nerve. The *frontalis* is supplied by the temporal branches of the same nerve.

Actions.—The *epicraneus* is usually rudimentary. By the contraction of the fibres of the *frontalis* muscle the skin of the forehead is thrown into horizontal parallel folds.

FIG. 398.—THE MUSCLES OF THE FACE AND SCALP (Muscles of Expression).

The **extrinsic muscles of the ear** are three in number: posterior, superior, and anterior. They are rudimentary and usually functionless.

The *m. auricularis posterior* (O.T. *retrahens aurem*) is a narrow fleshy slip which arises from the surface of the mastoid process and is inserted into the cranial surface of the auricle. It bridges across the groove between the mastoid process and the auricle, and conceals the posterior auricular vessels and nerve.

The *m. auricularis superior* (O.T. *attollens aurem*) is a small fan-shaped muscle which arises from the temporal fascia, and descends to be inserted into the top of the root of the auricle.

The *m. auricularis anterior* (O.T. *attrahens aurem*) is a similar small muscle, placed in front of the *auricularis superior*, and stretching obliquely between the temporal fascia and the top of the root of the auricle.

The Muscles of the Face.

The facial muscles are divided into three groups, associated with the several apertures of the eye, nose, and mouth.

1. The **muscles of the eyelids** include four muscles: the levator palpebræ superioris (described with the orbital muscles (p. 452)), orbicularis oculi, lacrimal part of the orbicularis, and corrugator supercilii.

M. Orbicularis Oculi.—The orbicularis oculi is a transversely oval sphincter muscle surrounding and occupying the eyelids. It is divisible into an *orbital portion* (*pars orbitalis*) composed of coarse fibres, spreading on to the forehead, temple, and cheek, and a *palpebral portion* (*pars palpebralis*), composed of finer fibres, situated beneath the skin of the eyelids. At the medial commissure of the eye the muscle (by its palpebral fibres) gains an **attachment** to the medial palpebral ligament and the borders of the naso-lacrimal groove. Its fibres enclose the lacrimal sac and the canaliculi. The posterior fibres, extending between the posterior edge of the naso-lacrimal groove and the tarsal ligaments behind the lacrimal sac, constitute the **pars lacrimalis** (O.T. **tensor tarsi muscle**). The fibres of the muscle which extend along the margins of the lids constitute a separate **ciliary bundle**.

Laterally the orbicularis oculi has no bony attachment; so that when it contracts and closes the eyelids, both lids at the same time tend to be drawn towards the medial commissure of the eye.

M. Corrugator Supercilii.—The corrugator supercilii arises from the medial part of the superciliary arch, and passing horizontally laterally, blends with the upper fibres of the orbicularis oculi on its deep surface. The contraction of this muscle throws the skin of the forehead into vertical folds, while at the same time drawing the medial half of the eyebrow upwards, it produces concentric curved folds on each side of the median plane of the forehead.

2. The **muscles of the nose** comprise five small muscles proper to the nose, and one common to the nose and upper lip: the m. procerus, nasalis, dilatores naris (anterior and posterior), depressor alæ nasi, and angular head of the quadratus labii superioris. They are all small and feeble muscles.

The m. procerus (O.T. **pyramidalis nasi**) arises from the epicranium muscle and the skin over the glabella; it is **inserted** into a membrane stretching over the nose, which gives attachment to the compressor naris also.

The m. nasalis (O.T. **compressor naris**) arises by a narrow origin from the maxilla, under cover of the quadratus. It passes forwards over the bridge of the nose, and ends in a membranous **insertion** common to it and the preceding muscle.

The mm. dilatores naris are feeble muscular slips placed on the lateral surface of the margin of the nostril, one anteriorly, the other posteriorly.

The m. depressor alæ nasi is a small muscle arising from the upper part of the incisor fossa of the maxilla; it divides into two parts as it passes upwards and medially, and is **inserted** into the ala and the septum of the nose (**depressor septi**).

The caput angulare (O.T. **levator labii superioris alæque nasi**) is a portion of the quadrate muscle of the upper lip, and is a narrow band arising from the root of the frontal process of the maxilla. It descends alongside the nose, and is **inserted**, partly into the ala of the nose and partly into the orbicularis oris muscle.

3. The **muscles of the mouth** comprise a number of muscles, of which all but one, the orbicularis oris, are bilaterally placed. The muscles are: (1) quadratus labii superioris, which includes the angular head just described, the infra-orbital head, and the zygomatic head; (2) the canine muscle; (3) zygomaticus; (4) risorius; (5) orbicularis oris; (6) triangularis; (7) quadratus labii inferioris; (8) mentalis; and (9) buccinator.

M. Orbicularis Oris.—The orbicularis oris is the sphincter muscle surrounding the lips. It is continuous with the other muscles converging to the mouth. It lies between the skin and mucous membrane of the mouth, and is limited superiorly by the nose, inferiorly by the junction of the lower lip and chin. Its medial fibres are attached above to the septum of the nose (*naso-labial band*) and

to the incisor fossa (*superior incisive bundle*); below they are attached to the mandible on each side of the symphysis (*inferior incisive bundle*). These bundles radiate laterally to join the rest of the muscle, which is joined at its margin by the elevators and depressors of the lower lip and angle of the mouth, and by the buccinator muscle. The *lower fibres* of the muscle are continued laterally into the buccinator and canine muscles; its *upper fibres* are continued into the buccinator and triangularis muscles.

M. Quadratus Labii Superioris.—The quadratus labii superioris comprises three muscles.

(1) The *caput angulare* (O.T. levator labii superioris alæque nasi) has already been described.

(2) The *caput infra-orbitale* (O.T. levator labii superioris) arises from the maxilla just above the infra-orbital foramen. It passes almost vertically downwards to join the orbicularis oris and the skin of the upper lip between the attachments of the caput angulare and the caninus. It conceals the infra-orbital vessels and nerve.

(3) The *caput zygomaticum* (O.T. zygomaticus minor) arises from the zygomatic bone, and is often continuous with the most peripheral fibres of the orbicularis oculi. It is directed obliquely downwards and forwards over the caninus, to be inserted along with the caput infra-orbitale into the margin of the orbicularis oris.

M. Caninus.—The caninus (O.T. levator anguli oris) arises from the canine fossa of the maxilla below the infra-orbital foramen and under cover of the caput zygomaticum. It is directed laterally and downwards, to be inserted into the orbicularis oris and the skin at the angle of the mouth.

M. Zygomaticus.—The zygomaticus (O.T. zygomaticus major) is a narrow muscular band which arises from the zygomatic portion of the zygomatic arch. It passes to the angle of the mouth, to be inserted partly into the skin, partly into the orbicularis oris.

M. Risorius.—The risorius is a thin flat muscle which forms in part a continuation of the platysma on the face, in part a separate muscle, with an origin from the parotideo-masseteric fascia. It passes transversely forwards, to be inserted at the angle of the mouth into the orbicularis oris and skin.

M. Triangularis.—The triangularis (O.T. depressor anguli oris) arises from the oblique line of the mandible and is continuous with the platysma (Fig. 398, p. 449). It is triangular in form, its fibres converging to the angle of the mouth, where they are inserted into the orbicularis oris and the skin. Some of the fibres reach the upper lip through the orbicularis muscle.

M. Quadratus Labii Inferioris.—The quadratus labii inferioris (O.T. depressor labii inferioris) arises from the lateral surface of the mandible deep and medial to the preceding muscle (Fig. 398, p. 449). It is quadrilateral in form, and is directed upwards, to be inserted into the orbicularis oris and the skin of the lower lip. Its lateral fibres are overlapped by the triangularis. Its medial fibres join with those of the opposite muscle.

M. Mentalis.—The mentalis (O.T. levator menti) is a small muscle which arises from the incisor fossa of the mandible and is inserted into the skin of the chin.

M. Buccinator.—The buccinator muscle forms the lateral wall of the mouth, and is in series posteriorly with the constrictor muscles of the pharynx. It arises (1) from the alveolar arches of the maxillæ and mandible (Fig. 407, p. 457), and between these attachments; (2) from the pterygo-mandibular raphe. Its fibres are directed forwards to the angle of the mouth, where they blend with the corresponding (upper and lower) portions of the orbicularis oris muscle. The *middle fibres* of the muscle decussate at the angle of the mouth, so as to pass, the lower set to the upper lip, the upper set to the lower lip. The buccinator is covered on its deep surface by the mucous membrane of the mouth. Superficially it is concealed by the muscles above mentioned, which converge to the angle of the mouth; it is separated from the masseter by the *corpus adiposum buccæ*; it is pierced by the duct of the parotid gland, and by branches of the buccinator nerve.

Nerve-Supply.—The facial and scalp muscles are all innervated by the facial nerve. The *posterior auricular branch* supplies the posterior auricular muscle and occipitalis; the branches into which it breaks up in the parotid gland supply the frontalis, superior and anterior auricular muscles, the several muscles associated with the apertures of the eye, nose, and mouth (including the buccinator), and the platysma.

Actions.—The almost infinite variety of facial expression is produced partly by the action of these muscles, partly by their inactivity, or by the action of antagonising muscles (antithesis). On the one hand joy, for example, is betrayed by the action of one set of muscles, while grief is accompanied by the contraction of another (opposing) set. Determination or eagerness is accompanied by a fixed expression due to a combination of muscles acting together; despair, on the other hand, is expressed by a relaxation of muscular action. For a philosophical account of the action of the facial muscles, the student should consult Darwin's *Expression of the Emotions in Man and Animals*, and Duchenne's *Mécanisme de la Physiologie humaine*.

The *platysma* retracts and depresses the angle of the mouth, and depresses the mandible. The *epicranius*, by its anterior belly, raises the eyebrows; both bellies acting together tighten the skin of the scalp; acting along with the *orbicularis oculi*, it shifts the scalp backwards and forwards. The *corrugator supercilii* draws the eyebrow medially and wrinkles the skin of the forehead vertically. The *procerus* draws downwards the skin between the eyebrows, as in frowning. The upper eyelid is raised by the *levator palpebræ superioris*. The closure of the lids is effected by the *orbicularis oculi*, whose fibres also assist in the lowering of the eyebrows, in the protection of the eyeball, and, by pressure on the lacrimal gland, in the secretion of tears. The *tarsal part*, acting along with the *orbicularis oculi*, compresses the lacrimal sac and aids in the passage of its contents into the naso-lacrimal duct. The *muscles of the ear and nose* have quite rudimentary actions. Of the muscles of the mouth, the *orbicularis oris* has a complex action, depending on the degree of contraction of its component parts. It causes compression and closure of the lips in various ways, tightening the lips over the teeth, contracting them as in osculation, or causing pouting or protrusion of one or the other. The *accessory muscles of the lips* draw them upwards (*zygomaticus*, *quadratus labii superioris*), laterally (*zygomaticus*, *risorius*, *platysma*, *triangularis*, *buccinator*), and downwards (*triangularis*, *quadratus labii inferioris*, *platysma*). The *mentalis* muscle elevates the skin of the chin and protrudes the lower lip. The *buccinator* retracts the angles of the mouth, flattens the cheeks, and brings them in contact with the teeth.

The Fasciæ and Muscles of the Orbit.

The eyeball, with its muscles, vessels, and nerves, is lodged in a mass of soft and yielding fat which entirely fills up the cavity of the orbit. Surrounding the

FIG. 399.—TRANSVERSE VERTICAL SECTION THROUGH THE LEFT ORBIT BEHIND THE EYEBALL TO SHOW THE ARRANGEMENT OF MUSCLES.

posterior part of the eyeball is the *fascia bulbi* (O.T. capsule of Tenon), which constitutes a large lymph space or synovial bursa in relation to the posterior part of the eyeball. Anteriorly the capsule is in contact with the conjunctiva, and intervenes between the latter and the eyeball; posteriorly it is pierced by and prolonged along the optic nerve. It is a smooth membrane connected to the globe of the eye by loose areolar tissue. It is

pierced by the tendons of the ocular muscles, along which it sends prolongations continuous with the muscular sheaths.

The *muscles of the orbit* are seven in number: one, the *levator palpebræ superioris*, belongs to the upper eyelid; the other six are muscles of the eyeball.

M. Levator Palpebræ Superioris.—The *levator palpebræ superioris* lies immediately beneath the orbital periosteum and covers the superior rectus muscle. It has a narrow origin above that muscle from the margin of the optic foramen.

It expands as it passes forwards, to end, in relation to the upper lid, in a membranous expansion which is inserted in a fourfold manner: (1) into the *orbicularis oculi* and skin of the upper lid, (2) mainly into the superior border of the superior tarsus, (3) into the conjunctiva, and (4) by its edges into the upper border of the margin of the orbital opening.

Nerve-Supply.—The muscle is supplied by the superior division of the oculo-motor nerve.

Actions.—It elevates the upper eyelid and antagonises the action of the orbicularis oculi muscle.

Mm. Recti.—The recti muscles are four in number—superior, inferior, medial, and lateral. They all arise from a membranous ring surrounding the optic foramen, which is separable into two parts—a *superior common tendon*, giving origin to the superior and medial recti and the superior head of the lateral rectus; and an *inferior common tendon*, giving origin to the medial and inferior recti and the inferior head of the lateral rectus. The two origins of the lateral rectus muscle are separated by the passage into the orbit of the oculo-motor, naso-ciliary, and abducent nerves. Forming flattened bands which lie in the fat of the orbit around the optic nerve and eyeball, the four muscles end in tendons which pierce the fascia bulbi, and are inserted into the sclera about eight millimetres (three to four lines) behind the margin of the cornea.

The superior and inferior recti are inserted in the vertical plane slightly medial to the axis of the eyeball; the lateral and medial recti in the transverse plane of the eyeball; and all are attached in front of the equator of the eyeball.

M. Obliquus Superior.—The obliquus superior arises from the margin of the optic foramen between the rectus superior and rectus medialis. It passes forwards as a narrow muscular band medial to the rectus superior, and at the anterior margin of the orbit forms a narrow tendon which passes through a special fibrous pulley (trochlea) attached to the roof of the orbit.

Its direction is then altered, and passing laterally between the tendon of the superior rectus and the eyeball, it is inserted into the sclera between the superior and lateral recti, midway between

FIG. 400.—MUSCLES OF THE RIGHT ORBIT (from above).

FIG. 401.—MUSCLES OF THE LEFT ORBIT (from lateral aspect).

the margin of the cornea and the entrance of the optic nerve.

M. Obliquus Inferior.—The obliquus inferior arises from the medial side of the floor of the orbit just behind its anterior margin, and lateral to the naso-lacrimal groove.

It forms a slender rounded slip, which curls round the inferior rectus tendon,

and passes between the lateral rectus and the eyeball, to be inserted into the sclera between the superior and lateral recti, and farther back than the superior oblique muscle.

M. Orbitalis (O.T. Müller's muscle) is a rudimentary bundle of non-striated muscular fibres bridging across the inferior orbital fissure and infra-orbital groove. It is supplied by fibres from the sympathetic, and may have a slight influence in the protrusion of the eyeball.

FIG. 402.—SCHEMATIC REPRESENTATION OF THE NERVES WHICH TRAVERSE THE CAVITY OF THE RIGHT ORBIT.

Nerve-Supply.—The muscles of the eyeball are supplied by the third, fourth, and sixth cerebral nerves. The trochlear (**fourth nerve**) supplies the obliquus superior; the abducent (**sixth**) supplies the rectus lateralis; the oculo-motor (**third nerve**) supplies the others—recti, superior, inferior, and medialis, and obliquus inferior.

Actions.—The six muscles inserted into the eyeball serve to move the longitudinal axis of the eyeball upwards, downwards, medially, and laterally, besides causing a rotation of the eyeball on its own axis. The following table expresses the action of individual muscles. It must be remembered that, while similar movements occur simultaneously in the two eyeballs, the horizontal movements may, by adduction of the muscles of both sides, cause convergence of the axes of the two eyeballs for the purposes of near vision.

a. Adduction.	Abduction.
Rectus medialis Rectus superior Rectus inferior	Rectus lateralis Obliquus superior } (correcting Obliquus inferior } adductors)
b. Elevation.	Depression.
Rectus superior Obliquus inferior	Rectus inferior Obliquus superior
c. Rotation laterally.	Rotation medially.
Obliquus inferior	Obliquus superior Rectus superior } (in adduction) Rectus inferior }

Muscles of Mastication.

The muscles of mastication comprise the masseter, temporal, external and internal pterygoids, and buccinator (described above).

M. Masseter.—The masseter is the most superficial. Covered by the parotid gland on the side of the face, it has an origin which is partly tendinous and partly fleshy. It arises in two parts: (1) superficially from the inferior border of the zygomatic arch in its anterior two-thirds, and (2) more deeply from the deep surface of the zygomatic arch in its whole length. The superficial fibres are

directed downwards and backwards towards the angle of the mandible; the deeper fibres are directed vertically downwards.

The muscle is inserted by fleshy and tendinous fibres into the lateral surface of the ramus and angle of the mandible and the coronoid process (Fig. 403). The deepest fibres blend with the fibres of the subjacent temporal muscle.

The muscle is partially concealed on the face by the parotid gland, accessory parotid gland, and parotid duct; by the external maxillary artery; the branches of the facial nerve; and by the zygomatic and platysma muscles. It conceals the ramus of the jaw, and, at its anterior border, is separated from the buccinator muscle by the *corpus adiposum buccae*.

M. Temporalis.—The temporal muscle is a fan-shaped muscle arising from the whole area of the temporal fossa, as well as from the temporal fascia which covers it. Its converging fibres pass beneath the zygomatic arch.

FIG. 403.—MUSCLE-ATTACHMENTS TO THE LATERAL ASPECT OF THE MANDIBLE.

FIG. 404.—MUSCLE-ATTACHMENTS ON THE MEDIAL SIDE OF THE MANDIBLE.

The muscle is inserted into the deep surface and apex of the coronoid process, and into the anterior border of the ramus of the mandible (Figs. 403 and 404).

The origin of the muscle is concealed by the temporal fascia. As it passes to its insertion the muscle is concealed by the zygomatic arch, the masseter muscle, and the coronoid process of the mandible. It is separated from the external pterygoid in a majority of cases by the internal maxillary artery. The masseteric

nerve and vessels appear at its posterior border; the buccinator nerve and vessels at its anterior border.

M. Pterygoideus Externus.—The external pterygoid muscle is deeply placed under cover of the temporal muscle, in the infra-temporal fossa. It arises by two heads, superior and inferior. The *superior* head is attached to the infra-temporal surface of the great wing of the sphenoid; the *inferior* head takes origin from the lateral surface of the lateral pterygoid lamina of the pterygoid process.

The muscle is directed laterally and backwards, to be inserted into (1) the

FIG. 405.—MUSCLES OF MASTICATION (superficial view).

FIG. 406.—THE RIGHT TEMPORAL MUSCLE. (The Zygomatic Arch and the Masseter Muscle have been removed.)

fovea pterygoidea on the anterior aspect of the neck of the mandible (Figs. 403 and 404, p. 455), and (2) the articular disc and capsule of the mandibular articulation.

This muscle is covered by the insertion of the temporal muscle and the coronoid process of the mandible, and is usually crossed by the internal maxillary artery. It conceals the mandibular branch of the trigeminal nerve, and the pterygoid origin of the internal pterygoid muscle.

M. Pterygoideus Internus.—The **internal pterygoid muscle**, placed beneath the external pterygoid muscle and the ramus of the mandible, has likewise a double **origin**—(1) from the deep surface of the lateral pterygoid lamina and the pyramidal process of the palate bone, and (2) by a stout tendon from the tuberosity

FIG. 407.—THE PTERYGOID MUSCLES OF THE RIGHT SIDE.

of the maxilla. Its two heads of origin embrace the inferior fibres of the external pterygoid muscle.

It is quadrilateral in form, and is directed downwards, laterally, and backwards over the auditory tube and the tensor and levator muscles of the palate, to be **inserted** into a triangular impression on the medial surface of the mandible, between the mylo-hyoid groove and the angle of the bone (Fig. 404, p. 455).

This muscle is covered by the ramus of the mandible and temporal muscle, and partially by the external pterygoid muscle. In contact with its superficial surface are the spheno-mandibular ligament, and the inferior alveolar and lingual nerves and their accompanying vessels. The muscle conceals the tensor veli palatini and the wall of the pharynx (superior constrictor).

Nerve-Supply.—The **mandibular division of the trigeminal nerve** supplies all the muscles of mastication except the buccinator, which is supplied by the **facial nerve**. The internal pterygoid muscle is supplied by the nerve before its division into anterior and posterior parts; the other muscles are innervated by the anterior trunk.

Actions—The above muscles, assisted by others in the neck, produce the various movements of the mandible as follows:—

a. Opening of the Mouth.	Closure of the Mouth.
Weight of the mandible	Masseter
Digastric	
Mylo-hyoid	Temporal
Genio-hyoid	
Genioglossus	Internal pterygoid
Infra-hyoid muscles	
b. Protrusion of the Mandible.	Retraction of the Mandible.

THE MUSCLES OF THE NECK.

In addition to those included among the muscles of the back (p. 438), the following series of muscles occur in the neck: (1) sterno-cleido-mastoid; (2) the muscles of the hyoid bone (supra-hyoid and infra-hyoid); (3) the muscles of the tongue (extrinsic and intrinsic); (4) the muscles of the pharynx and soft palate; and (5) the prævertebral muscles.

M. Sternocleidomastoideus.—The **sterno-mastoid muscle** is the prominent muscle projecting on the side of the neck, and separating the anterior from the posterior triangle. It arises by two heads—(1) a narrow tendinous *sternal* head, from the anterior surface of the manubrium sterni (Fig. 330, p. 370), and (2) a broader *clavicular* origin, partly tendinous, partly fleshy, from the superior surface of the clavicle in its medial third (Fig. 327, p. 366). The muscle is inserted into the lateral surface of the mastoid process and into the superior nuchal line of the occipital bone (Fig. 396, p. 444).

The muscle passes obliquely over the side of the neck separating the anterior from the posterior triangle. It is almost superficial in its whole extent, but is overlapped superiorly by the parotid gland and is covered in its inferior part by the platysma. It is crossed by the external jugular vein, and by superficial branches of the cervical plexus. Its deep surface is in contact with: (*a*) in its lower third, the infra-hyoid muscles, which separate it from the common carotid artery, and the subclavian artery and the internal jugular vein; (*b*) in its middle third, with the cervical nerves which emerge between the transverse processes of the cervical vertebræ to form the cervical plexus; and (*c*) in its superior third, with the splenius capitis muscle, and the accessory nerve which here pierces the deep surface of the muscle. Near its insertion the muscle is related to the splenius capitis, longissimus capitis, the posterior belly of the digastric, and the occipital artery.

The sterno-cleido-mastoid muscle is properly divisible into three parts: (1) **sterno-mastoid**, placed superficially, and passing obliquely from the sternum to the mastoid process; (2) **cleido-mastoid**, placed more deeply, and directed vertically upwards from the clavicle to the mastoid process; and (3) **cleido-occipitalis**, passing obliquely upwards and backwards behind the cleido-mastoid to the superior nuchal line of the occipital bone.

Nerve-Supply.—The sterno-mastoid muscle is innervated by the accessory nerve, joined by a branch from the cervical plexus (C. 2.).

Actions.—When one muscle acts alone, it flexes the head laterally, and rotates it to the opposite side. The two muscles acting together (1) flex the head in a forward direction, and (2) act as extraordinary muscles of inspiration, by raising the sternum and clavicles.

The Muscles of the Hyoid Bone.

The muscles attached to the hyoid bone are in three series: (1) infra-hyoid muscles, connecting the hyoid bone to the scapula, thorax, and thyreoid cartilage;

- (2) supra-hyoid muscles, connecting it to the mandible, cranium, and tongue; and
 (3) the middle constrictor muscle of the pharynx (p. 464).

The **infra-hyoid muscles** comprise the omo-hyoid, sterno-hyoid, sterno-thyreoid, and thyreo-hyoid muscles.

M. Omohyoideus.—The omo-hyoid is a muscle with two bellies, anterior and posterior. The *posterior* belly arises from the superior margin of the scapula and the superior transverse scapular ligament (Fig. 333, p. 372). It forms a narrow muscular band, which is directed obliquely forwards and upwards, to end in an intermediate tendon beneath the sterno-mastoid muscle.

From this tendon the anterior belly proceeds upwards to be inserted into the lateral part of the inferior border of the body of the hyoid bone.

The posterior belly of the muscle separates the posterior triangle into occipital and subclavian parts; the anterior belly crosses the common carotid artery at the

FIG. 408.—THE MUSCLES OF THE TONGUE AND HYOID BONE (right side).

level of the cricoid cartilage, and in the anterior triangle forms the boundary between the muscular and carotid triangles. A process of the deep cervical fascia binds down the tendon and the posterior belly to the scapula and the first rib.

M. Sternohyoideus.—The sterno-hyoid muscle arises from the posterior surface of the manubrium, from the back of the first costal cartilage, and from the clavicle (Fig. 327, p. 366).

It passes vertically upwards in the neck, medial to the omo-hyoid and anterior to the sterno-thyreoid muscle, to be inserted into the medial part of the body of the hyoid bone. Except near its origin, which is covered by the sternum, clavicle, and sternal head of the sterno-mastoid, the muscle is superficially placed.

M. Sternothyreoides.—The sterno-thyreoid muscle arises beneath the sterno-hyoid from the back of the manubrium and first costal cartilage.

Broader than the preceding muscle, it passes upwards and slightly in a lateral direction in the neck in front of the trachea and thyreoid gland, and beneath the sterno-mastoid, omo-hyoid, and sterno-hyoid muscles, to be inserted into the oblique

line of the thyroid cartilage. The muscle is marked by an oblique tendinous intersection in the middle of its length.

M. Thyreohyoideus.—The thyreo-hyoid muscle continues the line of the preceding muscle to the hyoid bone. Short and quadrilateral, it arises from the oblique line of the thyroid cartilage.

Passing over the thyreo-hyoid membrane beneath the omo-hyoid and sterno-hyoid, it is inserted into the body and great cornu of the hyoid bone.

The *levator glandulæ thyreoidæ* is an occasional slip stretching between the hyoid bone and the isthmus or pyramid of the thyroid gland.

FIG. 409.—THE MUSCLES OF THE SIDE OF THE NECK (anterior and posterior triangles).

Nerve-Supply.—The sterno-hyoid, sterno-thyreoid, and omo-hyoid are supplied by the *ansa hypoglossi*; the thyreo-hyoid, by a special branch from the hypoglossal nerve. Through the *ansa hypoglossi* the muscles are innervated by nerves which are ultimately derived from the first three cervical nerves. The *descendens hypoglossi* is derived from the first two cervical nerves, the *descendens cervicis* by the second and third; and these two trunks combine to form the *ansa*. The thyreo-hyoid muscle is innervated (through the hypoglossal) from the loop between the first and second cervical nerves.

Actions.—The sterno-hyoid, sterno-thyreoid, and omo-hyoid are depressors of the hyoid bone. The two former muscles are also accessory muscles of inspiration. The omo-hyoid is a feeble elevator of the scapula. The thyreo-hyoid is, on the one hand, an elevator of the thyroid cartilage, and acting with the previous muscles, on the other hand, it is a depressor of the hyoid bone.

The **supra-hyoid muscles** comprise the digastric, stylo-hyoid, mylo-hyoid, and

genio-hyoid muscles; and also two muscles, the genioglossus and hyoglossus, which will be described along with the extrinsic muscles of the tongue.

M. Digastricus.—The digastric muscle, as its name implies, possesses two bellies—*anterior* and *posterior*.

The *posterior belly* arises under cover of the sterno-mastoid muscle from the mastoid notch medial to the mastoid process. It is directed forwards and downwards, in company with the stylo-hyoid muscle, to end in an intermediate tendon, which is connected by a pulley-like band of cervical fascia to the body of the hyoid bone.

The *anterior belly* of the muscle is directed forwards and upwards over the mylo-hyoid muscle to the chin, and is inserted into the oval digastric fossa on the inferior border of the mandible close to the symphysis (Fig. 410).

The muscle forms the inferior boundary of the submaxillary division of the anterior triangle, containing the submaxillary gland. The posterior belly in company with the stylo-hyoid crosses the carotid arteries and internal jugular vein. The occipital artery extends posteriorly along its inferior margin, and the parotid gland covers its superior border. The hypoglossal nerve emerges from under cover of the muscle. The anterior belly lies upon the mylo-hyoid muscle on its way to its insertion.

Nerve-Supply.—The posterior belly is supplied by the facial nerve; the anterior belly by the nerve to the mylo-hyoid, a branch of the inferior alveolar nerve.

M. Stylohyoideus.—The **stylo-hyoid muscle** arises from the inferior border of the styloid process of the temporal bone.

Crossing the anterior triangle obliquely along with the posterior belly of the digastric muscle, it is inserted into the body of the hyoid bone by two slips which enclose the tendon of the digastric muscle.

Nerve-Supply.—Facial nerve.

M. Mylohyoideus.—The **mylo-hyoid muscle** forms with its fellow a diaphragm in the floor of the mouth. It arises from the inferior three-fourths of the mylo-hyoid ridge of the mandible (Fig. 410).

It is directed downwards and medially, to be inserted into (1) the superior border of the body of the hyoid bone, and more anteriorly (along with the opposite muscle) into (2) a median raphe extending from the hyoid bone nearly to the chin.

The muscle has in contact with its superficial or lateral surface the digastric muscle and the submaxillary gland. Its deep or medial surface is partially covered by the mucous membrane of the floor of the mouth, and is separated from the muscles of the tongue by the deep part of the submaxillary gland, the sublingual gland, the submaxillary duct, and the lingual and hypoglossal nerves.

Nerve-Supply.—The muscle is supplied by the nerve to the mylo-hyoid, a branch of the inferior alveolar nerve.

M. Geniohyoideus.—The **genio-hyoid muscle** arises from the inferior of the two mental spines on the posterior surface of the symphysis of the mandible (Fig. 410).

FIG. 410.—MUSCLE-ATTACHMENTS ON THE MEDIAL SIDE OF THE MANDIBLE.

It is directed downwards and somewhat posteriorly, along the inferior border of the genioglossus, to be inserted into the anterior surface of the body of the hyoid bone. The muscles of opposite sides are often fused together.

The muscle is placed deeper than the anterior belly of the digastric muscle and the mylo-hyoid, and is in contact with the inferior border of the genioglossus muscle.

Nerve-Supply.—It is supplied by the hypoglossal nerve, but its nerve can be traced back to an origin from the communication between that nerve and the first and second cervical nerves.

Actions.—The digastric, stylo-hyoid, mylo-hyoid, and genio-hyoid muscles are all elevators of the hyoid bone. The posterior belly of the digastric and stylo-hyoid also retract, while the anterior belly of the digastric and the genio-hyoid protract it. The anterior belly of the digastric, mylo-hyoid, and genio-hyoid also assist in opening the mouth.

The Muscles of the Tongue.

The muscular substance of the tongue consists of two symmetrical series of muscles placed on either side of a membranous raphe in the median plane. The

series comprise (1) **extrinsic muscles** arising from the soft palate, styloid process, hyoid bone and mandible, and (2) **intrinsic muscles** proper to the tongue itself. Each set consists of four series of muscles.

A. The **extrinsic muscles** are four in number: (1) genioglossus, (2) hyoglossus, (3) styloglossus, and (4) glossopalatinus.

M. Genioglossus.—The genioglossus muscle (O.T. geniohyoglossus) (Fig. 408, p. 459) is an extrinsic muscle of the tongue as well as a supra-hyoid muscle.

It is a fan-shaped muscle arising by its apex from

the superior of the two mental spines, behind the symphysis of the mandible (Fig. 410, p. 461).

From this origin the muscular fibres diverge; the lowest fibres are directed downwards and backwards, to be inserted into the body of the hyoid bone; the highest fibres curve forwards, to be attached to the tip of the tongue; the intermediate fibres are attached to the substance of the tongue in its whole length between the base and tip.

The muscles of opposite sides are separated by the median raphe of the tongue. On the lateral aspect of each are the hyoglossus and mylo-hyoid muscles.

M. Hyoglossus.—The hyoglossus muscle is also an extrinsic muscle of the tongue as well as a supra-hyoid muscle.

It arises from the body and great cornu of the hyoid bone.

It is directed upwards and forwards, to be inserted into the side of the tongue, its fibres interlacing with the fibres of the styloglossus.

The muscle is quadrilateral, and lies between the genioglossus and mylo-hyoid muscles, separated from the latter by the mucous membrane of the floor of the mouth, the sublingual and part of the submaxillary glands, the lingual and hypoglossal nerves, and the submaxillary duct.

The **chondroglossus** is a small separated slip of the hyoglossus, not always present.

FIG. 411.—A, TRANSVERSE, AND B, LONGITUDINAL VERTICAL SECTIONS THROUGH THE TONGUE (Krause).

M. Styloglossus.—The styloglossus muscle arises from the superior border of the styloid process near its tip, and from the stylo-hyoid ligament.

It sweeps forwards and medially, and is inserted into the side and inferior surface of the tongue, its fibres spreading out to decussate with those of the glossopalatinus and hyoglossus muscles beneath the submaxillary gland and the mucous membrane of the tongue.

M. Glossopalatinus.—The glossopalatinus (O.T. palatoglossus) is a thin sheet of muscular fibres arising from the inferior surface of the soft palate, where it is continuous with fibres of the opposite muscle.

It passes downwards in the glosso-palatine arch, and spreads out, to be inserted into the sides of the tongue, blending with the styloglossus and the deep transverse fibres of the tongue.

The muscle is placed directly beneath the mucous membrane of the soft palate and tongue.

B. Intrinsic Muscles of the Tongue.—Besides receiving the fibres of insertion of the extrinsic muscles, the substance of the tongue is composed of four intrinsic muscles on either side—two in the sagittal plane, the superior and inferior longitudinal muscles; two in the frontal plane, the transverse and vertical muscles.

M. Longitudinalis Superior.—The superior longitudinal muscle extends from base to tip of the tongue. It is placed on its dorsum immediately under the mucous membrane, into which many of its fibres are inserted.

M. Longitudinalis Inferior.—The inferior longitudinal muscle is a cylindrical band of muscular fibres occupying the inferior part of the organ on each side, in the interval between the genioglossus and the hyoglossus muscles. Posteriorly some of its fibres extend to the hyoid bone.

M. Transversus Linguae.—The transversus linguae (O.T. transverse fibres) arises from the median raphe, and radiates outwards to the dorsum and sides of the tongue, intermingling with the extrinsic muscles and the fibres of the vertical muscle. It occupies the substance of the tongue between the superior and inferior longitudinal muscles.

M. Verticalis Linguae.—The verticalis linguae (O.T. vertical fibres) arises from the dorsal surface of the tongue, and sweeps downwards and laterally to its sides, intermingled with the fibres of the preceding muscle and the insertions of the extrinsic muscles. The transverse and vertical muscles form a very considerable part of the total muscular substance of the organ.

Nerve-Supply.—All these muscles except the glossopalatinus are supplied by the hypoglossal nerve. The glossopalatinus is supplied by the accessory nerve through the pharyngeal plexus.

Actions.—The genioglossus and the hyoglossus are both elevators of the hyoid bone besides having actions in relation to the tongue. The tongue is protruded by the action of the posterior fibres of the genioglossus, retracted by the anterior fibres aided by the styloglossus. The styloglossus and glossopalatinus are elevators, while the genioglossus and hyoglossus are depressors of the tongue.

Actions of the Infra-hyoid and Supra-hyoid Muscles, and the Muscles of the Tongue.—These muscles have a complexity of action, owing to their numerous attachments to more or less movable points. The movements for which they are responsible in whole or part are: (1) movements of the hyoid bone in mastication and deglutition, (2) movements of the thyroid cartilage, (3) movements of the tongue, (4) movements of the head, (5) movements of the shoulder, and (6) respiration.

(1) **Movements of the Hyoid Bone.**—The hyoid bone is elevated or depressed, and moved forwards or backwards along with the mandible and tongue, in speech, mastication, and swallowing.

a. Elevation.	Depression.	b. Protraction.	Retraction.
Digastric	Thyreo-hyoid	Genio-hyoid	Stylo-hyoid
Stylo-hyoid	Sterno-hyoid	Genioglossus	Middle constrictor
Mylo-hyoid	Omo-hyoid		
Genio-hyoid	Sterno-thyreoid		
Genioglossus			
Hyoglossus			
Muscles closing the mouth			

(2) **Movements of the Thyreoid Cartilage.**—The thyreoid cartilage is raised and lowered during speech and deglutition.

Elevation.	Depression.
Thyreo-hyoid Stylopharyngeus Pharyngopalatinus Elevators of hyoid bone Muscles closing mouth	Sterno-thyreoid Crico-thyreoid Depressors of hyoid bone

(3) **Movements of the Tongue.**—The chief movements of the tongue in speech and deglutition are elevation and depression, protrusion and retraction, and lateral movements.

a. Elevation.	Depression.
Styloglossus (base) Glossopalatinus Muscles elevating hyoid bone Muscles closing mouth	Genioglossus Hyoglossus Chondroglossus Muscles depressing the hyoid bone
b. Protrusion.	Retraction.
Genioglossus (<i>posterior fibres</i>)	Genioglossus (<i>anterior fibres</i>) Styloglossus
c. Lateral Movements.—The muscles of one side only.	

(4) **Movements of the Head.**—The sterno-mastoid muscles, acting together, flex the head on the vertebral column, assisted by the supra-hyoid and infra-hyoid muscles. The sterno-mastoid muscle of one side, acting alone, bends the head to the same side, and simultaneously rotates it to the opposite side, as seen in *torticollis* (wryneck).

(5) **Movements of the Shoulder Girdle.**—The omo-hyoid and sterno-mastoid muscles have already been included among the elevators of the shoulder girdle.

(6) **Respiration.**—The muscles in the front of the neck are auxiliary muscles in extraordinary or difficult inspiration. The masseter and temporal muscles fix the mandible; the hyoid bone is raised and fixed by the supra-hyoid muscles; and the sternum is raised by the sterno-mastoid and infra-hyoid muscles.

The Muscles of the Pharynx.

The muscular envelope of the pharynx is composed of two strata. The *external* or *circular layer* consists of the three fan-shaped constrictor muscles; the *internal* or *longitudinal layer* consists of the fibres of the stylopharyngeus and pharyngopalatinus muscles.

M. Constrictor Pharyngis Superior.—The superior constrictor muscle arises successively from the inferior half of the posterior border of the medial lamina of the pterygoid process (**pterygopharyngeus**), from the pterygo-mandibular raphe (**buccopharyngeus**), from the mylo-hyoid line of the mandible (**mylopharyngeus**) (Fig. 410, p. 461), and from the mucous membrane of the floor of the mouth (**glossopharyngeus**).

The muscular fibres radiate backwards, and are inserted for the most part into a raphe extending down the posterior wall of the pharynx in the median plane. The highest fibres are attached to the pharyngeal tubercle of the occipital bone (Fig. 396, p. 444), and the lowest fibres are overlapped by the middle constrictor. A crescentic interval occurs above the muscle, below the base of the skull, in which the auditory tube and the levator and tensor veli palatini muscles appear. Its lower border is separated from the middle constrictor by the stylopharyngeus muscle.

M. Constrictor Pharyngis Medius.—The middle constrictor muscle arises from the stylo-hyoid ligament and from both cornua of the hyoid bone (**chondropharyngeus**, **ceratopharyngeus**).

From its origin the muscular fibres radiate backwards, to be inserted into the median raphe on the posterior aspect of the pharynx.

The superior fibres overlap the inferior part of the superior constrictor; the inferior fibres are concealed from view by the inferior constrictor muscle. In the interval between the middle and inferior constrictors are found the superior laryngeal artery and internal laryngeal nerve.

M. Constrictor Pharyngis Inferior.—The inferior constrictor muscle arises from the oblique line of the thyroid cartilage (**thyreopharyngeus**), and from the side of the cricoid cartilage (**cricopharyngeus**).

Its fibres radiate backwards, to be inserted into the median *raphe* on the posterior wall of the pharynx, the superior fibres overlapping the inferior part of the middle constrictor, the inferior fibres blending with the muscular fibres of the oesophagus. Below the inferior border of the muscle the inferior laryngeal artery and nerve enter into relation with the larynx.

Nerve-Supply.—The constrictors of the pharynx receive their nerve-supply through the pharyngeal plexus from the accessory nerve. The inferior constrictor is supplied also by the external laryngeal and recurrent branches of the vagus nerve.

The deeper longitudinal stratum of muscles in the pharyngeal wall is composed of the insertions of the stylopharyngeus and pharyngopalatinus muscles.

M. Stylopharyngeus.—The **stylopharyngeus** arises from the root of the styloid process on its medial side, and passes downwards between the external and internal carotid arteries. It enters the wall of the pharynx in the interval between the superior and middle constrictor muscles.

Spreading out beneath the middle constrictor muscle, it is inserted into the superior and posterior borders of the thyroid cartilage and into the wall of the pharynx itself, becoming continuous posteriorly with the palatopharyngeus. In the neck the glossopharyngeal nerve winds round it on its way to the tongue.

Nerve-Supply.—Glossopharyngeal nerve.

M. Pharyngopalatinus.—The **pharyngopalatinus** (O.T. **palatopharyngeus**) occupies the soft palate and the pharyngeal wall. In the substance of the soft palate it consists of *two layers*, a postero-superior layer, thin, and continuous across the median plane with the corresponding layer on the opposite side, and an antero-inferior layer, which is thicker, and is attached to the posterior border of the hard palate. The levator veli palatini and the musculus uvulæ are enclosed between the two layers, which unite at the posterior edge of the palate, receiving at the same time additional fibres arising from the auditory tube (**salpingopharyngeus**). The muscle descends to the pharynx in the pharyngo-palatine arch.

Its fibres spread out in the form of a thin sheet in the wall of the pharynx, in continuity anteriorly with the stylopharyngeus, and are inserted into the posterior border of the thyroid cartilage, and behind that into the aponeurosis of the pharynx, reaching down as far as the inferior border of the inferior constrictor. The muscle is placed beneath the middle and inferior constrictors, and the fibres

FIG. 412.—POSTERIOR VIEW OF THE PHARYNX AND CONSTRICTOR MUSCLES.

of the muscles of opposite sides decussate in the median plane, in the inferior part of the pharyngeal wall.

Nerve-Supply.—The muscle is innervated through the pharyngeal plexus, by the accessory nerve.

The Muscles of the Soft Palate.

The soft palate and uvula form a muscular fold, covered on each surface by mucous membrane, projecting backwards into the pharynx, and forming the posterior parts of the floor of the nasal cavities and the roof of the mouth.

The muscular fold is composed of five pairs of muscles—the pharyngopalatinus, m. uvulæ, levator veli palatini, tensor veli palatini, and glossopalatinus.

The **pharyngopalatinus** muscle has been already described (p. 465).

The **m. uvulæ** (O.T. **azygos uvulæ**) consists of two narrow bundles enclosed, along with the insertion of the levator veli palatini, between the layers of the pharyngopalatinus. The slips arise from the posterior nasal spine and the aponeurosis of the soft palate, and unite as they proceed backwards to end in the uvula.

M. Levator Veli Palatini.—The **levator veli palatini** has a double origin: (1) from the inferior surface of the apex of the petrous portion of the tem-

FIG. 413.—LATERAL VIEW OF THE WALL OF THE PHARYNX.

poral bone, and (2) from the inferior part of the cartilaginous part of the auditory tube. It passes obliquely downwards and medially, across the superior border of the superior constrictor muscle, and enters the soft palate between the two layers of the pharyngopalatinus muscle.

It is inserted into the aponeurosis of the soft palate, and some of its fibres become continuous with those of the opposite muscle.

It is separated from the tensor veli palatini muscle by the auditory tube and the deeper layer of the pharyngopalatinus muscle.

M. Tensor Veli Palatini.—The **tensor veli palatini** arises (1) from the scaphoid fossa and the angular spine of the sphenoid bone, and (2) from the lateral side of the cartilaginous part of the auditory tube.

It descends between the internal pterygoid muscle and the medial pterygoid lamina and ends in a tendon which hooks round the pterygoid hamulus, and is inserted beneath the levator veli palatini into the posterior border of the hard palate, and into the aponeurosis of the soft palate.

M. Glossopalatinus.—The **glossopalatinus** (O.T. **palatoglossus**), occupying the inferior surface of the soft palate and the glosso-palatine arch, has already been described with the muscles of the tongue (p. 463).

Nerve-Supply.—The muscles of the soft palate (except the tensor veli palatini, which is innervated through the otic ganglion by the trigeminal nerve) are supplied through the pharyngeal plexus by the accessory nerve.

Actions of the Muscles of the Pharynx and Soft Palate.—The muscles of the pharynx and soft palate are chiefly brought into action in the act of swallowing. This act is divided into a *voluntary stage*, in which the bolus lies anterior to the arches of the fauces, and an *involuntary stage*, during which the food passes from the mouth through the pharynx. The movements occurring during the passage of food through the mouth are as follows: the cheeks are compressed by the action of the buccinator muscles; the tongue, hyoid bone, and thyreoid cartilage are successively raised upwards by the action of the muscles which close the mouth and elevate the hyoid bone. By these means the food is pushed backwards between the palatine arches.

At the same time, by the contraction of the glosso-palatinus and pharyngo-palatinus, the palatine arches of the fauces are narrowed, while the muscles of the soft palate, contracting, tighten the soft palate, and by bringing it in contact with the posterior wall of the pharynx, shut off the nasal portion of the cavity. The elevation of the tongue, hyoid bone, and larynx simultaneously causes the elevation of the epiglottis and the superior aperture of the larynx, which is closed by the approximation of the arytenoid cartilages and the combined action of laryngeal muscles (arytænoides, thyreoarytænoides, and thyreoepiglotticus). The food thus slips over the posterior surface of the epiglottis and the closed superior aperture of the larynx, and between the palatine arches on either side, into the pharynx. It is now clasped by the constrictor muscles, which, by their contractions, force it down into the œsophagus. The contraction of the constrictor muscles results in a flattening of the pharynx and elevation of its anterior attachments.

During the act of swallowing, it is generally thought that the auditory tube is opened by the contraction of the tensor veli palatini muscle, which arises from it. It has been held, on the other hand, that the auditory tube is closed during swallowing by the compression of its wall by the contraction of the levator veli palatini.

Deep Lateral and Prævertebral Muscles of the Neck.

Three series of muscles are comprised in this group: (1) vertebro-costal (scaleni, anterior, medius, and posterior), (2) vertebro-cranial (longus capitis and rectus capitis anterior, and lateralis), and (3) vertebral (longus colli). They clothe the anterior surface of the cervical portion of the vertebral column for the most part, and are in relation anteriorly with the pharynx and œsophagus, and the large vessels and nerves of the neck.

M. Scalenus Anterior.—The **scalenus anterior** (O.T. **anticus**) arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebrae.

It descends posterior to the carotid sheath and subclavian vein, to be inserted into the scalene tubercle and ridge on the first rib (Fig. 414, p. 468).

It is separated posteriorly from the scalenus medius by the roots of the brachial plexus, the subclavian artery, and the pleura, and it is concealed by the sternomastoid muscle.

M. Scalenus Medius.—The **scalenus medius** arises from the posterior tubercles of the transverse processes of the cervical vertebrae, from the second to the sixth inclusive.

It descends in the posterior triangle behind the subclavian artery and the roots of the brachial plexus, to be inserted into the rough impression on the first rib behind the subclavian groove (Fig. 414, p. 468). The muscle is pierced by the dorsal scapular and long thoracic nerves.

It is separated from the scalenus anterior by the subclavian artery and the roots of the brachial plexus.

M. Scalenus Posterior.—The **scalenus posterior** arises behind the scalenus medius from the posterior tubercles of the fourth, fifth, and sixth cervical transverse processes. It is inserted into an impression on the lateral side of the second rib.

FIG. 414.—MUSCLE-ATTACHMENTS TO THE SUPERIOR SURFACE OF THE FIRST RIB, AND THE EXTERNAL SURFACE OF THE SECOND RIB (RIGHT SIDE). A, First rib; B, Second rib.

Nerve-Supply.—The muscle receives nerves directly from the anterior rami of the first four cervical nerves.

Action.—Flexion of the head and cervical vertebræ.

M. Rectus Capitis Anterior.—The *rectus capitis anterior* (O.T. *rectus capitis anticus minor*) arises, under cover of the preceding muscle, from the lateral mass of the atlas. It is inserted into the basilar part of occipital bone between the preceding muscle and the occipital condyle (Fig. 417, p. 469).

Nerve-Supply.—The muscle is innervated by the loop between the first two cervical nerves (anterior rami).

Action.—Flexion of the head on the vertebral column.

M. Longus Colli.—The *longus colli* is a flattened muscular band extending from the third thoracic vertebra to the atlas. It

Nerve-Supply.—The scalene muscles are supplied by branches which arise directly from the anterior rami of the lowest four or five cervical nerves.

Actions.—The actions of those muscles are twofold. They are lateral flexors of the vertebral column, and are also important muscles of respiration, as elevators of the first and second ribs.

M. Longus Capitis.—The *longus capitis* (O.T. *rectus capitis anticus major*) arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ.

It forms a flat triangular muscle, which is directed upwards alongside the *longus colli* muscle and behind the carotid sheath, to be inserted into an impression on the inferior surface of the basilar part of the occipital bone, anterior and lateral to the pharyngeal tubercle (Fig. 417, p. 469).

FIG. 415.—THE PRAEVERTEBRAL MUSCLES OF THE NECK.

is divisible into three portions—a vertical, an inferior oblique, and a superior oblique portion.

FIG. 416.—SCHEME OF MUSCULAR ATTACHMENTS TO CERVICAL VERTEBRÆ.

The **vertical portion** of the muscle arises from the bodies of the first three thoracic and the last three cervical vertebræ.

Passing vertically upwards, it is **inserted** into the bodies of the second, third, and fourth cervical vertebræ.

FIG. 417.—MUSCLE-ATTACHMENTS TO THE OCCIPITAL BONE.

The **inferior oblique portion** arises from the bodies of the first three thoracic vertebræ.

It is **inserted** into the anterior tubercles of the fifth and sixth cervical vertebræ.

The superior oblique portion arises from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebræ.

It is directed upwards, to be inserted into the anterior tubercle of the atlas.

Nerve-Supply.—It is supplied by nerves from the anterior rami of the second, third, and fourth cervical nerves.

Action.—A flexor of the vertebral column.

M. Rectus Capitis Lateralis.—The *rectus capitis lateralis*, in series with the posterior inter-transverse muscles in the neck, arises from the transverse process of the atlas.

It is inserted into the inferior surface of the jugular process of the occipital bone. It is placed alongside the *rectus capitis anterior*, separated from it by the anterior ramus of the first cervical nerve.

Nerve-Supply.—The loop between the anterior rami of the first two cervical nerves.

Actions.—A lateral flexor of the head and vertebral column. The movements produced by these muscles are considered along with those of other muscles acting on the head, vertebral column, and thorax (pp. 445, 446).

THE MUSCLES OF THE THORAX.

Muscles of Respiration.

The muscles which complete the boundaries of the thorax are the diaphragm and intercostal muscles (external and internal), along with three series of smaller muscles—the *transversus thoracis*, the *levator costarum*, and the *subcostal* muscles.

Mm. Intercostales.—The intercostal muscles are arranged in eleven pairs, which occupy the intercostal spaces.

Each external muscle arises from the sharp lower border of a rib, and is directed inferiorly and anteriorly, to be inserted into the external edge of the superior border of the rib below. It extends from the tubercle of the rib posteriorly nearly to the costal cartilage anteriorly. The *anterior intercostal aponeurosis* is continuous with it anteriorly, and extends forwards to the side of the sternum.

Each internal muscle arises from the costal cartilage and the internal or superior edge of the costal groove, and is directed inferiorly and posteriorly, to be inserted into the internal edge of the superior border of the rib and costal cartilage below. It extends from the side of the sternum anteriorly to the angle of the rib posteriorly, where it is replaced by the *posterior intercostal aponeurosis* extending to the tubercle of the rib.

The superficial surface of the external muscle is covered by the muscles of the chest, axilla, abdomen, and back. The deep surface of the internal muscle is in contact with the pleura.

Mm. Levatores Costarum.—The *levator costarum* are in series with the external intercostal muscles. They are twelve small slips arising from the transverse processes of the seventh cervical and upper eleven thoracic vertebræ. They spread out in a fan-like manner as they descend, to be inserted into the lateral surface of each of the ribs, posterior to the angles.

Mm. Subcostales.—The *subcostal* muscles are slips of muscles found on the internal surface of the lower ribs near their angles. They are in series with the internal intercostal muscles, but pass over the deep surface of several ribs.

M. Transversus Thoracis.—The *transversus thoracis* (O.T. *triangularis sterni*) occupies the posterior aspect of the anterior thoracic wall, and is separated from the costal cartilages by the internal mammary vessels. It arises from the posterior surface of the xiphoid process and body of the sternum as high as the level of the third costal cartilage.

From this origin its fibres radiate laterally, the lower horizontally, the upper fibres obliquely upwards, to be inserted into the second, third, fourth, fifth, and sixth costal cartilages. The muscle is continuous below with the *transversus abdominis*.

Diaphragma.—The diaphragm is the great membranous and muscular partition separating the cavities of the thorax and abdomen. It forms a thin lamella arching over the abdominal cavity, and clothed on this surface for the most part by peritoneum. It is related on its inferior concave surface to the liver, stomach, and spleen, the kidneys and suprarenal glands, and the duodenum and pancreas. Its superior convex surface projects into the thoracic cavity, rising higher on the right than on the left side, and is related to the pericardium and pleuræ, and along its margin to the chest wall. The œsophagus and thoracic aorta are in contact with it posteriorly.

It possesses a peripheral origin from the sternum, ribs, and vertebral column,

FIG. 418.—THE MUSCLES OF THE RIGHT SIDE OF THE THORACIC WALL.

and an insertion into a central tendon. It arises (1) *anteriorly* (*pars sternalis*) from the posterior surface of the xiphoid process by two slender fleshy slips, directed backwards; (2) *laterally* (*pars costalis*), from the deep surface of the lower six costal cartilages on each side by fleshy bands which interdigitate with those of the transversus abdominis; (3) *posteriorly* (*pars lumbalis*), from the lumbar vertebræ, by the crura, and the medial and lateral lumbo-costal arches. The *crura* are two elongated fibro-muscular bundles which arise on each side of the aorta from the anterior surface of the bodies of the lumbar vertebræ, on the right side from the first three, on the left side from the first two lumbar vertebræ. They are directed upwards and decussate across the median plane in front of the aorta, the fibres of the right crus passing anterior to those of the left crus. The fibres then encircle the œsophagus, forming an elliptical opening for its passage, and finally join the central tendon, after a second decussation anterior to the gullet.

The medial part of each crus is wholly tendinous and is sometimes called the *crus mediale*; it is connected with its fellow of the opposite side by a tendinous band called the **middle arcuate ligament**, which arches between them, in front of the aorta, and gives origin to fibres which join the crura as they decussate to encircle the gullet. The most outlying part of the crus is sometimes called the *crus laterale*; its infero-lateral margin is continuous with the medial lumbo-costal arch. The intermediate part of the crus is the *crus intermedium*; the splanchnic nerves pierce the diaphragm between it and the medial crus. The sympathetic trunk sometimes pierces the diaphragm between the intermediate and lateral crura.

The **arcus lumbo-costalis medialis** (O.T. **internal arcuate ligament**) is a thickening formed by the attachment of the psoas fascia to the body of the first lumbar vertebra medially and its transverse process laterally. Stretching across the superior end of the psoas muscle, the ligament gives origin to muscular fibres which join the fibres of the crus.

The **arcus lumbo-costalis lateralis** (O.T. **external arcuate ligament**) is the thickened superior border of the fascia over the quadratus lumborum muscle

FIG. 419.—THE DIAPHRAGM (from below).

and is attached medially to the transverse process of the first lumbar vertebra, and laterally to the last rib. It gives origin to a broad band of muscular fibres, separated by an interval from the fibres arising from the medial lumbo-costal arch which sweep upwards to the central tendon.

From this extensive origin the muscular fibres of the diaphragm converge to an **insertion** into a large trilobed **central tendon** called the **centrum tendineum**. Of its lobes the right one is the largest, the middle or anterior is intermediate in size, and the left is the smallest. It does not occupy the centre of the muscle, being placed nearer the front than the back. The fibres of the crura are consequently the longest; those from the xiphoid process are the shortest.

The diaphragm is pierced by numerous structures. The superior epigastric artery enters the sheath of the rectus abdominis between its sternal and costal origins; the musculo-phrenic artery passes between its attachments to the seventh and eighth ribs. The sympathetic trunk and the splanchnic nerves pierce, or pass posterior to the diaphragm; the last thoracic nerve passes beneath the lateral lumbo-costal arch; and the aorta, the azygos vein, and thoracic duct pass between the crura, underneath the middle arcuate ligament (*hiatus aorticus* or *aortic opening*). The special foramina are two in number. The *foramen vena cavae* (O.T. *foramen*

quadratum) in the right lobe of the central tendon transmits the inferior vena cava, and small branches of the right phrenic nerve. The *hiatus œsophageus* (*œsophageal opening*) is in the muscular substance of the diaphragm, posterior to the central tendon, and is surrounded by a sphincter-like arrangement of the crural fibres. Besides the œsophagus, this opening transmits the two vagi nerves.

Middle arcuate ligament

FIG. 420.—THE DIAPHRAGM AND POSTERIOR ABDOMINAL WALL.

The diaphragm is found as a complete septum between the thorax and abdomen only in mammals. It is occasionally deficient in the human subject, producing *hernia of the diaphragm*, either into the pericardial cavity through the central tendon, or into the pleural cavity through the lateral portions of the muscle. A rare condition is congenital deficiency of a part of the lateral half of the muscle, generally placed posteriorly, and on the left side. This produces, by continuity of the pleural and peritoneal cavities behind the diaphragm, a *congenital diaphragmatic hernia*.

Nerve-Supply.—The intercostal muscles, levatores costarum, subcostal muscles, and transversus thoracis, are all supplied by the anterior rami of the thoracic nerves. The diaphragm receives its chief, if not its entire, motor supply from the phrenic nerves (C. 3. 4. 5.). It is innervated also by the diaphragmatic plexus of the sympathetic, and is sometimes said to receive fibres from the lower thoracic nerves.

Actions.—The act of respiration consists of two opposite movements—inspiration and expiration.

1. The **movement of expiration** is performed by (1) the elasticity of the lungs, (2) the weight of the chest walls, (3) the elevation of the diaphragm, (4) the action of muscles—transversus thoracis and muscles of the abdominal wall. It is sometimes stated that the interosseous fibres of the internal intercostal muscles are depressors of the ribs.

2. The **movement of inspiration** results in the enlargement of the thoracic cavity in all its diameters. Its antero-posterior and transverse diameters are increased by the elevation and forward movement of the sternum, and by the elevation and eversion of the ribs, while its vertical diameter is increased by the descent of the diaphragm.

The muscles of inspiration are divided into two series—ordinary and accessory.

a. Ordinary Muscles.	b. Extraordinary and Accessory Muscles.
Diaphragm Intercostals Scaleni Serrati posteriores Levatores costarum Subcostales	Quadratus lumborum Pectorales Serratus anterior Sterno-mastoid Latissimus dorsi Infra-hyoid muscles Extensors of the vertebral column

Of the ordinary muscles the diaphragm is the most important. Its action is twofold—centrifugal, elevating the ribs and increasing the transverse and antero-posterior diameters of the thorax, and centripetal, drawing downwards the central tendon and increasing the vertical diameter of the thorax. Of the two movements the former is the more important. There has been considerable diversity of opinion regarding the action of the intercostal muscles. It is generally agreed that the external muscles elevate the ribs; it is probable that the whole of each internal muscle acts in the same way, although it has been stated by different observers that the whole internal muscle is a depressor; or that the interosseous part is a depressor, the interchondral portion of the muscle an elevator of the ribs.

FASCIÆ AND MUSCLES OF THE ABDOMINAL WALL.

The space between the base of the bony thorax and the pelvis is filled up by a series of muscular sheets, covered externally and internally by fasciæ.

FASCIÆ.

The fasciæ of the abdominal wall are—*externally*, the superficial and deep fasciæ; *internally*, the fascia transversalis, which clothes the interior of the abdominal cavity, and is continuous with the diaphragmatic, lumbo-dorsal, psoas, iliac, and pelvic fasciæ, and is lined within by the subserous coat of extra-peritoneal tissue.

The **superficial fascia** of the abdomen is liable to contain a large quantity of fat. In the groin it is separated into *two layers*: a superficial fatty layer continuous over the inguinal ligament with the fascia of the anterior surface of the thigh (p. 402), and a deeper membranous layer attached to the medial half of the inguinal ligament, and more laterally to the fascia lata of the thigh distal to the inguinal ligament. The two layers are separated by the lymph glands and the superficial vessels of the groin. Higher up in the abdominal wall the two layers blend together. Passing downwards over the spermatic funiculus, they unite to form the fascia and dartos muscle of the scrotum. The attachment of the fascia to the groin prevents the passage into the thigh of fluid extravasated in the abdominal wall.

The **deep fascia** of the abdominal wall resembles similar fasciæ in other situations. It forms an investment for the obliquus externus muscle, and becomes thin and almost imperceptible in relation to the aponeurosis of that muscle.

Fascia Transversalis.—The fascial lining of the abdominal cavity (*fascia transversalis*) consists of a continuous layer of membrane which receives different names in different parts of its extent. It covers the deep surface of the transversus muscle, and is continuous medially with the fasciæ of the quadratus lumborum and the psoas muscles. It is continuous above with the diaphragmatic fascia, and below the iliac crest and the inguinal ligament with the fascia iliaca. Along with the last-named fascia it forms the **femoral sheath**, enclosing the femoral vessels and the femoral canal in their passage to the thigh behind the medial part of the inguinal ligament (p. 405). It is pierced by the spermatic funiculus or

FIG. 421.—SUPERFICIAL ANATOMY OF THE GROIN.

round ligament of the uterus at the abdominal inguinal ring, and its prolongation into the inguinal canal around the funiculus forms the **internal spermatic** or **infundibuliform fascia**. It is lined internally by the peritoneum, from which it is separated by a layer of **extraperitoneal tissue**.

The subserous coat or **extraperitoneal tissue** is usually loaded with fat; it envelops the kidneys, ureters, suprarenal glands, abdominal aorta and inferior vena cava and their branches, and forms sheaths for the vessels and ducts (ureter, ductus deferens, etc.). It is continued upwards into the posterior mediastinum of the thorax through the aortic opening in the diaphragm, and below is in continuity with the extraperitoneal tissue in the pelvis. It not only completely invests the kidneys and suprarenal glands, but it also becomes interpolated between the layers of peritoneum upholding and enveloping the intestines. This tissue is absent in relation to the diaphragm, on the under surface of which there is no fat.

THE MUSCLES OF THE ABDOMINAL WALL.

The muscles of the abdominal wall are in three series—lateral, anterior, and posterior.

The lateral muscles of the abdominal wall comprise the obliquus externus abdominis, obliquus internus abdominis, and transversus abdominis.

M. Obliquus Externus Abdominis.—The obliquus externus abdominis is a broad thin sheet of muscle, with an origin from the lateral surfaces of the lower eight ribs, by slips which interdigitate with the serratus anterior and latissimus

FIG. 422.—THE DISSECTION OF THE INGUINAL CANAL.

dorsi muscles. The muscular fibres radiate downwards and forwards, the lowest fibres passing vertically downwards.

The lower and posterior part of the muscle is inserted directly by fleshy fibres into the external lip of the iliac crest in its anterior half or two-thirds (Fig. 369, p. 415). The rest of the muscle is inserted into an extensive triangular aponeurosis covering the anterior abdominal wall. This aponeurosis is broader below than above; it is united with part of the aponeurosis of the obliquus internus in the superior three-fourths of its extent, to form the anterior layer of the sheath of the rectus muscle. It thus gains an attachment, above to the xiphoid process, below to the symphysis pubis, and by its intermediate fibres to the linea alba, a broad interlacing band of fibres about half an inch in width which occupies the median plane of the anterior abdominal wall in its whole extent, is pierced by the umbilicus (annulus umbilicalis), and forms the greater part of the ultimate insertion of all the lateral abdominal muscles.

The superior part of the aponeurosis covers the insertion of the rectus abdominis muscle on the chest wall, and gives origin to fibres of the pectoralis major. Inferiorly, in the groin, it gives rise to the inguinal ligament, the ligamentum lacunare, the subcutaneous inguinal ring with its two crura, the intercolumnar fascia and the intercrural fibres, and the ligamentum inguinale reflexum of Colles.

Lig. Inguinale [Poupart].—The inguinal ligament (O.T. Poupart's ligament) is an aponeurotic band which extends from the anterior superior iliac spine to the tubercle of the pubis, arching over the iliacus, psoas, and pectineus muscles. It represents the inferior limit of the aponeurosis of the obliquus externus abdominis, and it gives attachment below to the iliac portion of the fascia lata of the thigh. Its lateral part affords partial origin to the obliquus internus and transversus muscles, and receives the attachment of the fascia transversalis and fascia iliaca; the medial part forms the gutter-like floor of the inguinal canal. At its medial end a triangular band of fibres is reflected horizontally backwards to the ilio-pectineal line, forming the **lig. lacunare [Gimbernati]** (O.T. Gimbernati's ligament), the lateral edge of which forms the medial boundary of the femoral ring. The femoral vessels enclosed in the femoral sheath enter the thigh posterior to the inguinal ligament (on the anterior surface of the psoas major muscle, and the term *superficial femoral arch* is given to the part of the ligament which covers the vessels.

FIG. 423.—TRANSVERSE SECTION THROUGH THE ABDOMEN, OPPOSITE THE SECOND LUMBAR VERTEBRA.

Annulus Inguinalis Subcutaneus.

The subcutaneous inguinal ring (O.T. external abdominal ring), the place of exit of an inguinal hernia, is a split in the aponeurosis of the obliquus externus, just above the tubercle of the pubis. It transmits the spermatic funiculus, or (in the female) the round ligament of the uterus, covered by the cremaster muscle or cremasteric fascia. The opening is of considerable extent, and its edges are drawn together by a thin fascia, strengthened superficially by a number of arched and horizontal fibres, called the **intercrural fibres**, which arise from the inguinal ligament and sweep medially across the cleft in the aponeurosis.

The margins of the ring constitute its crura. The **inferior crus** is narrow, and is formed from that part of the aponeurosis which joins the pubic tubercle, and is continuous with the medial end of the inguinal ligament. The **superior crus** is the part of the aponeurosis medial to the ring which is attached to the crest and symphysis of the pubis. It is flat and broad.

The intercrural fibres and the crura of the subcutaneous inguinal ring are continuous with a thin tubular sheath, the **intercolumnar** or **external spermatic fascia**, which is attached to the margins of the "ring," and forms an envelope for the

spermatic funiculus or round ligament in their further passage beyond the abdominal wall.

Lig. Inguinale Reflexum Collesi.—The reflexed inguinal ligament of Colles (O.T. triangular fascia), lastly, is a triangular band of fibres placed behind the medial superior crus of the subcutaneous inguinal ring. It consists of fibres from the

FIG. 424.—THE LEFT OBLIQUUS EXTERNUS ABDOMINIS.

opposite external oblique aponeurosis, which, having traversed the linea alba, gain an insertion into the crest and tubercle of the pubis.

The obliquus externus muscle is superficial in almost its whole extent. It is overlapped posteriorly by the latissimus dorsi muscle, but may be separated from it just above the iliac crest by an angular interval (*trigonum lumbale* or triangle of Petit).

M. Obliquus Internus Abdominis.—The obliquus internus abdominis, a broad thin sheet lying between the obliquus externus and the transversus, arises from

(1) the lumbo-dorsal fascia, (2) the anterior two-thirds of the iliac crest, and (3) the lateral half of the inguinal ligament.

Directed for the most part upwards and forwards, its highest fibres are inserted directly into the last three ribs. The rest of the fibres form an extensive aponeurosis, broader above than below, which splits along the *linea semilunaris*, to form, along with the aponeuroses of the obliquus externus and transversus muscles, the

FIG. 425.—THE RIGHT OBLIQUUS INTERNUS ABDOMINIS.

sheath of the rectus abdominis, and is inserted into the seventh, eighth, and ninth costal cartilages, and into the linea alba from the xiphoid process to the symphysis pubis. The fibres arising from the inguinal ligament join with those of the transversus muscle having a similar origin to form the *falx aponeurotica inguinalis* (O.T. conjoined tendon), which passes altogether anterior to the rectus muscle, to be attached to the pubic crest and tubercle, and to the ilio-pectineal line.

The obliquus internus is limited above by the inferior margin of the thorax.

Its lower fibres, arching over the spermatic cord, assist in forming, laterally, the anterior wall of the inguinal canal; medially, by means of the *falx inguinalis*, it helps to form the posterior wall of the canal.

Its lowest fibres are continued into the **cremaster muscle**, which is prolonged along the spermatic cord through the inguinal canal.

M. Cremaster.—The **cremaster muscle** forms an investment for the testis and spermatic funiculus beneath the intercolumnar fascia. In the female it is more largely represented by fascia than muscular fibres, and constitutes the **cremasteric fascia**. It may be said to have an **origin** from the inferior edge of the obliquus internus and the adjacent

FIG. 426.—THE LEFT INGUINAL CANAL. STRUCTURES SEEN ON REFLECTION OF THE OBLIQUUS EXTERNUS.

part of the inguinal ligament. Its fibres form loops over the spermatic funiculus and testis, the highest fibres getting an **insertion** into the pubic tubercle.

M. Transversus Abdominis.—The **transversus abdominis muscle** arises (1) from the deep surface of the costal cartilages of the lower six ribs, interdigitating with the origins of the diaphragm; (2) from the lumbo-dorsal fascia; (3) from the anterior half of the medial lip of the iliac crest; and (4) from the lateral third of the inguinal ligament.

The muscular fibres are directed for the most part horizontally forwards, and end in an aponeurosis which has a twofold **insertion**. (1) After forming (along with the aponeurosis of the obliquus internus) the posterior layer of the sheath of the rectus, the aponeurosis is attached to the xiphoid process and linea alba. (2) The inferior fibres of the muscle arising from the inguinal ligament are joined by the inferior part of the obliquus internus to form the larger part of the *falx*

aponeurotica inguinalis (O.T. conjoined tendon), which passes anterior to the inferior part of the rectus muscle, to be inserted into the crest and tubercle of the pubis and the ilio-pectineal line.

The transversus muscle is separated by the lower intercostal nerves from the obliquus internus muscle, and is lined on its deep surface by the fascia transversalis. Its inferior border forms a concave edge, separated from the inguinal ligament by a lunular interval in which the fascia transversalis appears, and through which the spermatic funiculus emerges at the abdominal inguinal ring, under cover of the obliquus internus muscle and the aponeurosis of the obliquus externus.

FIG. 427.—THE DISSECTION OF THE INGUINAL CANAL.

The anterior muscles of the abdominal wall include the pyramidalis and rectus abdominis, enveloped by the sheath of the rectus, on either side of the linea alba.

M. Pyramidalis Abdominis.—The *pyramidalis abdominis* is a small triangular muscle arising from the pubic crest, anterior to the rectus muscle (Fig. 428, p. 482).

It is directed obliquely upwards, to be inserted for a variable distance into the linea alba. The muscle is often absent.

M. Rectus Abdominis.—The *rectus abdominis muscle* is broad and strap-like, and arises, by a medial and a lateral head, from the symphysis and crest of the pubis (Fig. 428, p. 482).

Expanding as it passes upwards, the muscle is inserted, from medial to lateral side into the anterior surface of the xiphoid process (Fig. 428, p. 482), and into the superficial surface of the seventh, sixth, and fifth costal cartilages. On its anterior

surface, but not extending through the entire substance of the muscle, are three or more transverse tendinous intersections (*inscriptiones tendineæ*), adherent to the sheath of the muscle; the lowest opposite the umbilicus, and the highest about the level of the xiphoid process. The medial border of the muscle lies alongside the *linea alba*; its lateral border is convex, and corresponds to the *linea semilunaris*. The muscle is pierced by the terminal branches of the lower thoracic nerves.

FIG. 428.—DEEP DISSECTION OF THE ABDOMINAL WALL. THE RECTUS MUSCLE AND ITS SHEATH.

Vagina M. Recti Abdominis.—The sheath of the rectus muscle is derived from the aponeuroses of the lateral muscles of the abdominal wall, which, after enclosing the muscle, give rise, in the median plane, to the *linea alba*. At the *linea semilunaris* along the lateral border of the rectus muscle, the aponeurosis of the obliquus internus splits into anterior and posterior layers. The anterior layer, joined by the aponeurosis of the obliquus externus, passes in front of the rectus, and constitutes the anterior lamina of the sheath. The posterior layer, joined by

the aponeurosis of the transversus muscle, passes behind the rectus, and constitutes the posterior lamina of its sheath. This arrangement obtains in the superior three-fourths of the abdominal wall. Below the level of the iliac crest the sheath of the muscle is deficient posteriorly, and a crescentic border, the *linea semicircularis* (semilunar fold of Douglas), marks the inferior limit of the posterior lamina. In consequence, the rectus in the lower fourth of the abdominal wall rests directly upon the fascia transversalis. Close examination, however, usually reveals a thin layer behind the muscle in continuity with the fold of Douglas, and merging below with the fascia transversalis. In this region the rectus is covered anteriorly by the *falx aponeurotica inguinalis* of the obliquus internus and transversus, and by the aponeurosis of the obliquus externus, which gradually separates from the subjacent aponeurosis. The superior part of the rectus, lying on the chest wall, is only covered anteriorly by a single layer of aponeurosis derived from the obliquus externus, which in this situation is giving origin to the pectoralis major muscle.

Canalis Inguinalis.—**Inguinal canal.** The spermatic funiculus in the male, and the round ligament in the female, in their passage through the inferior part of the abdominal wall, pass through the inguinal canal, which is bounded by these abdominal muscles. The canal begins at the *abdominal inguinal ring*, placed half an inch above the inguinal ligament, and midway between the anterior superior iliac spine and the symphysis pubis. It ends at the *subcutaneous inguinal ring*, placed above the tubercle and crest of the pubis. The *anterior wall* of the canal is formed by the aponeurosis of the obliquus externus, and in its lateral part by the muscular fibres of the obliquus internus; the *posterior wall* of the canal is formed by the fascia transversalis, and in its medial part by the *falx aponeurotica inguinalis*; while the *floor* of the canal is formed by the inguinal ligament, and in its medial part by the lacunar ligament. The spermatic funiculus, piercing the transversalis fascia, enters the inguinal canal at the abdominal inguinal ring, and is there invested by its *first envelope*, the *infundibuliform* or *internal spermatic fascia*, a sheath of fascia derived from the margins of the ring and continuous with the fascia transversalis. It then passes obliquely medially, downwards, and forwards, and escapes below the inferior border of the obliquus internus muscle, from which it carries off a *second investment*, partly fascial, partly muscular,—the *cremaster muscle* or *cremasteric fascia*. Continuing its course in front of the *falx inguinalis*, it emerges through the subcutaneous inguinal ring, from the edges of which the *intercolumnar fascia* is derived, the *third* or *external investment* for the funiculus.

Hesselbach's triangle, bounded below by the line of the inguinal ligament, medially by the rectus abdominis muscle, and laterally by the inferior epigastric artery coursing upwards and medially beneath the fascia transversalis on the medial side of the abdominal inguinal ring, is the site of one form of inguinal hernia.

FIG. 429.—THE SHEATH OF THE RECTUS ABDOMINIS MUSCLE.

(I.) In the thoracic wall; (II.) In the superior three-quarters of the abdominal wall; (III.) In the inferior fourth of the abdominal wall.

A, RECTUS MUSCLE; B, OBLIQUUS EXTERNUS; C, DIAPHRAGM; D, OBLIQUUS INTERNUS; E, TRANSVERSUS ABDOMINIS. *a*, Anterior layer of rectus sheath; *b*, Fifth costal cartilage; *c*, Sixth costal cartilage; *d*, Xiphoid process; *e*, Posterior layer of rectus sheath; *f*, Fascia transversalis; *g*, Peritoneum; *h*, Linea alba. 1, Inferior epigastric artery.

The spermatic funiculus passes over the base of the triangle, covered over by the aponeurosis of the obliquus externus. Behind the funiculus, and forming the floor of the triangle, is the fascia transversalis partially covered in the medial portion of the triangle by the falx inguinalis of the obliquus internus and transversus muscles.

FIG. 430.—THE DIAPHRAGM AND POSTERIOR ABDOMINAL WALL.

Inguinal Hernia.—For an account of the anatomical relations of the inguinal canal to the various forms of inguinal hernia, see the section on “Applied Anatomy.”

Nerve-Supply.—The nerve-supply of the majority of the foregoing muscles is derived from the anterior rami of the lower six thoracic nerves. The pyramidalis muscle is innervated by the last thoracic nerve. The cremaster muscle receives its supply from the genito-femoral nerve (L. 1. 2.).

Actions.—(1) The chief action of these muscles is to retract the abdominal walls. By compressing the contents of the abdomen, they are powerful agents in vomiting, defaecation,

micturition, parturition, and laboured expiration. (2) They are also flexors of the vertebral column and pelvis—the muscles of both sides acting together; the vertebral column and pelvis are laterally flexed, when one set of muscles acts alone.

The posterior muscles of the abdominal wall and pelvis major include the psoas (major and minor) and iliacus, described already (p. 410), and the quadratus lumborum.

M. Quadratus Lumborum.—The quadratus lumborum lies on the posterior wall of the abdomen, lateral to the psoas, and extends between the iliac crest and the last rib. It arises from the posterior part of the iliac crest, from the ilio-lumbar ligament, and from the transverse processes of the lower lumbar vertebræ.

It is inserted above into the medial part of the inferior border of the last rib and the transverse processes of the lumbar vertebræ. Its lateral border is directed obliquely upwards and medially.

It is enclosed between the anterior and middle layers of the lumbo-dorsal aponeurosis (p. 437), between the psoas major muscle, in front, and the sacro-spinalis behind.

Nerve-Supply.—The quadratus lumborum is supplied directly by branches from the anterior, rami of the first three or four lumbar nerves.

Actions.—The muscle is a lateral flexor of the vertebral column, an extensor of the column and a muscle of inspiration.

FASCIÆ AND MUSCLES OF THE PERINEUM AND PELVIS.

FASCIÆ OF THE PERINEUM.

The superficial fascia of the perineum possesses certain special features. It is continuous with the superficial fascia of the abdominal wall, thigh, and buttock, and is prolonged on to the penis and scrotum. In relation to the penis, it is devoid of fat and consists only of areolar tissue. In relation to the scrotum, it is intermingled with involuntary muscular fibres, and constitutes the **dartos muscle**, which assists in suspending the testes and corrugating the skin of the scrotum. This fascia also forms the **septum of the scrotum**, which, extending upwards, incompletely separates the two testes and their coverings. In the female the superficial fascia, in which there is a considerable quantity of fat, takes a large share in the formation of the mons Veneris and labia majora pudendi.

The fascia over the posterior part of the perineum fills up the ischio-rectal fossæ, in the form of two pads of adipose tissue, on either side of the rectum and anus. Over the tuberosities of the ischium the fat is intermingled with bands of fibrous tissue closely adherent to the subjacent deep fascia.

The fascia in the anterior part of the perineum closely resembles the same fascia in the groin. It is divisible into a superficial fatty and a deeper membranous layer; the former continuous with the same layer in the thigh, and with the fat of the ischio-rectal fossa posteriorly. The deeper membranous layer is attached laterally to the pubic arch, posteriorly to the base of the fascia inferior of the urogenital diaphragm and in the median plane to the root of the penis (bulb and corpus cavernosum urethra) by a median raphe continuous, farther forwards, with the septum of the scrotum mentioned above. Anteriorly the fascia is continued over the spermatic funiculi to the anterior abdominal wall. The importance of this fascia lies in relation to the extravasation of urine from a rupture of the urethra in the perineum. By the fascial attachments the fluid is prevented from passing posteriorly into the ischio-rectal fossa, or laterally into the thigh. It is directed forwards into relation with the scrotum and penis, and along the spermatic funiculus to the anterior abdominal wall. The septum of the scrotum being incomplete, fluid extravasated on one side can pass across the median plane to the opposite half of the perineum and scrotum.

The deep fascia of the perineum exists only in the form of the delicate fasciæ of the muscles.

THE MUSCLES OF THE PERINEUM.

The perineal muscles are naturally separated into a superficial and a deep set by the fascia inferior of the urogenital diaphragm. Superficial to it are the sphincter ani externus, transversus perinei superficialis, bulbocavernosus, and ischiocavernosus; deep to it are the sphincter muscle of the membranous urethra and the transversus perinei profundus.

M. Sphincter Ani Externus.—This muscle is fusiform in outline, flattened, and obliquely placed around the anus and anal canal. It can be separated into three layers,—subcutaneous, superficial, and deep. (1) The most superficial lamina

FIG. 431.—THE MUSCLES AND NERVES OF THE MALE PERINEUM.

consists of subcutaneous fibres decussating posterior and anterior to the anus, but without bony attachments. (2) The **sphincter ani superficialis** constitutes the main portion of the muscle. It is attached posteriorly to the coccyx, and, anterior to the anus, it reaches the central point of the perineum. (3) The **deep fibres** of the muscle form for the most part a complete sphincter for the anal canal. They are continuous with the fibres of the levator ani: they encircle the anal canal, and blend anteriorly with the central point of the perineum and the transversus perinei superficialis muscle.

M. Corrugator Cutis Ani.—The **corrugator cutis ani** consists of bundles of unstriated muscular fibres which radiate from the margin of the anal opening superficial to the external sphincter.

Nerve-Supply.—The external sphincter is supplied by the inferior hæmorrhoidal branch of the pudendal nerve (S. 3. 4.), by the perineal branch of the fourth sacral nerve, and by the deep perineal branch of the pudendal nerve (S. 3. 4.).

Actions.—The muscle closes the anal aperture. It is a voluntary muscle.

M. Transversus Perinei Superficialis.—The *transversus perinei superficialis* is not always present. It consists of a more or less feeble bundle of fibres, arising from the inferior ramus of the ischium and the fascia over it, and from the base of the fascia inferior of the urogenital diaphragm.

It passes obliquely over the base of the fascia inferior to be inserted into the central point of the perineum.

Nerve-Supply.—Deep perineal branch of pudendal nerve (S. 3. 4.).

Action.—The two muscles acting together draw backwards and fix the central point of the perineum.

M. Bulbocavernosus.—The *bulbocavernosus* (O.T. *ejaculator urinæ*), in the male, surrounds the bulb, corpus cavernosum urethræ, and root of the penis. It is sometimes separated into two parts—*posterior* (compressor bulbi), and *anterior* (compressor radicis penis). It arises from the central point of the perineum, and from a median raphe on the under surface of the bulb and corpus cavernosum urethræ.

The muscular fibres are directed laterally and forwards and have a triple insertion: from behind forwards, (1) into the inferior surface of the fascia inferior of the urogenital diaphragm; (2) into the dorsal aspect of the corpus cavernosum urethræ; and (3), after encircling the corpora cavernosa penis, into the fascia covering the dorsum of the penis.

The *ischio bulbosus*, not always present, arises from the ischium, and passes obliquely medially and forwards over the bulbocavernosus, to be inserted into the raphe superficial to that muscle. It belongs to the same stratum as the *transversus perinei superficialis* and *ischio cavernosus*.

The *compressor hemispheriorum bulbi* is frequently absent. It consists of a thin cap-like layer of muscular fibres surrounding the extremity of the bulb under cover of the bulbocavernosus.

M. Bulbocavernosus.—The *bulbocavernosus*, in the female (O.T. *sphincter vaginæ*), is separated into lateral halves by the vaginal and urethral openings. It forms two thin lateral layers covering the bulb of the vestibule, and arises behind the vaginal orifice from the central point of the perineum.

Anteriorly it is inserted into the root of the clitoris, some of its fibres embracing the corpora cavernosa clitoridis so as to reach the dorsum of the clitoris.

FIG. 432.—THE MUSCLES OF THE FEMALE PERINEUM (after Peter Thompson).

Nerve-Supply.—Deep branch of the perineal nerve (pudendal, S. 3. 4.).

Actions.—**In the male.**—The bulbocavernosus contracts the urethra in the emission of urine and semen, and is an accessory muscle in erection of the penis.

In the Female.—The muscle contracts the vaginal orifice, and compresses the bulb of the vestibule of the vagina.

M. Ischiocavernosus.—The **ischiocavernosus** (O.T. **erector penis**), *in the male*, covers the crus penis. It arises from the ischial tuberosity and the sacrotuberous ligament.

Passing forwards, it is inserted by a fascial attachment into the inferior surface of the crus penis, and into the lateral and dorsal aspects of the corpus cavernosum penis.

The **ischiocavernosus** (O.T. **erector clitoridis**), *in the female*, has a similar disposition, but is of much smaller size than in the male.

The **pubocavernosus** is an occasional slip arising from the pubic ramus, and inserted into the dorsum of the penis. It corresponds to the levator penis of lower animals.

Nerve-Supply.—Deep branch of the perineal nerve (pudendal, S. 3. 4.).

Action.—The muscle assists in erection of the penis (or clitoris).

FIG. 433.—THE FASCIAE OF THE UROGENITAL DIAPHRAGM OF THE PERINEUM, AND THE TERMINATION OF THE PUDENDAL NERVE.

Diaphragma Urogenitale.—The sphincter urethrae membranacea and the transversus perinei profundus constitute the deeper muscular stratum of the perineum and form the **urogenital diaphragm**. They lie between two layers of fascia called the *fascia inferior*, and *fascia superior* of the *urogenital diaphragm* (O.T. *superficial and deep layers of the triangular ligament*).

M. Sphincter Urethrae Membranacea.—The **sphincter** of the membranous urethra (O.T. **compressor urethrae**) arises from the inferior part of the pubic ramus, and is directed medially, its fibres radiating so as to enclose the membranous urethra.

It is inserted into a median raphe, partly anterior to the urethra, but for the most part posterior to it. The fibres most intimately related to the urethra form a muscular sheath for the canal, and have no bony attachments.

M. Transversus Perinei Profundus.—The **transversus perinei profundus** consists of a bundle of fibres on each side, arising from the inferior ramus of the ischium just below the sphincter urethrae membranacea. It is inserted into a median raphe continuous with that of the sphincter urethrae membranacea. The muscle, in fact, constitutes a separate bundle below and behind the sphincter.

The **ischiopubicus** is a term applied to a feeble bundle of fibres which, when present, lies above and in front of the sphincter urethrae membranacea. It arises from

the pubic ramus, and is inserted into a median raphe on the dorsum of the membranous urethra. This muscle is homologous with the **compressor venæ dorsalis penis** of lower animals.

The **sphincter urethræ in the female** is smaller than in the male. Its insertion is modified by the relations of the urethra to the vagina. The anterior fibres are continuous with those of the opposite side above the urethra; the intermediate fibres pass between the urethra and vagina, and the posterior fibres are attached, along with the **transversus perinei profundus** (*transversus vaginæ*), into the side of the vagina.

Nerve-Supply.—Deep branch of the perineal nerve (pudendal, S. 3. 4.).

Action.—It is a feeble compressor of the membranous urethra, and by no means a sphincter. In the female it has an accessory influence in constricting the vagina.

THE FASCIÆ OF THE PELVIS.

The **extra-peritoneal tissue** in the pelvic cavity is of great importance. The hypogastric vessels and their branches, the visceral nerves and plexuses, the ureters, and ductus deferentes, take their course in this tissue beneath the peritoneum. It forms in relation to the **rectum** a thick sheath, for the most part devoid of fat, which encloses the lower part of the rectum completely, down to its termination in the anal canal. It forms a kind of packing for the parts of the **bladder** uncovered by peritoneum, and is present under the organ in relation to the symphysis pubis and pubo-prostatic ligaments. In the female it forms, in addition, the basis or matrix of the **broad ligament**, and also occurs as a layer devoid of fat, which loosely connects the anterior surface of the **cervix uteri** with the base of the bladder.

FASCIA PELVINA.

The cavity of the pelvis minor in the erect position resembles a basin tilted forward, with its margin formed by the superior aperture of the pelvis, with a cylindrical wall, and a concave floor, formed by bones, ligaments, and muscles. The deficiencies in the bony walls of the cavity are filled up laterally by the obturator membrane and the sacro-tuberous and sacro-spinous ligaments. Inferiorly and anteriorly, behind the symphysis pubis, the **fascia diaphragmatis urogenitalis inferior** fills up the pubic arch, and separates the anterior part of the pelvic cavity from the perineum. Within this osseo-ligamentous chamber a series of muscles clothe its interior; the piriformis and coccygeus posteriorly, the obturator internus on each side, and the sphincter urethræ membranaceæ and transversus perinei profundus, inferiorly and anteriorly, on the pelvic surface of the inferior fascia of the urogenital diaphragm.

The **pelvic fascia**, continuous above with the fascial lining of the abdominal cavity, forms a continuous cylindrical investment for these muscles. On the pelvic surface of the pubis, where muscles are absent, it is merged with the periosteum. It gains an attachment to the spine of the ischium as that projects between the piriformis and obturator internus muscles. Perforations occur in relation to it for the transmission of the obturator nerve and the parietal branches of the hypogastric artery. Reaching the inferior aperture of the pelvis, it is attached to the posterior border or base of the fascia inferior of the urogenital diaphragm, to the ischial ramus and tuberosity, and to the lower edge of the sacro-tuberous ligament. Different names are applied to the fascia in relation to the several muscles which it covers. Posteriorly it constitutes the **piriformis fascia**: laterally it is the **obturator fascia**, while that part of the sheet of fascia which covers the pelvic surface of the sphincter urethræ membranaceæ and transversus perinei profundus is known as the **fascia diaphragmatis urogenitalis superior**.

The disposition of the pelvic fascia is complicated by its relations to (1) the structures which constitute the pelvic floor, and (2) the genito-urinary passages and the rectum.

The pelvic floor, tense in its anterior part and flexible posteriorly, is formed behind the symphysis pubis by, successively, (1) the fasciæ of the urogenital diaphragm and the transversus perinei profundus and sphincter muscle of the membranous urethra between them, the latter enclosing the urethra; and the vagina in the female. (2) The perineal body. (3) The levator ani and external sphincter of the anus on each side of the anal canal; (4) the ano-coccygeal body, between the anal canal and the coccyx, containing the main insertions of the levatores ani and external sphincter.

FIG. 434.—RELATIONS OF THE PELVIC FASCIA TO THE RECTUM AND PROSTATE.

The levator ani muscle completes the concave floor of the pelvic cavity, sweeping downwards and backwards from its lateral wall, so as to form a muscular diaphragm, with an intra-pelvic and a perineal surface. Its superior concave pelvic surface occupies the lateral part of the pelvic floor. Its inferior convex surface forms the oblique medial wall of the ischio-rectal fossa, the lateral wall of which is formed by the obturator fascia covering the pelvic surface of the obturator internus. In this wall is a fascial sheath containing the pudendal vessels and nerve. The levator ani is covered on both surfaces by pelvic fascia. The anal fascia clothing its perineal surface is thin and unimportant. The fascia covering its intra-pelvic surface is thick and strong. At the origin

of the muscle it is continuous with the general fascial lining of the pelvic cavity, and gives rise to a conspicuous thickening, the **tendinous arch** (*arcus tendineus*) of the pelvic fascia, which stretches like a bow-string from the back of the symphysis pubis to the ischial spine. This band is related not so much to the origin of the levator ani muscle, which often extends higher up beneath the pelvic fascia, as to the attachments of the fascial investments of the genito-urinary passages, to be described below. There are sometimes additional thickenings of the fascia, branching upwards from the **tendinous arch** towards the superior aperture of the pelvis. At the insertion of the levator ani, the fascia clothing its pelvic surface is attached to the perineal body, the margin of the anal canal, and the ano-coccygeal body, over which it passes to be continuous, above the raphe of insertion of the levatores ani, with the layer of the opposite side. At the antero-

FIG. 435.—RELATIONS OF PELVIC FASCIA TO THE RECTUM AND PROSTATE
(Median Section of the Pelvis).

inferior border of the muscle the fasciae enclosing it become continuous with the **superior fascia of the urogenital diaphragm**; at its postero-superior border they join the fascia enclosing the coccygeus muscle.

Within the pelvic basin, the walls and floor of which are thus continuously invested by the pelvic fascia, are contained the rectum and bladder, and in the female the uterus, suspended and maintained in position by the peritoneum, extra-peritoneal tissue, and the pelvic vessels and nerves. They are essentially free to distend or collapse, and are not bound down by the pelvic fascia. The rectum in both sexes extends down to the floor of the pelvis, where the anal canal takes its origin. It is invested by the peritoneum and extra-peritoneal tissue, and occupies a special **rectal channel**; this is lined by pelvic fascia, which gains an attachment to the floor of the pelvis at the margin of the anal canal.

The arrangement of the fascia in relation to the genito-urinary passages is essentially different.

Just as from the perineal aspect the inferior aperture of the pelvis is divisible into two different parts,—a posterior or dorsal part, comprising the ischio-rectal

fossæ for the passage of the anal canal, and characterised by looseness and distensibility; and an anterior or ventral part,—the urethral triangle for the genito-urinary passages, and characterised by firm fixation to the pubic bones; so also from the abdominal aspect it is found that, while in the posterior part of the pelvis a rectal channel exists, in which the rectum is free to collapse and distend, in the ventral part of the basin the genito-urinary passages are firmly fixed by means of

FIG. 436.—RELATIONS OF THE PELVIC FASCIA TO THE RECTUM, URETHRA, AND VAGINA (Median Section).

the pelvic fascia, which gives rise to a special suspensory ligament for the prostate gland and the prostatic urethra in the male, and for the urethra and vagina in the female.

A crescentic fold of pelvic fascia (**suspensory ligament**) arises in the neighbourhood of the sciatic spine from the general fascia covering the pelvic wall. It has a posterior free edge, through which the ductus deferens, vesical vessels, and nerves pass. Sweeping across the median plane, this border is continuous with the fold of the opposite side, the two together constituting the anterior limit of the rectal

channel. The fascial fold is composed of two layers, posterior and superior, between which is a large plexus of veins. They have separate attachments laterally to the general pelvic fascia. The **posterior (recto-vesical) layer** passes across the pelvis between the prostate gland and the rectum. Its inferior edge is attached to the perineal body between the base of the fascia of the urogenital diaphragm and the beginning of the anal canal. It forms a sheath for the *vesiculæ seminales* and *ductus deferentes*. This is rather in the form of a septum than a complete sheath; it effectually separates the *vesiculæ seminales* and the bladder from the rectum, forming the anterior wall of the **rectal channel**, but it allows the *vesiculæ seminales* to rest directly against the bladder. The **superior layer** extends forwards to the symphysis pubis. It has a lateral origin from the **arcus tendineus** in its whole length, and sweeping over the prostate gland, it is inserted along its line of junction with the bladder, and constitutes the so-called **lig. puboprostaticum laterale (lateral true ligament of the bladder)**. It contains numerous bundles of muscular fibres in its anterior part, and forms a sheath for the passage of the inferior vesical vein along the lateral surface of the prostate gland. In front the fascia stretches from the back of the symphysis pubis, the arcuate ligament of the pelvis, and the superior fascia of the urogenital diaphragm to the neck of the bladder and the prostate gland, forming the **lig. puboprostaticum medium**. It is continuous across the median plane with the ligament of the opposite side. In the median line, where the two ligaments unite, a hollow occurs behind the symphysis pubis, known as the **cavum Retzii**. This ligament is composed of several layers separated by large veins (the **puddendal plexus**), which connect the inferior vesical vein with the dorsal vein of the penis and the hypogastric vein.

The sheath of the prostate gland (*fascia prostatæ*) is formed by (1) the superior fascia of the urogenital diaphragm on which it lies, (2) by the general pelvic fascia covering the intra-pelvic surfaces of the *levator ani* on each side, and (3) it is completed above and behind by the two special layers of pelvic fascia just described. By these means the prostate gland and prostatic urethra are given a firm attachment to the anterior part of the pelvic walls and floor.

In the female an essentially similar arrangement of the pelvic fascia occurs in relation to the vagina and urethra. A crescentic fold of the fascia springs from the pelvic wall in the neighbourhood of the *spina ischiadica*, and sweeping medially to the lateral fornix of the vagina and in front of the rectum, separates into two layers, **posterior** and **superior**. Between the layers are numerous vessels, which, along with the visceral nerves, pierce its free edge. The **posterior (recto-vaginal) layer** passes medially behind the vagina, and gaining the median plane between the vagina and rectum, gives rise to the anterior wall of the rectal channel, and is attached below to the perineal body in the floor of the pelvis. The **superior layer**, taking origin from the *arcus tendineus*, is attached medially to the neck of the bladder, and constitutes the **lateral pubo-vesical ligament**. It is continuous in front with the **anterior pubo-vesical ligament**, which, as in the male, is divisible into several layers separated by veins. An **intermediate (urethro-vaginal)** layer of the fascia passes between and separates the urethra and vagina.

The urethra and vagina are by means of these layers of fascia firmly bound to the pelvic walls and floor, while the uterus and bladder are free to distend in the pelvic cavity.

MUSCLES OF THE PELVIS.

Diaphragma Pelvis.—The pelvic diaphragm is formed by the *levator ani* and *coccygeus* muscles, which serve to uphold the pelvic floor, and are related to the rectum and the prostate gland or vagina.

M. Levator Ani.—The *levator ani* arises from (1) the inferior part of the posterior surface of the body of the pubis, (2) the general pelvic fascia above or along the *arcus tendineus*, and (3) the pelvic surface of the spine of the ischium.

Its fibres are directed downwards and backwards, to be inserted into (1) the central point of the perineum (perineal body), (2) the external sphincter around

the origin of the anal canal, (3) the ano-coccygeal raphe behind the anus, and (4) into the sides of the lower coccygeal vertebræ.

The levator ani muscle fills up and completes the pelvic floor on each side of the median plane. Enclosed in a sheath derived from the general pelvic fascia along the arcus tendineus, the muscle presents an upper concave surface in relation to the pelvic cavity, prostate gland (or vagina), and rectum, and an

FIG. 437.—THE FASCIAL AND MUSCULAR WALL OF THE PELVIS AFTER REMOVAL OF PART OF THE LEFT HIP BONE.

inferior convex surface which appears in the perineum and forms the medial wall of the ischio-rectal fossa.

The **levator ani** is divisible into four parts—puborectalis, pubococcygeus, ilio-coccygeus, and iliosacralis. The **puborectalis** (levator prostatae) is the part inserted into the central point of the perineum. The **pubococcygeus** is the part inserted into the anus and the ano-coccygeal raphe, and the **iliococcygeus** and **ischiococcygeus** are represented by the fibres attached to the sacrum and coccyx. The first two are best developed; the last two series of fibres are the most rudimentary. These several parts of the muscle represent the remains of the flexor caudæ of tailed animals.

Nerve-Supply.—The levator ani is supplied from two sources: by the **perineal** (muscular) branch of the pudendal nerve, and, on its pelvic surface, by special branches from the **third** and **fourth** sacral nerves.

Actions.—(1) The levator ani muscle serves to uphold and slightly raise the pelvic floor. (2) It is likewise capable of producing slight flexion of the coccyx. (3) The anterior fibres of the levator ani, in the female, sweeping round the vagina, compress its walls laterally, and along with the sphincter vaginae, help to voluntarily diminish the lumen of the tube. (4) The same part of the muscle in the male elevates the prostate gland (*levator prostatae*). (5) The chief action of the levator ani is in *defaecation*. Along with the external sphincter it acts as a sphincter of the rectum, closing the anal canal. During defaecation the muscle draws upwards the anus over the faecal mass, and so assists in its expulsion. (6) *In parturition*, in the same way, the muscle, contracting below the descending foetal head, retards delivery. Contracting on the foetal head, it draws upwards the pelvic floor over the foetus, and so assists delivery.

M. Coccygeus.—The **coccygeus** is a rudimentary muscle overlapping the posterior border of the levator ani. It arises from the ischial spine and the sacro-spinous ligament.

It is inserted into the sides of the lower two sacral and upper two coccygeal vertebrae. The muscle is in contact by its anterior border with the levator ani. It is enclosed in pelvic fascia, assists in forming the pelvic floor, and is in contact laterally with the sacro-tuberous and sacro-spinous ligaments.

Nerve-Supply.—The coccygeus is supplied on its pelvic surface by the **third and fourth sacral nerves**.

Actions.—The muscle is a feeble lateral flexor of the coccyx, and assists the levator ani to uphold the pelvic floor.

THE DEVELOPMENT AND MORPHOLOGY OF THE SKELETAL MUSCLES.

The mesoderm on either side of the embryonic medullary tube separates into three main parts—the **myotome**, **nephrotome**, and **sclerotome** or **lateral plates** (somatopleure and splanchnopleure).

The **myotomes** are probably directly or indirectly the source of the striated muscles of the whole body. Each consists at first of a quadrilateral bilaminar mass, resting against the medullary tube and notochord on either side. The cleft between its two layers represents the remains of the coelomic cavity. In the early stages of embryonic life the growth of the myotome is rapid. On its medial side masses of cells arise, which grow medially and surround the medullary tube and notochord to form the foundation of the vertebral column. On its lateral side cells appear to be given off which participate in the formation of the cutis vera. At the same time the dorsal and ventral borders of the myotome continue to extend, and present extremities (growing points) with an epithelial structure for a considerable period. *On the dorsal side* it overlies the medullary tube, and gives rise to the muscles of the back; while by its *ventral extension*, which traverses the somato-pleuric mesoderm in the body wall, it produces the lateral and ventral muscles of the trunk. By a medial extension it probably gives rise also to the hypaxial muscles of the neck and loin. The cells of the medial layer of the myotome are responsible for the formation of the muscle fibres. The cells elongate in a direction parallel to the long axis of the embryo, and give rise, by fusion with the cells of neighbouring myotomes, to the columns and sheets of muscles of the back and trunk. For the most part (*e.g.* back and abdomen) the originally segmental character of the muscular elements is lost by the more or less complete fusion of adjacent myotomes. The intercostal muscles, however, are the direct derivatives of individual myotomes.

Muscles of the Limbs.—In fishes and (doubtfully) reptiles there is evidence that the myotomes are concerned in the formation of the limb-muscles by their extension into the limb-bud in a manner similar to that described for the trunk. In birds and mammals, however, in which the limb-bud arises as an undifferentiated, unsegmented mass of mesodermic tissue, partly from the mesoderm surrounding the notochord, and partly from the somato-pleuric mesoblast, the myotomes stop short at the root of each limb, and do not penetrate into its substance. Instead, the muscular elements of the limb take origin independently as *double dorsal* and *ventral strata* of fusiform cells on the dorsal and ventral surfaces of the limb-bud. These strata are *unsegmented*; they are grouped around the skeletal elements of the limb, and they gradually become differentiated into the muscle masses and individual muscles of the limb.

Muscles of the Head.—Notwithstanding the obscurity and complexity of this

THE NERVOUS SYSTEM.

I.—THE CENTRAL NERVOUS SYSTEM.

ORIGINALLY WRITTEN BY D. J. CUNNINGHAM, F.R.S.,

Late Professor of Anatomy, University of Edinburgh;

REVISED AND PARTLY REWRITTEN BY G. ELLIOT SMITH, F.R.S.,

Professor of Anatomy, University of Manchester

[In its original form this chapter represented perhaps the most characteristic work of the late Editor of this Text-book, which continues to bear his name, and is a lasting memorial of his personality and scientific attainments. By his lamented death the difficult task has fallen upon the reviser of making such considerable alterations as the rapid changes in the state of our knowledge of the nervous system have rendered unavoidable, while endeavouring at the same time to preserve unaltered the general character of his friend's work.]

ELEMENTS OF THE CENTRAL NERVOUS SYSTEM.

EVERY type of nervous system with which we are acquainted, from the simplest and most primitive, such as that of Hydra, to the most complex and highly elaborated mechanism found in man, is composed essentially of three categories of elements. These are

(1) **sensory cells**, so situated and so specialised in structure as to be capable of being affected by changes in the animal's environment, and of transmitting the effects of such stimulation, directly or indirectly, to (2) **efferent nerve-cells**, which influence the muscles or other active tissues, so that it may find expression in some appropriate action; and (3) **intercalated nerve-cells**, which regulate such responsive behaviour by bringing it under the influence of other sensory impressions and of the state and activities of the body as a whole.

FIG. 439.—A DIAGRAM REPRESENTING THE ESSENTIAL FEATURES IN THE ARRANGEMENT OF THE MOST PRIMITIVE TYPE OF NERVOUS SYSTEM.

The study of a simple scheme representing the relationship that obtains between these three classes of elements in the extremely primitive animal, Hydra (Fig. 439), will make these fundamental facts plain. Changes in the animal's environment affect the extremities of the **peripheral processes** of the sensory cells (*A*, *B*, and *C*), which in Hydra are situated amongst the ordinary tegumentary cells: the effect is transmitted by the **central processes** of such cells (*A*, for example), either directly to the efferent cell, represented in the diagram by a **motor nerve-cell**, or more usually to an intercalated nerve-cell (*a*, *b*, or *c*). Into this (*a*) impulses stream from other intercalated cells (*b* and *c*), bringing the impulse from the sensory cell *A* under the influence of those coming from *B* and from more distant parts of the body through the intermediation of the intercalated cell *c*. The cells *a*, *c*, and *d* are connected with the motor nerve-cell. Thus, there is provided a mechanism whereby the conditions affecting other regions of the body, *B* and *C*, may influence the nature of the response which the stimulation of *A* evokes—either increasing or diminishing its effect or perhaps altering its character.

In this way the intercalated nerve-cells form a great co-ordinating mechanism, linking together all parts of the body in such a way that the activity of any part of the organism may be influenced by the rest, and thus be enabled to act in the interest of the whole.

Hence the nervous system becomes the chief means whereby the various parts of the body are brought into functional relationship one with the other, and co-ordinated into one harmonious whole.

Throughout the whole course of its subsequent evolution the nervous system is formed of these three kinds of elements; and the essential feature in its elaboration and increasing complexity is the multiplication of the intercalated cells, and their concentration, together with the motor nerve-cells, to form a definite organ, which we call the **central nervous system**.

During this process of development of the more complex forms of nervous system, most of the sensory cells migrate from their primitive positions in the skin (Fig. 439); and, as the free extremity of the peripheral process retains its primitive relationship to the skin, such migration of the cell bodies necessitates a great elongation of their peripheral processes. Although these sensory cells thus move inwards into the deeper tissues of the body, the great majority of them do not become incorporated in the central nervous system, but become collected into groups, which form the **ganglia** of the sensory nerves.

In addition to its primary functions of (*a*) providing the means whereby the organism can be brought under the influence of its surroundings, and (*b*) co-ordinating the activities of the whole body, the nervous system also comes to perform other functions of wider significance.

In the course of its evolution the co-ordinating mechanism formed by the intercalated cells becomes so disposed in each animal that an appropriate stimulus applied to the sensory nerves can evoke a definite response, often of great complexity and apparent purposiveness. In other words, the nervous system becomes the repository of those inherited dispositions of its constituent parts which determine the instincts: and in the course of time it eventually provides also the apparatus by which individual experience and the effects of education can be brought to bear upon and modify such instinctive behaviour. In other words, from the nervous system is formed the instrument of intelligence; and the relatively great bulk and extreme complexity of that instrument—the brain—in man are in a sense the physical expression of human intellectual pre-eminence.

In conformity with its primary function of affording a means of communication with the outside world, almost the whole nervous system in the human embryo, as in other animals, is developed from the ectoderm, as has already been explained in the chapter dealing with General Embryology (p. 30 *et seq.*). In the most primitive Metazoa the sensory cells remain in the ectoderm (Fig. 439), but other ectodermal cells become converted into motor nerve-cells and intercalated nerve-cells, which wander into the underlying tissues (Fig. 439). In the human embryo there is an analogous process of development, but with the important difference that the various nervous elements do not wander into the mesoderm individually. A

definite patch of ectoderm is set apart to produce the greater part of the nervous tissues for the whole body; and all except the margins of this area sinks into the body, *en masse*.

In one area of ectoderm all the motor nerve-cells develop (Fig. 440, *d*), in another (*c*) only intercalated nerve-cells, in yet another (*b*) the sensory cells originate; and the rest forms the skin (*a*).

With our knowledge of the fact that the sensory cells were originally distributed throughout the skin (Fig. 439), the idea naturally suggests itself that in man also the units of the sensory ganglia might be formed *in situ* in the ectoderm, and that the collection of such sensory cells in the ganglia might possibly be brought about by the migration of such sensory cells inwards, while their peripheral processes elongate to permit such migration of the cell bodies without disturbing their original endings in the skin. But there is no evidence to show, or even to suggest, that such a process takes place in the human embryo. The facts at our disposal seem to indicate that the sensory cells are derived from sharply circumscribed patches of ectoderm, and that the peripheral processes of these cells are distributed to the outlying area of ectoderm beyond them, from which the epidermis is eventually formed (Fig. 440).

At the beginning of the second week the nervous system of the human embryo is represented by two thickened plates of ectoderm lying parallel the one to the

FIG. 440.—DIAGRAM REPRESENTING (IN BLACK) THE LEFT HALF OF A TRANSVERSE SECTION OF A 2 MM. HUMAN EMBRYO. Superimposed upon it there is shown (in colours) the hypothetical primitive arrangement of the nervous elements derived from each part of the ectoderm.

FIG. 441.—THE DORSAL ASPECT OF A VERY EARLY HUMAN EMBRYO (after von Spee).

other, alongside the median axis of the embryo (Fig. 441), which is occupied by a shallow furrow.

Upon a diagram (Fig. 440), representing a transverse section through one-half of such an embryo (the uncoloured part), colours (corresponding to those employed in

Fig. 439) have been placed to indicate the nature of the elements that are known to develop in relation with each area of the ectoderm at a later period in the history of the embryo: *b* represents an area which later will form the **crista neuralis**, from which the sensory cells will be developed. The peripheral processes of these cells will pass into the skin (*a*) and their central processes into the area *cd*, which will become part of the neural tube. In the area *c* intercalated cells will develop to receive the incoming sensory nerves; and in the area *d* the motor nerve-cells (as well as other intercalated cells) will be formed.

When it is recalled that all the elements of the primitive nervous system of *Hydra* are modified ectodermal cells, and, moreover, that when the intercalated and motor nerve-cells wander into the deeper tissues the protoplasm of the whole nervous network remains in uninterrupted continuity (Fig. 439), it is instructive to note that in the primitive human nervous system the rudiment of the skin is linked to the medullary plate by the patch of ectoderm from which the sensory ganglia will be formed.

In the discussion of the inter-relationships of the various constituent elements of the nervous system, there will be occasion to refer to this matter again. But while we are studying Fig. 440 it is important to emphasise the fact that in accordance with the commonly accepted ideas it is taught that the area *b* becomes completely severed from *a* and *c*, and shortly afterwards fibres are budded off from the cells in the area *b* to form the sensory nerves linking *a* to *c*, thus re-establishing a connexion which existed a few days earlier. This suggests the possibility that the connexions between these three series of elements may not have been completely sundered during the intermediate phase of development. Early in the second week in the human embryo the axial groove separating the two bands of thickened ectoderm (Fig. 441) that form the medullary plate becomes deepened by the tilting-up of the lateral margins of the two bands. This process becomes accentuated during the next day or two until a deep cleft is formed, the walls of which consist of the thickened ectoderm and the floor of the thinner ectoderm (**floor-plate**) joining them together. Before the end of the week the dorsal edges of these thickened plates become joined in the region which will develop into the neck; and during the third week the sealing of the lips of the neural groove extends upwards (headwards) and downwards (caudally), so that the neural tube becomes completely closed by the end of that week. The extreme anterior (head-) end and the dorsal aspect of the caudal extremity of the tube are the last parts to close, the latter being, as a rule, a little later than the former. When the tube is in the stage of being patent only at its two ends, the openings are known as the **neuroporus anterior** and **neuroporus posterior**, respectively.

In the process of closing, the extreme dorsal edge of the medullary plate becomes excluded, in the greater part of its extent, from participation in the constitution either of the neural tube or of the skin, and forms a column of cells lying between the two. This is the **neural crest** (Fig. 442, A, B, and C; *x* and *y* represent the places where the apparent sundering occurs).

It is commonly supposed that the neural crests do not extend the whole length of the neural tube. Nevertheless, peculiar ectodermal areas, which ultimately give origin to sensory nerves, are found at the junction of the medullary plate with the skin in those regions where the neural crest is supposed to be lacking. At the extreme anterior end of the neural tube the margins of the anterior neuropore become thickened to form crest-like patches; but when the tube closes these areas do not separate from the skin (at *x*, Fig. 442, D), as the rest of the neural crest does. They remain part of the skin and become the olfactory areas, in which sensory cells, precisely like those found in *Hydra* (Fig. 439), develop.

A little farther on the caudal side of the olfactory region a very large crest-like mass of ectoderm fails to separate from the medullary plate as it closes, and becomes a constituent part of the neural tube (Fig. 442, E). It develops into the optic diverticulum from which the cells of origin of the optic nerve are formed.

In several other regions sensory nerves originate from cells of ectodermal, and possibly even entodermal, areas which do not form parts of the neural crest, as that term is usually understood. The nerves of hearing and taste are developed

in a way that seems at first sight utterly abnormal, until it is remembered that they afford examples of very primitive methods of nerve-formation.

The essential part of the organ of hearing is an ectodermal sac (otic vesicle) that develops as a diverticulum on the side of the head, from a thickened patch of ectoderm, which in the lower vertebrates forms part of a more extensive area, known as the **dorso-lateral placode**. Some of the cells of this area seem to become transformed into nerve-cells, which migrate into the space between the otic vesicle and the neural tube (Fig. 443) and form the acoustic ganglion.

At the upper margins of the branchial clefts a series of ectodermal (and possibly also entodermal) thickenings develop, which are known as the **epibranchial placodes**. Comparison with the process of development in fish embryos, which has been elucidated by Landacre (*Journal of Comparative Neurology and Psychology*, 1910-1912), suggests that the nerve-cells may arise from these placodes, from which the nerves of taste originate.

FIG. 442.—DIAGRAMS OF TRANSVERSE SECTIONS REPRESENTING THREE STAGES (A, B, AND C) IN THE DEVELOPMENT OF A SENSORY GANGLION FROM THE NEURAL CREST; AND TWO DIAGRAMS (D AND E) SUGGESTING A POSSIBLE HOMOLOGY OF THE OLFACTORY (D) AND VISUAL (E) EPITHELIUM WITH THE NEURAL CREST.

FIG. 443.—RECONSTRUCTION OF THE GANGLIA OF THE FACIAL, ACOUSTIC, GLOSSO-PHARYNGEAL, AND VAGUS NERVES OF A HUMAN EMBRYO 5 MILLIMETRES LONG (ABOUT THREE WEEKS OLD).

The epithelium of three branchial clefts and the otic vesicle is represented diagrammatically; and the supposed mode of origin of the gustatory nerve-cells (and their fibres) from the epibranchial placodes is indicated in blue, and of the acoustic nerve-cells from the otic vesicle in purple.

Such fibres are constituent elements of the facial, glosso-pharyngeal, and in some animals also the vagus cerebral nerves (Fig. 443), in connexion with the ganglia of which these epibranchial placodes are formed (Froriep and Streeter). The observations of Professor J. P. Hill upon embryos of *Echidna* seem to suggest that in mammals these gustatory neuroblasts are derived from the entoderm.

When first formed, the neural tube is compressed from side to side and presents an elliptical outline in transverse section (Fig. 444). The two lateral walls are very thick, whilst the narrow dorsal and ventral portions of the wall are thin, and are termed the **roof-plate** and **floor-plate** respectively (Fig. 444). The cavity of the tube in transverse section appears as a narrow slit. The wall of the neural tube consists at first of low columnar epithelium arranged in a fairly regular series, but with a certain number of large spherical so-called **germinal cells** scattered between the columns. But this regular disposition as a single layer

FIG. 444.—DIAGRAM OF TRANSVERSE SECTION OF EARLY NEURAL TUBE.

of cells does not last long. For even by the second week the rapid proliferation of the cells has led to a marked increase in the thickness of the lateral wall and a scattering of the more numerous nuclei, apparently irregularly, throughout its substance (Fig. 444). The latter consists of a network of protoplasm in which definite outlines of cells cannot be detected. As growth proceeds the innermost part of this nucleated protoplasmic syncytium becomes condensed to form a delicate membrane termed the **internal limiting membrane**, which lines the lumen of the tube, whilst its outermost part presents a similar relation to an **external limiting membrane**, which invests the outer surface of the tube. Toward the end of the first month the lateral walls of the tube show signs of a differentiation into three layers. Next to the central canal there is an epithelial-like arrangement of the innermost cells of the syncytium, forming the **ependyma**. Then there is an intermediate layer crowded with nuclei, hence known as the nuclear or **mantle layer**. On the surface is a layer singularly free from nuclei, which is called the non-nuclear or **marginal layer**. The germinal cells are

placed in the ependymal layer between its radially arranged cells as they pass in towards the internal limiting membrane; and the protoplasm of the germinal cells forms part of the syncytium.

At one time it was imagined that the germinal cells were embryonic nerve-cells, the parent-cells of the real **neuroblasts**, and that the whole of the rest of the syncytium represented the supporting tissues, which in the adult form the **neuroglia**. But it is now known that from the proliferation of the germinal cells, in which mitotic figures can usually be seen, some cells are formed which become ependymal epithelium, and others which migrate peripherally into the mantle layer. There, while forming part of the mantle syncytium, they undergo further proliferation and some of the resulting cells develop into **spongioblasts**, which constitute the supporting framework, the embryonic neuroglia; others become rudimentary nerve-cells or **neuroblasts**, and others again are known as **indifferent cells**. The latter are destined to undergo further subdivision and become the parents of more spongioblasts and neuroblasts.

From this it is clear that the greater part—all except the germinal cells—of the syncytium, which is known as the **myelospongium**, is not merely supporting neuroglial tissue, as was once supposed, but is the rudiment of both neuroglia and true nervous tissues.

The details of the process by which the neuroblasts become dissociated from the neuroglial network are quite unknown. It is commonly supposed that a spherical cell in the mantle layer that is to be transformed into a neuroblast frees itself from the syncytium, and remains for a time independent and wholly unattached amidst the meshes of the neuroglial network: it is supposed further that its true nature as a neuroblast becomes revealed when it takes on a pear-shape, and a protoplasmic process, the stalk of the pear, pushes its way into some other part of the nervous system, or out of it into the mesoderm to reach some muscular or glandular tissue, and becomes the axis cylinder process or axon of the nerve-cell.

Such an interpretation of the appearances exhibited in the walls of the neural tube at the end of the first month is adduced in support of a view concerning the constitution of the nervous system known as the **neurone theory**. "Neurone" is the term applied to a nerve-cell and all its processes; and the neurone doctrine assumes that there is no continuity whatever between the substance of one neurone and that of another, such as occurs in *Hydra* (Fig. 439), and that the functional connexions between them are brought about merely by the contact of the processes of one element with the processes, or the cell-body itself, of another element. In accordance with this conception the facts of embryology are supposed (by His) to demonstrate that when the axon grows out from a previously spherical and unattached cell it is able to push into the surrounding tissues, and, as it were guided by some instinct, eventually finds its way to that particular area of skin, muscle, gland, or other part of the body where nature intends it to go.

This is the current teaching in regard to the neurone-theory; and it is supposed to have been conclusively demonstrated by the facts revealed not only by embryology and the study of the minute structure of the nervous system, but also by the phenomena of degeneration and regeneration. Harrison has shown that the outgrowth of processes can be witnessed in the living nerve-cells of the frog. There are certain facts, however, which have always led some anatomists to refuse to believe in the validity of the neurone doctrine as a true expression of the real constitution of the nervous system. It has been clearly demonstrated by Graham Kerr that at a very early stage of development the neural syncytium of the spinal medulla (of the mud-fish *Lepidosiren*) is in free and uninterrupted continuity with the protoplasm of the muscle-plate, which lies in contact with the neural tube; and no stage is known in which these connexions do not exist. When, in the course of the subsequent growth of the embryo, the muscle-plate becomes removed further and further away from the central nervous system the protoplasmic strand, which links them the one to the other, gradually becomes stretched and elongated. As the neuroblast matures its chemical constitution becomes modified; it becomes specialised in structure to fit it for the peculiar functions it has to perform. These

changes manifest themselves first in the body of the neurone itself and thence spread along its processes. With the knowledge that protoplasmic bridges exist long before the time His supposed the axon of his neuroblast to push its way outward, it seems not unreasonable to suppose that it is the chemical modification of these existing bridges which has been revealed in stained specimens, as it spreads from the cell body outwards into its processes.

It is now a well-recognised fact that soon after the neural tube becomes closed the outlines of its constituent cells become blurred and then disappear, and a continuous protoplasmic network or syncytium is formed. No one has ever been able to detect the process of detachment of embryonic nerve-cells (neuroblasts) from this syncytium; and it is at least a possibility that the free anastomosis of the protoplasmic processes of many of the cells is not destroyed in the way demanded by the neurone doctrine. The known facts might be interpreted, at least as reasonably, by supposing that when nerve currents begin to traverse the syncytium (Fig. 444) structural modifications occur around the nuclei of the cells affected, and gradually spread along their processes, so as to give the appearance (in sections stained by special methods) of processes growing out from each neurone.

Impulses brought from the skin by the sensory nerves, the nutrition of which is controlled by the cells in the sensory ganglion (Fig. 443), are carried into the wall of the neural tube, where they are received by processes of intercalated cells, which in turn transmit their effects directly or indirectly to (*a*) motor nerve-cells (or other kind of efferent nerve-cells), which stimulate a muscle, a viscus, or other active tissue to perform some work, or (*b*) to intercalated cells, the axons of which proceed to some other part of the nervous system, perhaps above or below the place where the sensory nerve enters (Fig. 444, *funicular cells*). As the walls of the neural tube increase in size the various neurones gradually become drawn apart, and the protoplasmic links uniting them become stretched and extended to form processes of varying length.†

It is right to explain that most writers give an explanation of the process of development which is at variance with that just sketched. The neuroblast is supposed to originate as a free-lying spherical cell, which is stimulated by some unknown force, sometimes assumed to be of the nature of a chemical attraction (chemotaxis), to protrude a process, which gradually elongates and pushes its way through the tissues, perhaps to some particular patch of skin, muscle, gland, or some other nerve-cell. The difficulty involved in such a conception is not only that it is opposed to all that is known of the early stages in the evolution of the nervous system, but also that it is difficult to conceive that every one of the millions of nerve-cells, muscle-cells, visceral and cutaneous elements can each have some specific attractive power which leads every individual nerve fibril to its appropriate and predestined place in the body.

The Efferent Nerves.—The efferent cells of the neural tube are distinguished by the fact that their axons leave the central nervous system and traverse the mesoderm for a longer or shorter distance to end in relation to some muscle, gland, or other tissue outside the nervous axis. At an early stage of development (Fig. 445) such efferent fibres pass not only to muscles but also to viscera and other kinds of tissues. In the course of the growth of the body these various structures supplied by efferent fibres become removed progressively further and further from the central nervous system; and in this process a distinction can be detected in the behaviour of the efferent fibres proceeding (*a*) to the striped or voluntary muscles, (*c*) and the viscera and unstriped muscle, respectively. The efferent cells (*a*) which innervate voluntary muscles retain their positions in the central nervous system, their axis-cylinder processes (motor nerves) becoming elongated in proportion to the migration of the muscle from its original situation. But the cells (*c*) innervating non-striped muscles and viscera behave in a different manner. As the viscus or muscle migrates (Fig. 445, B), the nerve-cell (*c*) follows it more or less closely, being as it were dragged out of the wall of the neural tube by its axon into a peripheral position, where it becomes a constituent element of one of the so-called **sympathetic** or **autonomic ganglia**. As these sympathetic cells migrate from the central nervous system, each of them appears to draw out with it the axon of an inter-

calated cell (*d*); and it is customary to distinguish these latter elements (within the central nervous system) as **splanchnic efferent cells**. It is, however, a matter of fundamental importance to recognise clearly that the real splanchnic efferent cells, the homologues of the **somatic efferent cells**, are found in the sympathetic ganglia, and that the elements to which this term is usually applied are in reality intercalated cells.

This account is at variance with the customary description of the development of the sympathetic system, according to which the cells of the sympathetic ganglia are said to be wholly derived from the sensory ganglia; but it offers a reasonable explanation of the facts (i.) that the cells in the sympathetic ganglia are of the efferent, and not of the sensory, type, and (ii.) that the fibres from the central nervous system establishing relations with them emerge along the motor roots. Moreover, the information brought to light by recent research in embryology (Frobiep, Kuntz, and others) affords positive evidence in support of this view. Elliott, however, opposes this interpretation (*Journal of Physiology*, 1907, p. 438).

FIG. 445.—DIAGRAM OF A TRANSVERSE SECTION THROUGH THE LEFT HALF OF THE NEURAL TUBE REPRESENTING TWO STAGES IN THE DEVELOPMENT OF THE EFFERENT NERVES, TO SUGGEST THE POSSIBLE ORIGIN OF THE CELLS OF THE SYMPATHETIC GANGLIA BY MIGRATION FROM THE NEURAL TUBE.

Many, if not all, of the sympathetic cells are derived from the walls of the neural tube, and they migrate along the pathways formed by the motor, rather than the sensory, nerves. In the case of the spinal medulla they pass out chiefly along the anterior roots, and from the brain along the motor nerves—the oculo-motor, and the motor divisions of the facial and vagus nerves.

Nerve Components.—From the statements in the preceding paragraphs it must be evident that there are several varieties of afferent and efferent nerves respectively entering and leaving the central nervous system. The cells of origin of the efferent nerves are all placed in the ventral part of the lateral wall of the neural tube; and for this reason this part of the wall becomes swollen at an early stage of development (Figs. 445 and 446). It is called the **basal lamina**. Most of the cells that emit afferent fibres are situated in the sensory ganglia outside the central nervous system, so that their growth can have no direct influence upon the form of the neural tube; but their central processes become inserted into the dorsal part of the lateral wall of the tube, which is called the **alar lamina**; and groups of intercalated cells collect around the entering fibres to form **receptive** or **terminal nuclei**. The growth of these terminal nuclei leads to an expansion of the alar lamina which is analogous to, but much less extensive than, that seen in the basal lamina. This unequal swelling of the dorsal and ventral parts of each lateral wall of the neural tube leads to the development of a longitudinal groove, **sulcus limitans**, as a demarcation between the alar and basal laminae.

The nuclei of origin of the efferent fibres, which are found in the basal laminae, may be divided into two (and, in some regions of the nervous axis, three) main groups. There is first the group of large multipolar nerve-cells which emit fibres to innervate the ordinary striped voluntary muscles. This is commonly called

the **somatic efferent nucleus**. Then there is a group of small multipolar cells, the axons of which pass out into sympathetic ganglia, and indirectly control the involuntary unstriped muscles and other active parts of viscera. These cells form the **splanchnic efferent nucleus**.

In the upper cervical and lower cranial region a portion of the somatic efferent nucleus is set apart to innervate the striped muscles developed in the branchial arches. This is the **lateral somatic or intermediate efferent nucleus**. Many recent writers are of the opinion that this nucleus is **splanchnic**; but its fibres directly innervate striped voluntary muscles, which are developed from the same material

FIG. 446.—DIAGRAM OF A TRANSVERSE SECTION THROUGH THE RIGHT HALF OF THE FETAL RHOMBENCEPHALON AND EPITHELIAL AREAS ASSOCIATED WITH IT TO ILLUSTRATE THE DIFFERENT CATEGORIES OF NERVE COMPONENTS AND THEIR CENTRAL NUCLEI.

(myotomes) from which the other striped muscles are formed (Agar and Graham Kerr).

The alar lamina also can be subdivided into a series of functional areas (Fig. 446).

At the dorsal edge is the **somatic afferent terminal nucleus**, which receives impulses coming from the skin. In one region a part of this nucleus is specialised for the reception of impulses coming from the internal ear (**acoustico-lateral terminal nucleus**). Then there is a group of cells collected around the incoming visceral sensory nerves—the **splanchnic afferent terminal nucleus**. A part of this is specialised to receive taste impressions—the **gustatory nucleus**—but this has not yet been clearly demarcated from the rest of the nucleus.

This analysis of the various functional elements that may enter into the constitution of the various cerebral and spinal nerves is made use of in elaborating the **theory of nerve components**, which will help us to understand many features of the structure of the nervous system that otherwise would be unintelligible.

Nerve-cells.—We have already noticed that there is a broad distinction between the nerve-cells which are found in the ganglia of sensory nerves and those

found in the rest of the nervous system. They differ not only in their mode of origin and in their subsequent development, but also in the connexions of their nerve-fibre processes.

Nerve-cells of the Brain and Spinal Medulla.—The cells in the cerebro-spinal axis are variable both in size and form. Some are relatively large, as, for example, certain of the pyramidal cells of the cerebral cortex and the motor cells in the spinal medulla, which almost come within the range of unaided vision; others are exceedingly minute, and require a high power of the microscope to bring them into view. The cell consists of a protoplasmic nucleated body, from which the axon proceeds, and the protoplasmic processes of Deiters, or the dendrites (Fig. 447).

The axon presents a uniform diameter and a smooth and even outline. It gives off in its course fine collateral branches, but does not suffer thereby any marked diminution in its girth. The most important point to note in connexion with the axon, however, is the fact that it becomes continuous with the axis-cylinder of a nerve-fibre. The axon then is simply a nerve-fibre, and in certain circumstances it assumes one or two investingsheaths, of which more will be said later. The axon may run its entire course within the substance of the brain or spinal medulla, either for a short or a long distance (intercalated cells), or it may emerge from the brain or spinal medulla in one of the cerebral or spinal

FIG. 447.—THREE NERVE-CELLS FROM THE ANTERIOR COLUMN OF GRAY MATTER OF THE HUMAN SPINAL MEDULLA.

nerves as the essential part of an efferent nerve-fibre, and run a variable distance before it finally reaches the peripheral structure in relation to which it ends (efferent nerve-cells). The axon and the collaterals which spring from it appear to terminate either in small button-like swellings or knobs, or more frequently in terminal arborisations, the extremities of which seem to be furnished with exceedingly small terminal varicosities. In those cases where the axon or its collaterals end within the brain or spinal medulla, some of the terminal arborisations interlace with the dendrites of nerve-cells, whilst others are twined around the bodies of other cells. In the latter case the interlacement may be so close and complete that it almost presents the appearance of an enclosing basket-work. In cases where the axon emerges from the cerebro-spinal axis its terminal arborisation ends in relation to a muscle-fibre or some other tissue in the manner described below.

FIG. 448.—Two MULTIPOLAR NERVE-CELLS (from a specimen prepared by the Golgi method).

view, therefore, four different forms of nerve-fibre may be recognised :—

Non-medullated—

1. Naked axis-cylinders.
2. Axis-cylinders with primitive sheaths.

Medullated—

3. Primitive sheath absent.
4. Primitive sheath present.

Every nerve-fibre near its origin and as it approaches its termination is unprovided with sheaths of any kind, and is simply represented by a non-medullated naked axis-cylinder. The fibres of the olfactory nerves afford us an example of non-medullated fibres furnished with a primitive sheath.

Medullated fibres are present in greater quantity in the cerebro-spinal system than non-medullated fibres. Thus, all the nerves attached to the

Nerve-fibres.—Nerve-fibres, arranged in bundles of greater or less bulk, form the nerves which pervade every part of the body. They also constitute the greater part of the brain and spinal medulla. Nerve-fibres are the conducting elements of the nervous system; they serve to bring the nerve-cells into relation both with each other and with the various tissues of the body.

There are different varieties of nerve-fibres, but in all the leading and essential constituent is a delicate thread-like axon. The most obvious difference between individual fibres depends upon the nature of the covering of the axon. When it is coated on the outside by a more or less thick sheath of a fatty substance, termed **myelin**, it is said to be a myelinated or medullated fibre. When the coating of myelin is absent, the fibre is termed a non-myelinated or a non-medullated fibre. A second sheath—thin, delicate, and membranous, and placed externally—may also be present in both cases. It is termed the **primitive sheath** or the **neurolemma**. From a structural point of

FIG. 449.—NERVE-CELL FROM CEREBELLUM (CELL OF PURKINJE) SHOWING THE BRANCHING OF THE DENDRITIC PROCESSES (from a photograph by Professor Symington).

brain and spinal medulla, with the exception of the olfactory and optic, are formed of medullated fibres provided with a primitive sheath; whilst the entire mass of the white substance of the brain and spinal medulla, and also the optic nerves, are formed of medullated fibres devoid of a primitive sheath.

It is important to note that the distinction between the medullated and non-medullated fibres is not one which exists throughout all stages of development. As will be presently pointed out, every fibre is the prolongation of a cell, and in the first instance it is not provided with a medullary sheath. Indeed, it is not until about the fifth month of foetal life that those fibres which are to form the white substance of the cerebro-spinal axis begin to acquire their coating of myelin. Further, this coating appears in the fibres of different fasciculi or tracts at different periods, and a knowledge of this fact has enabled anatomists to follow out the connexions of the tracts of fibres which compose the white matter of the brain and spinal medulla.

Every nerve-fibre is directly continuous by one extremity with a nerve-cell, whilst its opposite extremity breaks up into a number of ramifications, all of which end in relation to another nerve-cell, or in relation to certain tissues of the body, as, for example, muscle-fibres or the epithelial cells of the epidermis. The length of nerve-fibres, therefore, varies very greatly. Some fibres are short and merely bring two neighbouring nerve-cells into relation with each other; others travel long distances. Thus, a fibre arising from one of the motor cells of the lower end of the spinal medulla may, after leaving the spinal medulla, extend to the most outlying muscle in the sole of the foot, before it reaches its destination. But even when a fibre does not leave the central axis, a great length may be attained, and cells situated in the uppermost part of the brain give origin to fibres which pass down to the lower end of the spinal medulla.

It has already been explained that fibres which form the nerves may be classified into two sets, afferent and efferent. **Afferent nerve-fibres** conduct

impressions from the peripheral organs into the central nervous system; and as a change of consciousness, or, in other words, a sensation is a frequent result, these fibres are often called *sensory*. **Efferent nerve-fibres** carry impulses out from the brain and spinal medulla to peripheral organs. The majority of these fibres go to muscles and are termed *motor*; others, however, go to glands and are called *secretory*; whilst some are *inhibitory* and serve to carry impulses which restrain or check movement or secretion.

The **dendrites**, or protoplasmic processes of the nerve-cell, are thicker than the axon, and present a rough-edged irregular contour. They divide into numerous branches, and these gradually, as they pass from the cell-body, become more and more attenuated until finally they appear to end in free extremities. The branching of the dendritic processes sometimes attains a marvellous degree of complexity (Fig. 449), but it is commonly supposed that there is no anastomosis between the dendrites of neighbouring cells, or between the dendrites of the same cell.

It is commonly believed that the neuroblast passes through stages analogous to those shown in the diagram (Fig. 451); that just as a seed gives off a root which strikes downward, and leaves which grow upward, so the neuroblast sprouts out an

axon (*a*) and subsequently develops a bunch of dendritic processes (*b*). In the case of the axon reasons have already been given for not accepting this view as the whole explanation; and in the case of the dendrites, although the appearance of microscopic sections seems to favour the view expressed in the diagrams, the fact that the neuroblasts are united into a continuous network or syncytium at an early stage of development (see p. 503) raises the possibility that the dendrites may be formed by the gradually drawing out of the existing bridges as the linked cell-bodies become moved apart.

The Ganglia of the Sensory Nerves.—The cells found in the ganglia of the cerebral nerves and on the posterior or dorsal roots of the spinal nerves have a different origin, and present many points of contrast with neurones in the gray matter of the brain and spinal medulla. As already indicated, the ganglia in question are derived from the neural crest. The cells forming these ganglionic masses are somewhat oval in form, and each extremity or pole becomes drawn out into a process, so that the neurones become bipolar. These processes are distinguished as central and peripheral, according to the direction which they take. The central processes

penetrate the wall of the neural tube. In the region of the spinal medulla they form almost the whole of the fibres which enter into the composition of the posterior roots of the spinal nerves. In the substance of the cerebro-spinal axis they give off numerous collaterals, and after a course of varying extent they end, after the manner of an axon, in terminal arborisations, which enter into relationships with certain nerve-cells in the cerebro-spinal axis. The peripheral processes proceed along the path of the particular nerve with which they are associated, and they finally reach the skin or other sensory surface. Thus, to take one example: the majority of the fibres which go to the skin break up into fine terminal filaments, which end freely between the epithelial cells of the epidermis. The two processes of a ganglion cell, therefore, form the afferent fibres of the cerebro-spinal nerves, and constitute the path along which the influence of peripheral impressions is conducted towards the brain and spinal medulla. The

FIG. 452.—THREE STAGES IN THE DEVELOPMENT OF A CELL IN A SPINAL GANGLION.

body of the cell is, as it were, interposed in the path of such impulses.

But the original bipolar character of these cells, with very few exceptions (ganglia in connexion with the acoustic nerve and the bipolar nerve-cells in the olfactory mucous membrane), gradually undergoes a change which ultimately leads to their transformation into unipolar cells. This is brought about by the tendency which the cell-body has to grow to one side, viz., the side towards the surface of the ganglion (v. Lenhossek). This unilateral growth leads to a gradual approximation of the attached ends of the processes, and finally to a condition in which they appear to arise from the extremity of a short common stalk in a T-shaped manner (Fig. 452). It is interesting to note that in fishes the original bipolar condition of these cells is retained throughout life, without change.

Both the central and peripheral processes of these ganglionic cells become the axis-cylinders of nerve-fibres, which, acquiring a medullary sheath, belong therefore to the medullated variety. From this it might very naturally be thought that the ganglionic neurone, with its two axons and no typical dendrites, is a nervous unit very different from a neurone in the gray matter of the cerebro-spinal axis. It is believed by some, however (van Gehuchten and Cajal), that the peripheral process, in spite of its enclosure within a medullary sheath, and though presenting all the characters of a true axon, is in reality a dendrite. If this is the case, the

morphological difference between a dendrite and an axon disappears, and van Gehuchten's functional distinction alone remains characteristic, viz., that the axon is *cellulifugal* and conducts impulses away from the cell, whilst the dendrites are *cellulipetal* and conduct impulses towards the cell.

It is, however, more in accordance with the facts to regard the sensory neurones as genetically quite distinct from the rest of the nervous system (see p. 498).

Neuroglia.—The neuroglia is the supporting tissue of the cerebro-spinal axis. It may be considered to include two different forms of tissue, viz., the lining ependymal cells and the neuroglia proper. We place these under the one heading, seeing that they have a common developmental origin.

The **ependymal cells** are the columnar epithelial cells which line the central canal of the spinal medulla and the ventricles of the brain. In the embryonic condition a process from the deep extremity of each cell, traverses the entire thickness of the neural wall, and reaches the surface. It is not known whether this process exists in the adult.

The **neuroglia proper** is present in both the white and the gray matter of the cerebro-spinal axis. It constitutes an all-pervading basis substance, in which the various nerve elements are embedded in such a way that they are all bound together into a consistent mass, and are yet all severally isolated from each other. Neuroglia consists of cells and fine filaments. The fibrils are present in enormous numbers, and by their interlacements they constitute what appears to be a fine feltwork. At the points where the fibrils intercross may be seen the flattened *glial cells*. Whilst the neuroglia is for the most part intimately intermixed with the nerve elements, there are, in both brain and spinal medulla, certain localities where it is spread out in more or less pure layers. Thus, upon the surface of the brain and of the spinal medulla there is such a layer; likewise beneath the epithelial lining of the central canal and of the cavities of the brain there is a thin stratum of neuroglia.

The ependymal cells are derived from the original neuro-epithelial cells of the early neural tube, and in all probability the neuroglia proper has a similar origin. They both, therefore, are products of the ectoderm.

Summary.—1. The cerebro-spinal nervous system is composed of two parts, viz., (a) a **central part**, consisting of the brain and spinal medulla, with the efferent nerve-fibres which pass out from them; (b) the **ganglionic part**, with the afferent nerve-fibres.

2. Each of these parts has a different origin, and is composed of neurones which possess characteristic features.

3. The ganglionic neurones are derived from the primitive cells of the neural crest, and have each one process, which divides into two. Of these the central division enters the cerebro-spinal axis, whilst the peripheral division becomes connected with a peripheral part. The central fibres from the ganglionic cells in the region of the spinal medulla form the dorsal or posterior roots of the spinal nerves. The cells of origin of these posterior roots are outside the spinal medulla, and carry impulses into its substance.

4. The cerebro-spinal neurones are derived from the neuroblasts in the wall of the early neural tube. Certain of these furnish efferent nerve-fibres, which issue from the spinal medulla in separate bundles termed the anterior or ventral roots of the spinal nerves. In the case of the cerebral nerves, however, with the exception of the trigeminal and facial nerves, the efferent fibres are not thus separated from the afferent fibres at their attachment to the brain.

A, Ependymal cell.

B, Neuroglial cell.

[Note that the dorsal (posterior) aspect is below.]

5. The brain and spinal medulla, when studied by the naked eye, are seen to be composed of white matter and gray matter. The white matter forms very nearly two-thirds of the entire cerebro-spinal axis. It is composed of medullated nerve-fibres embedded in neuroglial tissue. The gray matter is composed of nerve-cells with their dendrites and axons. Some of the axons are in the form of naked axis cylinders, whilst others have a coating of myelin. Intimately intermixed with these parts is the neuroglia, which isolates them more or less completely from each other.

THE NATURE OF THE BRAIN

In the foregoing account it has been explained that the nervous system is composed of a series of afferent nerves bringing information from every part of the body into the central nervous system, from which efferent nerves pass out to the muscular and other active parts of the body, providing the means for translating such information into appropriate action. But it has been seen that the essential part of the central nervous system is the intercalated cells, which provide the means whereby the information brought in by any sensory nerve may be placed at the service of the whole body, and the response which it excites may be controlled and regulated by the condition of the rest of the body. The system of intercalated cells links together into one co-ordinated mechanism the whole nervous system, and, through it, every part of the body itself.

In some very primitive and remote ancestor of man (and in fact of the vast majority of animals) the front end of the nervous system became enhanced in importance to form a brain, which assumed a dominant influence over the rest. This was brought about in the first place by the fact that in an elongated prone animal moving forwards, the front end would naturally come first into relationship with any change in environment; and this earlier acquisition of information concerning the outside world would necessarily give the head end of the nervous system exceptional opportunities for influencing the rest of the nervous system. This predominance is further accentuated by the development in the head region of the organs of special sense, which provide mechanisms specially adapted to be influenced by light, sound, and such delicate chemical forms of stimulation as excite in ourselves sensations of smell and taste. As the information conveyed by these special senses, such as the scent of food or the visual impression of some enemy, must be able immediately to influence the movements of the whole body, it follows that a specially abundant system of intercalated elements link the central ends of these nerves of the special senses with the rest of the central nervous system. Moreover the predominant influence of the head end of the central nervous system implies that it must be provided with a specially large series of nerve-fibres, not only for the purpose of bringing this influence to bear upon the rest of the nervous system, but also of being itself brought into intimate relationship with the nervous system as a whole, seeing that sensory impulses are constantly pouring into every part of it.

Thus the head end of the central nervous system becomes the brain, which is characterised by a series of large irregular swellings, due to (*a*) the development around the insertion of each special sensory nerve of a mass, or group of masses, of intercalated cells which will enable the effects of the visual, acoustic, olfactory, gustatory or other sensations to influence the whole nervous system, and (*b*) the evolution of complicated systems of intercalated cells, which receive, and in a sense blend, impressions coming from all parts of the nervous system, and emit fibres which pass, directly or indirectly, to the various groups of motor nerve-cells and control their activities and, through them, the behaviour of the animal.

In the development of the human embryo this distinction between the head end and the rest of the central nervous system is indicated even before the medullary plate is completely folded up to form the neural tube. The widened

part represents the rudiment of the **encephalon** or brain; and the rest of the tube will become converted into the **medulla spinalis**.

If the attempt is made to analyse the meaning of the early broadening of the brain rudiment it will be found to be due in great measure to the fact that there is added to the margins of the medullary plate (see Fig. 442, E, p. 501) the material from which the sensitive part of the eye and the optic nerve will be developed; but soon after the neural tube is closed irregular swellings will make their appearance around the attachments of the nerves of smell, vision, hearing, and taste (Fig. 454),

FIG. 454.—DIAGRAM REPRESENTING THE CONNEXIONS OF SOME IMPORTANT SENSORY AND MOTOR TRACTS IN THE BRAIN to which references are made in pages 513 to 517. Motor paths in red; sensory in other colours.

and also the great vagus nerve that is widely distributed to the viscera of the neck, thorax, and abdomen.

But there are other factors besides these irregularities of growth of its walls which add complexity to the form of the encephalon in the embryo. In the course of their growth both parts (encephalon and medulla spinalis) of the neural tube undergo great extensions in length, breadth, and thickness; but in the case of the spinal medulla it is the increase in length that is most distinctive, whereas in the encephalon, the irregular expansion in breadth and thickness is more obtrusive. Nevertheless, the brain elongates more rapidly than that part of its mesodermal capsule which ultimately becomes the brain-case or cranium; and hence it becomes bent to permit of its being packed in the limited length of the cranial cavity. But if it is admitted that these mechanical considerations are in a measure responsible for the three bends which develop in the embryonic encephalon, their situation and the forms they assume are determined by the irregularities of growth inherent in the brain itself.

Even at a time, during the second week, when the anterior (oral) end of the neural tube is still open (**neuroporus anterior**), a right-angled bend has already developed in the rudiment of the brain (**cerebral vesicle**). Slightly less than half of the length of the vesicle had projected beyond the upper (anterior) end of the notochord and became flexed ventrally round it (Fig. 455).

FIG. 455.—LEFT LATERAL ASPECT OF AN EARLY HUMAN EMBRYO (after His's model, reversed).

Shortly after the appearance of the cephalic flexure a similar bending occurs in the region where the encephalon becomes continuous with the medulla spinalis (Fig. 456, A). This is the **cervical flexure**.

But at this stage, or even earlier (Fig. 456), there has been developing a third bend which produces effects differing from those just mentioned. At the end of the second week a slight bulging can be detected on the ventral side of the hind-

This bend is known as the **cephalic flexure**. The region of the brain vesicle in which it develops will later on become the **mesencephalon** or **mid-brain**; and even at the early stage of development now under consideration (Fig. 455) there is a slight narrowing of the tube (**isthmus**) that marks the boundary between the mid-brain and the **rhombencephalon** or **hind-brain**. Just beyond the end of the notochord there is an even fainter trace of a constriction indicating the line of demarcation between the mid-brain and the **prosencephalon** or **fore-brain**.

FIG. 456.—TWO STAGES IN THE DEVELOPMENT OF THE HUMAN BRAIN (after His).

A, Brain of an embryo of the third week. B, Brain of an embryo of five weeks.

brain (Fig. 455): during the next four weeks this steadily becomes accentuated and forms the **pontine flexure**. The convexity of the bend is directed ventrally, differing in this respect from both of the other flexures. This difference in direction has a profound influence upon the form which the hind-brain assumes. If a plastic tube is bent a strain is thrown upon the wall in the concavity

of the flexure. If this wall is strong and resisting, like the floor-plate of the neural tube (in the cases of the cephalic and cervical flexures) the bending does not affect the outline of the tube (in section) very materially. But when the strain is thrown upon the thin roof-plate during the development of the pontine flexure it is not strong enough to resist; it becomes stretched and allows the lateral walls of the neural tube to splay laterally in precisely the same manner as occurs when a rubber tube is bent towards a side which has been split (or weakened) longitudinally (Fig. 457). This mechanical factor determines the curious form assumed by the hind-brain at the end of the first month; and gives its cavity, the fourth ventricle, a lozenge or rhomboid form, when seen from its dorsal aspect through the thin translucent roof. For this reason the hind-brain is known as the **rhombencephalon**.

The rhombencephalon forms at first more than half of the encephalon, and as it expands it appears to become marked off from the rest by a constriction (the **isthmus rhombencephali**).

The development of the pontine flexure subdivides the rhombencephalon into two parts, one joined to the spinal medulla, the **myelencephalon**, and the other, joined to the rest of the brain, the **metencephalon**.

In the myelencephalon develop the nuclei of the nerves that regulate the activities of the heart, lungs, and a considerable part of the alimentary canal, and also the receptive nuclei of the nerves of taste. It is known as the **medulla oblongata**.

The insertion of the nervus acusticus in the neighbourhood of the outplayed lateral angle of the rhombencephalon leads to the profound transformation of the metencephalon. The nervus acusticus conveys into the hind-brain impulses which are stimulated by movements of fluid in the closed sac developed from the otic vesicle (Fig. 443, p. 501). The truly acoustic function of this apparatus is called into activity when the movements of this fluid

are caused by waves of sound transmitted to it from the outside world. But it is obvious that motion may also be set up in this fluid by changes in position of the body itself; in other words, movements in the fluid of the otic vesicle may stimulate nerves to convey to the brain information concerning the position and movements of the body itself. A great mass of nerve-cells develops around the insertion of the nervus acusticus (that part of it, however, which is called vestibular and is not concerned with the function of hearing) to make use of this information for the regulation of the movements of the body in balancing or equilibration. To enable this terminal vestibular nucleus the better to perform this function of equilibration, depending as it does upon the co-operation and adjustment of the movements of vast numbers of widely separated muscles, nerve tracts coming from muscles and skin areas of all parts of the body make their way into this vestibular nucleus; and it expands and forms a great excrescence which is known as the **cerebellum**. And as this cerebellum has to adjust the activities of all the muscles of the body it necessarily becomes the great organ of muscular co-ordination, and as such it is made use of by those parts of the brain which have to initiate and control complex actions such as skilled movements. It will be shown in the subsequent account how the

FIG. 457.—PROFILE VIEW OF THE BRAIN OF A HUMAN EMBRYO OF TEN WEEKS (His).

The various cerebral nerves are indicated by numerals.

- A, Cerebral diverticulum of hypophysis cerebri.
- B, Buccal diverticulum of hypophysis cerebri.

cerebellum becomes linked to the mesencephalon to co-ordinate the movements of the body which are excited by this part of the encephalon; and later how it becomes associated with the prosencephalon, when the latter becomes responsible for the acquisition and control of the most highly skilled actions. For the latter purpose a great pathway of nerve-fibres is laid down to connect the fore-brain with the cerebellum: the terminal stage of this connexion is situated upon the ventral (anterior) aspect of the metencephalon in the form of a great mass of transverse fibres. At one time these strands of nerve-fibres were looked upon as a bridge between the two lateral parts of the cerebellum: hence the name **pons** was applied to them. This term is now applied not only

to the fibres themselves, but also to the upward prolongation of the medulla oblongata, to the surface of which they are applied.

The subdivision of the rest of the encephalon into **mesencephalon** and **prosencephalon** develops later and is less fundamental than the primary demarcation between them and the rhombencephalon.

The visual apparatus is connected both with the mid-brain and the fore-brain, but at first more intimately with the former, to which nerve pathways are established to convey from the spinal medulla and medulla oblongata sensory impressions of touch and hearing. From the alar laminae of the mesencephalon there are developed four little hillocks (**colliculi**)—**corpora quadrigemina**—to receive these varied impressions and to enable them to influence the actions of the whole body. Special nerve paths are laid down from the corpora quadrigemina (Fig. 454) to the spinal medulla to enable the mid-brain to

FIG. 453.—THE BRAIN OF A HUMAN EMBRYO IN THE FIFTH WEEK (from His).

control the motor nuclei of the muscles of the trunk and limbs. These are called the **fasciculi tectospinales** (*tectum* being a synonym for corpora quadrigemina). A group of intercalated cells known as the **nucleus ruber** develops upon each side of the mesencephalon for the purpose of establishing connexions between the cerebellum and the mid-brain. When an impulse passes out of the mid-brain by the tectospinal bundle to excite some movement of the body, the red nucleus provides the link by which the cerebellum can co-ordinate the actions of the muscles involved. By means of a **fasciculus rubrospinalis** it can bring its influence to bear directly upon the nuclei of motor nerves in the brain and spinal medulla (Fig. 454).

The prosencephalon is at first, and in some of the lower fishes remains, the most insignificant of the three brain vesicles, but in the human brain (as also in that of most other vertebrates, though in varying degrees) a pair of enormous

excrescences—the cerebral hemispheres—are budded off from it; and they become the dominant part of the nervous system (Fig. 458).

Each hemisphere is formed, however, from a relatively small part of the lateral wall of the prosencephalon, the rest of which goes to form the optic diverticula, the thalamus, and the hypothalamus, among other structures. The cerebral hemisphere is at first pre-eminently olfactory in function, the nerves of smell being inserted directly into it. But impressions of the associated sense of taste make their way into the cerebral hemisphere in the most primitive vertebrates: the gustatory nerves are inserted into the medulla oblongata, but fibre-paths are laid down to establish connexions with the hypothalamus, which in turn emits fibres to the cerebral hemisphere (Fig. 454). The thalamus is a greatly swollen part of the prosencephalic wall adjoining the mesencephalon. Its main part receives sensory impressions brought up from the spinal medulla and the terminal nuclei of the sensory cerebral nerves and transmits them to the cerebral hemisphere. Its caudal portion becomes specialised as a special receptive nucleus for visual and acoustic impressions for transmission to the cerebral hemisphere. It is called the *metathalamus* or *corpora geniculata*. Thus the cerebral hemisphere from being essentially a receptive organ for smell impressions ultimately becomes the terminus of all the sensory paths, and the structure that is concerned with the consciousness of all kinds of sensations. It also controls the voluntary movements of one-half of the body and emits a great strand of fibres—*pedunculus cerebri*—to establish relations with the cerebellum and all the motor nuclei on the other side of the encephalon and spinal medulla (Fig. 454, p. 513).

MEDULLA SPINALIS.

The **spinal medulla** is that part of the central nervous system which occupies the upper two-thirds of the vertebral canal. It is an elongated cylindrical structure, slightly flattened in front and behind, which extends from the margin of the foramen magnum to the level of the inferior border of the body of the first lumbar vertebra or to the superior border of the body of the second lumbar vertebra. Its average length in the male is 45 cm. and in the female 43 cm.

A considerable amount of variation within certain limits (viz., the mid-point of the body of the last thoracic vertebra and the superior border of the body of the third lumbar vertebra) is observed in different individuals as to the precise level at which the spinal medulla ends inferiorly, and in the female there would appear to be a tendency for the medulla to reach a slightly lower point in the canal than in the male. Further, the relation presented by the spinal medulla to the vertebral column differs in a marked degree in the foetus and infant at different periods of development. Up to the third month of intra-uterine life the spinal medulla occupies the entire length of the vertebral canal; it extends downwards to the lowest limit of the vertebral canal. But from this time onwards, as growth proceeds, the vertebral column lengthens at a more rapid rate than the medulla. The spinal medulla, therefore, has the appearance of shrinking in an upward direction within its canal, and at birth its inferior end is usually found to be opposite the body of the third lumbar vertebra.

The attitude assumed by the individual affects to a small degree the position of the inferior end of the spinal medulla. Thus, when the trunk is bent well forwards, it is noticed that the terminal part of the spinal medulla rises slightly within its bony canal.

FIG. 459.—HUMAN FŒTUS IN THE THIRD MONTH OF DEVELOPMENT, WITH THE BRAIN AND SPINAL MEDULLA EXPOSED FROM BEHIND.

At the margin of the foramen magnum the spinal medulla becomes continuous with the medulla oblongata of the brain, whilst below, it tapers rapidly to a point and forms a conical extremity termed the **conus medullaris**. From the end of the conus medullaris a slender glistening thread is prolonged downwards within the vertebral canal, and finally anchors the spinal medulla to the back of the coccyx. This prolongation receives the name of the **filum terminale**. The diameter of the spinal medulla is very much shorter than that of the vertebral canal within which it lies. A wide interval is left between its surface and the walls of its canal, and this excess of space is clearly a provision for allowing free movement of the vertebral column without producing any jarring contact between the delicate spinal medulla and the surrounding bones.

Three protective membranes are wrapped around the spinal medulla. From within outwards these are termed (1) the **pia mater**, (2) the **arachnoid**, and (3) the **dura mater**. The **pia mater** is a fibrous membrane which forms the immediate investment. It is closely applied to the spinal medulla, and from its deep

FIG. 460.—THE CONUS MEDULLARIS AND THE FILUM TERMINALE EXPOSED WITHIN THE VERTEBRAL CANAL.

FIG. 461.—THE ROOTS OF ORIGIN OF THE SEVENTH THORACIC NERVE (semi-diagrammatic).

surface numerous fine septa penetrate into the substance of the spinal medulla. The **arachnoid** is an exceedingly delicate transparent membrane which is loosely wrapped around the spinal medulla so as to leave a considerable interval, termed the **subarachnoid space**, between itself and the **pia mater**, in which there is always a varying amount of cerebro-spinal fluid. Outside the **arachnoid**, the **dura mater** forms a wide, dense, fibrous, tubular sheath, which extends downwards within the vertebral canal for a considerable distance beyond the conical extremity of the spinal medulla. The spinal medulla is suspended within its sheath or *theca* of **dura mater** by two lateral wing-like ligaments, termed the **ligamenta denticulata**. These extend laterally from the sides of the spinal medulla and are attached by a series of pointed or tooth-like processes to the inner surface of the *theca* of **dura mater**. Between the wall of the vertebral canal and the **dura mater** there is a narrow interval, which is filled up by soft areolo-fatty tissue and numerous thin-walled veins arranged in a plexiform manner.

Thirty-one pairs of spinal nerves arise from the sides of the spinal medulla.

These are classified into eight cervical, twelve thoracic, five lumbar, five sacral, and one coccygeal; and according to the attachments of these groups of nerves the spinal medulla is arbitrarily subdivided into cervical, thoracic, lumbar, and sacral regions. In employing these terms, therefore, for different districts of the spinal medulla, it must be understood that the regions are determined by the nerve attachments and not by any direct relationship between these parts of the spinal medulla and the sections of the vertebral column which bear the same names.

Each spinal nerve is attached to the spinal medulla by an anterior or ventral and a posterior or dorsal root, and as these are traced to their central attachments they are seen to break up into a number of separate nerve fascicles or bundles, which spread out, in some cases very widely from each other, as they approach the side of the spinal medulla (Fig. 461). Each pair of nerves is therefore attached to a portion of spinal medulla of some length, and such a portion, with its pair of nerves, receives the name of a "segment of the spinal medulla." It must be clearly understood, however, that, in so far as the surface of the spinal medulla is concerned, there is no means of marking off one segment from another except by the nerve attachments.

In the cervical and lumbar regions of the spinal medulla the nerve-roots are somewhat crowded together, so that little or no interval is left between the adjoining root fila or fascicles of neighbouring nerves. In the thoracic region, however, distinct intervals may be observed, and the root fila are more loosely arranged. From this, it will be evident that the segments in different parts of the spinal medulla are not of equal length. In the cervical region the segments measure about 12 mm. in length, in the thoracic region from 20 to 24 mm., and in the lumbar region about 10 mm. The number of fila which attach the different nerve-roots to the spinal medulla is very different in different nerves, and is not necessarily the same in the same nerve-root in different individuals.

Owing to the great difference which exists between the length of the spinal medulla and the length of the vertebral column, the farther we pass down the greater the distance becomes between the attachment of the various nerve-roots to the spinal medulla and the intervertebral foramina through which the corresponding nerves leave the vertebral canal. The lower nerve-roots, therefore, have to traverse the vertebral canal for a considerable distance before they reach their apertures of emergence. It thus happens that the nerve-roots which spring from the lumbar and sacral regions of the spinal medulla attain a very great length and descend vertically in the lower part of the vertebral canal in a bunch or leash, in the midst of which lie the conus medullaris and the filum terminale. This great bundle of nerve-roots receives the appropriate name of the *cauda equina*.

Enlargements of the Spinal Medulla.—Throughout the greater part of the thoracic region, the spinal medulla presents a uniform girth and a very nearly circular outline when seen in transverse section. In the cervical and lumbar regions, however, it shows marked swellings. The *intumescentia cervicalis* or **cervical enlargement** is the more evident of the two. It begins very gradually at the upper end of the spinal medulla, attains its greatest breadth (12 to 14 mm.) opposite the fifth or sixth cervical vertebra, and finally subsides opposite the second thoracic vertebra. To this portion of the spinal medulla are attached the great nerves which supply the upper limbs. The *intumescentia lumbalis* or **lumbar enlargement** begins at the level of the tenth thoracic vertebra, and acquires its maximum transverse diameter (11 to 13 mm.) opposite the last thoracic vertebra. Below, it rapidly tapers away into the conus medullaris. To the lumbar enlargement are attached the great nerves of the lower limbs.

FIG. 462.—SECTION THROUGH THE CONUS MEDULLARIS AND THE CAUDA EQUINA AS THEY LIE IN THE VERTEBRAL CANAL.

These enlargements of the spinal medulla are associated with the outgrowth of the limbs. In the earlier developmental stages of the spinal medulla they are not present, and they take form only as the limbs become developed. In different animals their size corresponds with the degree of development of the limbs. Thus, in the long-armed orang and gibbon the cervical swelling stands out with a remarkable degree of prominence.

Development of the Spinal Medulla.—The early stages of the process by which the originally simple epithelial neural tube becomes converted into the central nervous system have already been considered. It remains to be explained how the features specially distinctive of the spinal medulla are produced.

In the early stages of the development of the spinal medulla (Fig. 463), the neuroblasts are found to be scattered in the intermediate of the three bands of

FIG. 463.—DIAGRAM OF TRANSVERSE SECTION OF THE LEFT HALF OF EARLY NEURAL TUBE.

which the thick lateral wall of the neural tube is composed—the mantle layer. These primitive nerve-cells soon congregate in much larger numbers in the ventral part of the basal lamina (Fig. 464), so that the mantle layer expands there into a broad excrescence, which is the rudiment of the *columna anterior* or *anterior cornu* of gray matter. This anterior column contains the efferent or motor nerve-cells, the axons of which emerge as the *radix anterior* of a spinal nerve. At this stage the rest of the mantle layer consists of a thin stratum of neuroblasts (Fig. 463), mainly intercalated cells, which receive the sensory impressions entering the spinal medulla through the *radix posterior*, and transmit impulses into axons passing (a) to the motor nuclei, (b) to the other side of the spinal medulla through the floor-plate (Fig. 463), or (c) into the superficial stratum (peripheral layer) of the spinal medulla where they bend upwards or downwards as constituent elements of the *funiculi* (or white columns). As development proceeds (Fig. 463) the *substantia grisea* formed of these intercalated cells becomes much more abundant and forms a broad blunt boss (Figs. 464, B and C), which is the rudiment of the *columna posterior* (O.T. *posterior cornu*).

The surfaces of these gray columns become coated with a layer of white sub-

stance, composed at first mainly of the axons of cells in the root ganglia and intercalated cells in the spinal medulla; and as these funiculi increase in size they help to mould the form of the columnæ griseæ. This is displayed best in the case of the posterior column (O.T. posterior cornu). The major portion of the white substance, *funiculus posterior*, which accumulates behind (and afterwards lies on the medial side of) the posterior column, does not consist of fibres springing from intercalated cells, either of the spinal medulla or any other part of the central nervous system, but of the direct continuations of the central processes of the cells in the spinal ganglion on the posterior root (Figs. 463 and 464). A large proportion of the fibres of the posterior root do not enter the gray columns immediately after their insertion into the alar lamina, but bifurcate to form two vertical nerve-fibres, one passing upwards, and the other downwards, in the *funiculus posterior* before they end in the *columna grisea*, some distance above or below the place where they gained admission to the medulla spinalis. As the spinal medulla grows, the originally blunt *columna posterior* becomes drawn backwards into an increasingly attenuated process, and the *funiculus posterior*, which was placed originally upon its lateral surface (Fig. 464, A), and then upon its posterior surface (Fig. 464, B), gradually assumes a wedge-shaped form (Figs. 464, C, and 466), upon the medial side of the gray matter.

Development of the Anterior Median Fissure, Posterior Median Septum, and of the Central Canal.—As the anterior columns of gray matter and the anterior funiculi of white matter increase in size, the anterior surface of the spinal medulla, on either side of the median plane, bulges forwards, and the *fissura mediana anterior* (Fig. 464, A, B, and C) is produced as the natural result.

There has been considerable discussion as to the mode of formation of the *posterior median septum*; but there is now no doubt as to the essential facts. Early in the third month the walls of the posterior three-fourths (of the sagittal extent) of the *central canal* of the spinal medulla become approximated (Fig. 464), and later they fuse to obliterate that part of the canal. But the part of the septum thus formed is only an insignificant portion of the whole. For most of the septum is produced by the gradual elongation of the epithelial cells lining the remnant of the central canal as the fibre-masses of the posterior funiculi expand and separate the posterior surface of the spinal medulla further and further from the situation of the canal (see Fig. 453, p. 511).

FIG. 465.—DIAGRAM OF THE SPINAL MEDULLA AS SEEN FROM BEHIND.

CVI shows the level of the 1st cervical vertebra; CVV of the 5th cervical vertebra; THVII of the 2nd thoracic vertebra; THVX of the 10th thoracic vertebra; THVXII of the 12th thoracic vertebra; LVII of the 2nd lumbar vertebra.

medulla are made, it is seen to be a bilateral structure which is partially subdivided into a right and left half by a median cleft (*fissura mediana anterior*) in front and a septum (*septum medianum posterius*) behind. The *fissura mediana anterior* penetrates only for a distance corresponding to somewhat less than a third of the antero-posterior diameter of the spinal medulla. The pia mater dips down into it and forms a fold or reduplication within it. The septum in the cervical and thoracic regions penetrates into the spinal medulla until it reaches a point somewhat beyond its centre. It is extremely narrow, and consists of ependymal and neuroglial elements, and is intimately connected with the adjacent sides of the two halves of the spinal medulla, between which it intervenes. The pia mater, which invests the surface of the spinal medulla, passes continuously over the posterior median septum and sends no prolongation of any kind into it. In the lumbar region of the spinal medulla the septum becomes shallower, whilst the anterior median fissure deepens, and ultimately in the inferior part of the spinal medulla the fissure and septum present a very nearly equal depth.

The two halves of the spinal medulla may show trifling differences in the arrangement of the parts which compose them; but to all intents and purposes they are symmetrical. They are joined together by a more or less broad band or commissure, which intervenes between the median fissure and the septum.

An inspection of the surface of each lateral half of the spinal medulla brings into view a longitudinal groove or furrow, at some little distance from the posterior median septum, which extends along the whole length of the spinal medulla. Along the bottom of this groove the fascicles of the posterior nerve-roots enter the spinal medulla in accurate linear order. It is called the **sulcus lateralis posterior**. There is no corresponding furrow on the anterior part of each lateral half of the spinal medulla in connexion with the emergence of the fascicles of the anterior nerve-roots. These fascicles emerge irregularly over a broad strip of the surface of the spinal medulla, which corresponds in its width to the thickness of the subjacent extremity of the anterior column of gray matter.

The **sulcus lateralis posterior** subdivides each lateral half of the spinal medulla into a small **funiculus posterior** and a much larger antero-lateral funiculus, and it is customary to map arbitrarily off the latter into a **funiculus lateralis** and a **funiculus anterior** by a line corresponding to the emergence of the most lateral of the fascicles of the anterior nerve-roots.

In the cervical region a distinct longitudinal groove may be observed on the surface of the posterior funiculus. It is placed rather nearer to the posterior median septum than to the posterior lateral furrow, and as it is traced down into the thoracic region it gradually becomes indistinct and finally disappears. This is called the **sulcus intermedius posterior**, and it marks on the surface the position of a septum of pia mater which dips into the spinal medulla and subdivides the posterior funiculus into a lateral part, termed the **fasciculus cuneatus** or the **column of Burdach**, and a medial portion, which receives the name of the **fasciculus gracilis** or the **column of Goll**.

INTERNAL STRUCTURE OF THE SPINAL MEDULLA.

The spinal medulla is composed of a central core of gray matter thickly coated on the outside by white matter. At only one spot does the gray matter come close to the surface, viz., at the bottom of the sulcus lateralis posterior.

Gray Matter of the Spinal Medulla.—The gray matter in the interior of the spinal medulla has the form of a fluted column, but it is customary to describe it as it appears in transverse sections. It then presents the appearance of the capital letter H. In each lateral half of the spinal medulla there is a semilunar or crescentic mass, shaped somewhat like a comma, the concavity of which is directed laterally and the convexity medially. The two crescents of opposite sides are connected across the median plane by a transverse band, which receives the name of the *commissura grisea* (gray commissure). The posterior median septum cuts through the spinal medulla until it reaches the gray commissure. The bottom of the anterior median fissure, however, is separated from it by an intervening strip of white matter, which is termed the *commissura anterior alba*, or anterior white commissure. In the gray commissure may be seen the central canal of the spinal medulla (*canalis centralis*), which tunnels the entire length of the spinal medulla and is just visible to the naked eye as a minute speck. The portion of the gray commissure which lies behind the central canal is called the *commissura posterior*; whilst the portion in front receives the name of the *commissura anterior grisea*.

Each crescentic mass of gray matter presents certain well-defined parts. The projecting portions which extend behind and in front of the connecting transverse gray commissure are termed respectively the posterior and the anterior columns of gray matter (*columnæ griseæ*). These stand out in marked contrast to each other. The *columna anterior* (O.T. *anterior cornu*) is short, thick, and very blunt at its extremity. Further, its extremity falls considerably short of the surface of the spinal medulla and is separated from it by a tolerably thick coating of white matter. Through this the fascicles of the anterior nerve-roots, as they emerge from the gray matter of the anterior column, pass on their way to the surface. Throughout the greater part of the spinal medulla the *columna posterior* (O.T. *posterior cornu*) is elongated and narrow, and is drawn out to a fine point, which almost reaches the bottom of the posterior lateral sulcus. This pointed extremity receives the name of the *apex columnæ posterioris*; the slightly swollen part which succeeds it is the *caput columnæ*; whilst the slightly constricted part adjoining the gray commissure goes under the name of the *cervix columnæ posterioris*.

The apex or tip of the posterior column differs considerably in appearance from the general mass of the gray matter. It is composed of a material which presents a lighter hue and has a somewhat translucent look. It is called the *substantia gelatinosa* [Rolandi], and, when seen in transverse section, it exhibits a V-shaped outline and fits on the posterior column like a cap.

A pointed and prominent triangular projection juts out from the lateral aspect of the gray matter nearly opposite the gray commissure. This is the *columna lateralis* (O.T. *lateral cornu*), and it is best marked in the upper thoracic region (Fig. 467, B). Traced upwards it becomes absorbed in the greatly expanded anterior column of the cervical swelling, but it reappears again in the upper part of the spinal medulla, and is particularly noticeable in the second and third cervical

FIG. 466.—TRANSVERSE SECTION THROUGH THE SUPERIOR PART OF THE CERVICAL REGION OF THE SPINAL MEDULLA OF AN ORANG. (From a specimen prepared by the Weigert-Pal method, by which the white matter is rendered dark whilst the gray matter is bleached.)

segments; followed in a downward direction it blends with the anterior column in the lumbar swelling and contributes to the thickening of that column.

The gray matter is for the most part mapped off from the surrounding white matter with a considerable degree of sharpness; but in the cervical region, on the lateral aspect of the crescentic mass and in the angle between the anterior and posterior columns, fine bands of gray matter penetrate the white matter, and, joining with each other, form a network, the meshes of which enclose small islands of white matter. This constitutes what is called the *formatio reticularis*. Although best marked in the cervical region, traces of the same reticular formation may be detected in lower segments of the spinal medulla.

Characters presented by the Gray Matter in Different Regions of the Spinal Medulla.—The gray matter is not present in equal quantity nor does it exhibit the same form in all regions of the spinal medulla. Indeed, each segment presents its own special characters in both of these respects. It is not necessary, however, in the present instance, to enter into this matter with any degree of minute detail. It will be sufficient if the broad distinctions which are evident in the different regions are pointed out.

It may be regarded as a general law that, wherever there is an increase in the size of the nerves attached to a particular part of the spinal medulla, a corresponding increase in the amount of gray matter will be observed. It follows from this that the regions where the gray matter bulks most largely are the lumbar and the cervical swellings. The great nerve-roots which go to form the nerves of the large limb-plexuses enter and pass out from those portions of the spinal medulla. In the thoracic region there is a reduction in the quantity of gray matter in correspondence with the smaller size of the thoracic nerves.

In the *thoracic region* (Fig. 467, B) both columns of gray matter are narrow, although the distinction between the anterior column and the still more attenuated posterior column is sufficiently manifest. In this region the lateral column of gray matter is likewise characteristic, and the *substantia gelatinosa* in transverse section is pointed and spear-shaped.

In the *upper three segments* of the *cervical region* the anterior columns of gray matter are not large and resemble the corresponding columns in the thoracic region. A lateral column also is present. But in these segments (and more especially in the first and second) there is a marked attenuation of the neck of the posterior column, and the posterior commissure is very broad.

In the *cervical swelling* the contrast between the two columns is most striking; the anterior column is of great size and presents a very broad surface towards the anterior aspect of the spinal medulla, whilst the posterior column remains narrow. This great increase in the bulk of the anterior column is due to a marked addition of gray matter on the lateral side of the column, and seeing that this additional matter is traversed by a greater number of fibres, it stands out, in well-prepared specimens, more or less distinctly from the part of the column which lies to the medial side, and which may be considered to represent the entire anterior column in the thoracic and upper cervical segments. Within this lateral addition to the anterior column are placed those collections of cells which constitute the nuclei of origin of the motor nerves of the muscles of the upper limb. The characteristic thickening of the anterior column of gray matter is evident, therefore, in those segments of the spinal medulla to which the nerves which enter the brachial plexus are attached, viz., the lower five cervical segments and the first thoracic segment.

In the *lumbar swelling* the anterior columns again broaden out, and for the same reason as in the case of the corresponding columns in the cervical swelling. The nuclear masses which contain the cells from which the motor fibres which supply the muscles of the lower limbs take origin are added to the lateral aspect of the columns and give them a very characteristic appearance. In this region of the spinal medulla, however, the posterior columns are also broad and are capped by *substantia gelatinosa* which in transverse section presents a semilunar outline. There is consequently no difficulty in distinguishing, from an inspection of the gray matter alone, between transverse sections of the spinal medulla taken from the cervical and lumbar swellings of the spinal medulla.

In the lower part of the *conus medullaris* the gray matter in each lateral half of the spinal medulla assumes the form of an oval mass joined to its fellow of the opposite side by a thick gray commissure. Here, almost the entire bulk of the spinal medulla consists of gray matter, seeing that the white matter is reduced to such an extent that it forms only a thin coating on the outside.

White Matter of the Spinal Medulla.—In transverse sections of the spinal medulla the three funiculi into which the white matter is subdivided become very

B.—Through the mid-thoracic region.

A.—Cervical region—at the level of the fifth cervical nerve.

C.—Through the lumbar region at the level of the fourth lumbar nerve.

D.—Through the sacral region at the level of the third sacral nerve. (From a specimen prepared by Dr. A. Bruce.)

FIG. 467.—SECTION THROUGH EACH OF THE FOUR REGIONS OF THE MEDULLA SPINALIS. (From specimens prepared by the Weigert-Pal method; therefore the white matter is rendered dark in colour whilst the gray matter is bleached.)

apparent. The **posterior funiculus** is wedge-shaped, and lies between the posterior median septum and the posterior column of gray matter. The **lateral funiculus** occupies the concavity of the gray crescent. Behind, it is bounded by the posterior column of gray matter and the sulcus lateralis posterior, whilst in front it extends as far as the most lateral fasciculi of the anterior nerve-roots as they pass out from the anterior column. The **anterior funiculus** includes the white matter between the anterior median fissure and the anterior column of gray matter, and also the white

matter which separates the broad extremity of the anterior column from the surface of the spinal medulla. This latter portion of the anterior funiculus is traversed by the emerging fascicles of the anterior nerve-roots.

In cross-sections of the spinal medulla the partition of pia mater, which dips in at the sulcus intermedius posterior and divides the posterior funiculus into the medial *fasciculus gracilis* and the lateral *fasciculus cuneatus*, is very strongly marked in the cervical regions, but as it is traced downwards into the thoracic region it becomes shorter and fainter, and finally disappears altogether at the level of the eighth thoracic nerve. Below this point there is no visible demarcation of the posterior funiculus into two parts.

The white matter is not present in equal quantity throughout the entire length of the spinal medulla. It increases steadily from below upwards, and this increase is most noticeable in the lateral and posterior funiculi. In the lower part of the *conus medullaris* the amount of gray matter is actually greater than that of the white matter: but very soon this state of affairs is changed, and in the lumbar region the proportion of gray to white matter is approximately as 1:2.1; in the thoracic region as 1:5; and in the cervical region as 1:5.1. When it is remembered how the gray matter expands in the lumbar and cervical regions, and how greatly it becomes reduced in the thoracic region, the significance of these figures will become more apparent.

Canalis Centralis.—As previously stated, the **central canal** is found in the gray commissure. It is a very minute tunnel, barely visible to the naked eye when seen in transverse section, and it traverses the entire length of the spinal medulla. Above, it passes into the medulla oblongata, and finally opens into the fourth ventricle of the brain; below, it is continued for a variable distance into the *filum terminale*, and in this it ends blindly. Only in the lumbar region does the central canal occupy the centre of the spinal medulla. Above this level, in the thoracic and cervical regions, it lies very much nearer the anterior than the posterior aspect of the spinal medulla; whilst below the lumbar region, as it is traced down into the *conus medullaris*, it inclines backwards and approaches the posterior aspect of the spinal medulla. The calibre of the canal also varies somewhat in different parts of the spinal medulla. It is narrowest in the thoracic region; and in the lower part of the *conus medullaris* it expands into a distinct fusiform dilatation (very nearly 1 mm. in transverse diameter), which is termed the **ventriculus terminalis** (Krause).

The central canal is lined with a layer of ciliated columnar cells, the deep tapering ends of which are prolonged into slender processes which penetrate into the substance of the spinal medulla. These cells constitute the lining ependymal cells of the canal. The cilia of the epithelial cells are very early lost, and it is not uncommon to find the canal blocked up by epithelial debris.

The central canal is of interest because it represents in the adult the relatively wide lumen of the early ectodermal neural tube from which the spinal medulla is developed.

Filum Terminale.—The delicate thread to which this name is applied is continuous with the inferior tapered end of the *conus medullaris*. It is easily distinguished by its silvery and glistening appearance from the numerous long nerve-roots (*cauda equina*) amidst which it lies. It is about six inches long, and down to the level of the second sacral vertebra it is enclosed with the surrounding nerve-roots within the dura mater. Below this point the dura mater is applied directly to the surface of the *filum terminale* and is called ***filum duræ matris spinalis***. The *filum terminale* proceeds downwards in the sacral canal, and finally receives attachment to the periosteum on the posterior aspect of the coccyx (Fig. 460, p. 518). It is customary to speak of the *filum* as consisting of two parts, viz., the *filum terminale internum* and the *filum terminale externum*, or the part inside and the part outside the tube of dura mater.

The ***filum terminale externum*** is simply a fibrous thread, strengthened by the prolongation it receives from the dura mater. The ***filum terminale internum*** is composed largely of pia mater; but in its superior half it encloses the terminal part of the central canal, and around this a variable amount of the gray substance of the cord is prolonged downwards into the *filum*. When transverse sections are made through

the superior part of the filum terminale internum some bundles of medullated nerve-fibres are observed clinging to its sides, and with these are associated some nerve-cells identical with those in the spinal ganglia. These represent rudimentary or aborted caudal nerves (Raubert).

SUMMARY OF THE CHIEF CHARACTERS PRESENTED BY THE SPINAL MEDULLA
IN ITS DIFFERENT REGIONS.

Cervical Region.	Thoracic Region.	Lumbar Region.	Sacral Region.
In transverse section, outline of spinal medulla transversely oval; in the middle of the cervical swelling the transverse diameter being nearly one-third longer than the antero-posterior diameter.	In transverse section, outline of spinal medulla more nearly circular; but still the transverse diameter is greater than the antero-posterior diameter.	In transverse section, outline of spinal medulla more nearly circular than in thoracic region.	In transverse section, outline of spinal medulla , nearly circular, but still somewhat compressed from before backwards.
Postero-median septum very deep, extending beyond the centre of the spinal medulla; antero-median fissure shallow.	Postero-median septum very deep, extending beyond centre of the spinal medulla: antero-median fissure shallow.	Postero-median septum not nearly so deep as in regions above: antero-median fissure , on the other hand, much deeper.	Postero-median septum and antero-median fissure of equal depth.
Gray matter greatly increased in quantity in the cervical swelling: anterior column thick and massive; posterior column slender in comparison. Lateral column evident only above the level of the fourth cervical nerve. Processus reticularis strongly marked.	Gray matter greatly reduced in quantity. Both columns slender. Lateral column well marked. Processus reticularis scarcely apparent.	Gray matter greatly increased in the lumbar swelling. Both columns very thick and massive. Lateral column absorbed in anterior column. Processus reticularis absent.	Both columns of gray matter very thick and massive. Lateral column apparent. No processus reticularis.
White matter in great quantity, and especially massed in the lateral and posterior funiculi.	White matter less in quantity than in cervical region, but bulking largely in comparison with the quantity of gray matter.	White matter small in quantity compared with higher regions, and very small in amount in relation to increased quantity of gray matter.	White matter very small in quantity in comparison with the gray matter.
Sulcus intermedius posterior and corresponding septum well marked.	Sulcus intermedius posterior absent; but the corresponding septum can be traced as low down as the eighth thoracic nerve.	No sulcus intermedius posterior or corresponding septum.	No sulcus intermedius posterior and no corresponding septum.
Central canal considerably nearer the anterior surface than the posterior surface of the spinal medulla.	Central canal considerably nearer the anterior surface than the posterior surface of the spinal medulla.	Central canal in the centre of the spinal medulla.	Central canal in the centre of the spinal medulla.

COMPONENT PARTS OF THE GRAY MATTER OF THE SPINAL MEDULLA.

Neuroglia enters largely into the constitution of the gray matter of the spinal medulla. It forms a bed within which the nervous elements are distributed. These nervous elements consist of (1) nerve-cells and (2) nerve-fibres—both medullated and non-medullated. The nerve-cells lie in small spaces in the

neuroglia, whilst the nerve-fibres traverse fine passages the walls of which are formed of the same substance. The neuroglia is thus an all-pervading basis substance, which isolates more or less completely the nervous elements one from the other, and at the same time binds them together into a consistent solid mass. In two situations the gray matter presents peculiar features, viz., the apex of the posterior column and the tissue surrounding the central canal. In both situations the gray matter stains more deeply with carmine and presents a more translucent appearance; in other respects the *substantia grisea centralis* and the *substantia gelatinosa* are very different.

The *substantia grisea centralis* forms a thick ring around the central canal. It is traversed by the fine processes which proceed from the deep ends of the ependymal cells which line the canal. It is composed almost entirely of neuroglia.

In transverse sections of the spinal medulla the *substantia gelatinosa*, in the cervical and thoracic regions, presents the appearance of a V-shaped mass, embracing the extremity of the posterior column of gray matter; in the lumbar region this cap assumes a semilunar outline.

In the *substantia gelatinosa* the neuroglia is present in small quantity, and small nerve-cells are developed within it in considerable numbers.

Nerve-Cells.—The nerve-cells are scattered plentifully throughout the gray matter, but perhaps not in such great numbers as might be expected when we note the enormous number of nerve-fibres with which they stand in relation. They are all, without exception, multipolar, and send off from their various aspects several branching protoplasmic processes or dendrites, and one axon, which becomes the axis-cylinder of a nerve-fibre. In size they vary considerably, and as a rule (to which, however, there are many exceptions) the bulk of a nerve-cell has a more or less definite relation to the length of the axis-cylinder which proceeds from it.

When the nerve-cells are studied in a series of transverse sections of the spinal medulla, it will be noticed that a large proportion of them are grouped in clusters in certain districts of the gray matter; and as these groups are seen in very much the same position in successive sections, it is clear that these cells are arranged in longitudinal columns of greater or less length. Thus we recognise (1) a ventral group or column of cells in the anterior column of gray matter; (2) an intermedio-lateral group or column in the lateral column of gray matter, where this exists; and (3) a posterior vesicular column of cells (*nucleus dorsalis*), forming a most conspicuous group in the medial part of the neck of the posterior column in the thoracic region of the spinal medulla.

Other cells, besides those forming these columns, are scattered somewhat irregularly throughout the gray matter of the posterior column and the part of the gray crescent which lies between the two columns; and although these also in some measure may be classified into groups, the arrangement thus effected is not of so definite a character as to justify us in dwelling upon it in the present instance.

Ventral Cell-Column and the Origin of the Fibres of the Anterior Nerve-roots.—The ventral cell-group occupies the anterior column of gray matter, and in it are found the largest and most conspicuous cells in the spinal medulla. It extends from one end of the medulla to the other. These ventral nerve-cells have numerous wide-spreading dendritic processes, and it is to be noticed that certain of these dendrites do not confine their ramifications to the gray matter. Thus, some of the cells along the medial border of the anterior column of gray matter send dendrites across the median plane in the anterior commissure to end in the anterior gray column of the opposite side; whilst others, lying along the lateral margin of the anterior column of gray matter, send dendrites in amongst the nerve-fibres of the adjoining white matter.

The axons or axis-cylinder processes of a large proportion of the ventral cells converge together; and, becoming medullated, they form bundles which pass out from the gray matter, and through the white matter which separates the thick end of the anterior column from the surface of the spinal medulla, to emerge finally as the fila of the anterior nerve-roots. These cells, then, are the sources from which the nerve-fibres of the anterior nerve-roots proceed, and in consequence they are frequently spoken of as the "motor cells" of the spinal medulla. Whilst this is

the arrangement of the axons of the great majority of the motor cells, it should be noted that a few cross the median plane in the anterior white commissure and emerge in the fila of origin of the opposite anterior nerve-root.

The ventral cells are not scattered uniformly throughout the anterior column of gray matter. They are aggregated more closely together in certain parts of the anterior column, and thus form sub-groups or columns more or less perfectly marked off from each other.

Thus, one sub-group or column of ventral cells occupies the medial part of the anterior column of gray matter throughout almost its whole length. In only two segments of the medulla is it absent, viz., the fifth lumbar and the first sacral; at this level in the spinal medulla alone is its continuity broken (Bruce). It is termed the *antero-median column* or *group* of ventral cells. Behind this cell-column there is another classed with it to which the name of *postero-median column* or *group* is given, but this column of cells is not continuous throughout the entire length of the medulla. It is present in the thoracic region of the spinal medulla, where the motor nuclei for the muscles of the limbs are absent; and it is seen also in two or three of the segments of the cervical region and in the first lumbar segment (Bruce); elsewhere it is not represented.

In the cervical and lumbar swellings of the medulla, where the marked lateral out-

FIG. 468.—SECTION THROUGH THE FIFTH CERVICAL SEGMENT OF THE SPINAL MEDULLA.
(To a large extent founded on Plates in Dr. Bruce's *Atlas*.)

growth is added to the lateral side of the anterior column of gray matter, certain groups of large multipolar cells are visible. These are the nuclei of origin of the motor-fibres which supply the muscles of the limbs, and consequently they are not represented in the upper three cervical segments of the spinal medulla; nor in any of the thoracic segments, with the exception of the first thoracic segment; nor in the lowest two sacral segments.

These *lateral cells* are arranged in several columns, which extend for varying distances in the superadded lateral parts of the anterior column of gray matter. The two main columns are an *antero-lateral* and a *postero-lateral column*; in certain segments there is likewise a *retro-postero-lateral column*, and in a number of segments in the lumbar and sacral regions a *central column* of cells (Bruce).

There cannot be a doubt that the grouping of the motor cells in the anterior horn of gray matter of the medulla stands in relation to the muscle groups to which their axis-cylinder processes are distributed; but from what has been said it will be apparent that sharply defined cell-clusters associated with particular muscles do not exist. Still, much can be learned regarding the localisation of the motor nuclei in the anterior column of gray matter of the medulla from the study of the changes which occur in the cell-columns after atrophy of isolated muscles or groups of muscles, and after complete or partial amputations of limbs. It has been pointed out that the long muscles of the trunk (as, for example, the different parts of the sacro-spinalis muscle) receive nerve-fibres from all the

segments of the medulla. Now, we have noted that there is only one cell-column, the ventro-median column, which pursues an almost uninterrupted course throughout the entire length of the medulla. It may be assumed, therefore, that the nerve-fibres which go to these long trunk-muscles take origin in these medial cells.

Edinger states that in the anterior column of gray matter the nuclei of origin of the nerves which supply the proximal muscles are medially placed; that those for the distal muscles are in general situated laterally. If this were the case, the cells connected with the shoulder muscles would lie nearer the middle of the anterior column of gray matter than those which are connected with the hand-muscles. In cases where the forearm and hand, or the leg and the foot, are amputated, it would appear that it is the pos-

FIG. 469.—SECTION THROUGH THE EIGHTH THORACIC SEGMENT OF THE SPINAL MEDULLA. (To a large extent founded on Plates in Dr. Bruce's *Atlas*.)

tero-lateral column of cells that shows changes in consequence of its separation from the muscles to which its fibres are distributed.¹

Intermedio-lateral Cell-column.—The intermedio-lateral cells form a long slender column which extends throughout the entire thoracic region of the medulla in the lateral column of gray matter. It is also prolonged downwards into the first and second lumbar segments, where it disappears. In transverse sections through the medulla this cell-group presents a very characteristic appearance, because the cells which compose it are small and are closely packed together. Although these cells, as a continuous column, are restricted to the region indicated, it should be noted that the same group of cells reappears above, in certain of the cervical segments, and also in the third and fourth sacral segments. From these cells very fine fibres arise and leave the medulla spinal, intermingled with the motor fibres of the anterior nerve-roots; they pass into the sympathetic ganglia, of which they con-

FIG. 470.—SECTION THROUGH THE THIRD LUMBAR SEGMENT OF THE SPINAL MEDULLA TO SHOW THE GROUPING OF THE MOTOR CELLS. (To a large extent founded on Plates in Dr. Bruce's *Atlas*.)

¹ Those who seek further information regarding the grouping of the ventral cells of the medulla may with advantage study Dr. Alexander Bruce's *Atlas of the Spinal Cord*.

stitute the white rami communicantes. They represent the splanchnic efferent fibres of the medulla spinalis.

Nucleus Dorsalis (O.T. Clarke's Column).—This occupies the posterior column of gray matter and is the most conspicuous of all the cell-groups in the medulla. It does not, however, extend along the whole length of the medulla; indeed it is almost entirely confined to the "dorsal" region, which is the reason for the designation "nucleus dorsalis." (*When, in the recent revision of nomenclature, the term "thoracic" was substituted for "dorsal" the revisers omitted to change the name of this structure to "thoracic"*). Above, it begins opposite the seventh or eighth cervical nerve, whilst below, it may be traced to the level of the second lumbar nerve, where it disappears. In transverse section of the medulla it presents an oval outline, and is seen in the median part of the cervix of the posterior column of gray matter, immediately behind the gray commissure (Fig. 469, p. 530). On the lateral side it is circumscribed by numerous curved fibres from the entering posterior nerve-root, and in the lower thoracic region of the spinal medulla (opposite the eleventh and twelfth thoracic nerves) it becomes so marked that it forms a bulging on the median aspect of the posterior gray column.

The cells of the nucleus dorsalis are large, and possess several dendritic processes. The axons enter the lateral funiculus of white matter and there form a strand of fibres, which will later on be described under the name of the *fasciculus spino-cerebellaris* (*wrongly called "cerebellospinalis" in the B.N.A.*).

Nerve-fibres in the Gray Matter of the Medulla Spinalis.

Nerve-fibres both of the medullated and non-medullated variety pervade every part of the gray matter. They are of three kinds, viz., (1) collaterals, (2) terminations of nerve-fibres, (3) axons given off by the cells. Many of the nerve-fibres which compose the funiculi of the medulla give off numerous fine collateral branches, which pass into the gray matter from all sides and finally end in relation with the nerve-cells. The majority of the nerve-fibres themselves, which thus give off collaterals, finally enter the gray matter, and end similarly. The axons of the majority of the cells leave the gray matter and emerge either for the purpose of entering a peripheral nerve or for the purpose of entering a strand of fibres in the white matter of the spinal medulla.

The nerve-fibres thus derived are interwoven together in the gray matter in a dense inextricable interlacement.

COMPONENT PARTS OF THE WHITE MATTER OF THE SPINAL MEDULLA.

The white matter of the spinal medulla is composed of medullated nerve-fibres, embedded in neuroglia. The fibres, for the most part, pursue a longitudinal course; and, from the deep surface of the pia mater which surrounds the medulla, fibrous septa or partitions are carried in along vertical planes between the fibres so as

FIG. 471.—SECTION THROUGH THE FIRST SACRAL SEGMENT OF THE SPINAL MEDULLA TO SHOW THE GROUPING OF THE MOTOR NERVE-CELLS. (To a large extent founded on Plates in Dr. Bruce's *Atlas*.)

to form an irregular and very imperfect fibrous framework of support. The neuroglia is disposed in a layer of varying thickness around the medulla, subjacent to the pia mater, and is carried into the medulla so as to give a coating to both sides of the various pial septa. The neuroglia is disposed also around the various nerve-fibres, so that each of these may be said to lie in a canal or tunnel of this substance. The nerve-fibres are all medullated, but they are not provided with primitive sheaths. It is the medullary substance of the nerve-fibres which gives to the white matter its opaque, milky-white appearance. When a thin transverse section of the medulla is stained in carmine and examined under the microscope the white matter presents the appearance of a series of closely applied circles, each with a dot in the centre. The dot is the transversely divided axis-cylinder of a nerve-fibre, and the dark ring which forms the circumference of the circle represents the wall of the neuroglial canal which is occupied by the fibre. The medullary substance is very faintly seen. It presents a filmy or cloudy appearance between the axis-cylinder and the neuroglial ring.

FIG. 472.—TRANSVERSE SECTION THROUGH THE WHITE MATTER OF THE MEDULLA SPINALIS, as seen through the microscope.

Arrangement of the Nerve-fibres of the White Matter in Fasciculi or Tracts.—When the white matter of a healthy adult spinal medulla is examined, the fibres which compose it are seen to vary considerably in point of size; and although there are special places where large fibres—or it may be small fibres—are present in greater numbers than elsewhere, yet, as a rule, both great and small fibres are mixed up together. No conclusive evidence can be obtained in such a medulla, by any means at our disposal, of the fact that the longitudinally arranged fibres are grouped together in more or less definite tracts or fasciculi, the fibres of which run a definite course and present definite connexions. Yet this is known to be the case, and the existence of these separate tracts has been proved both by embryological investigation as well as by the examination of the effects of injuries produced experimentally or accidentally on the nervous system in living beings.

By the **experimental method** it has been shown that when a nerve-fibre is severed the part which is detached from the nerve-cell from which it is an offshoot degenerates, whilst the part which remains connected with the nerve-cell undergoes little or no change. This is called the law of "Wallerian" degeneration. Thus, if in a living animal one-half of the spinal medulla is cut across, and after a few weeks the animal is killed and the medulla examined, it will be seen that there are degenerated tracts of fibres in the white matter, both above and below the plane of division; but, still further, it will also be manifest that the tracts which are degenerated above the plane of division are not the same as those which are degenerated in the part of the medulla which lies below this level. The interpretation of this is obvious. The nerve-tracts which have degenerated above the plane of section are the offshoots of nerve-cells which lie in lower segments of the medulla or in spinal ganglia below the plane of section. Severed from these nerve-cells, they undergo what is called ascending degeneration. The nerve-tracts, on the other hand, which have degenerated in the portion of the medulla below the plane of division are the axons of cells which lie at a higher level than the plane of section, either in higher segments of the spinal medulla or in the brain itself. Cut off from the nerve-cells from which they proceed, they present an example of descending degeneration.

The **embryological method** was first employed by Flechsig, and it is often referred to as Flechsig's method. It is based upon the fact that nerve-fibres in the earliest stages of their development consist of naked axis-cylinders, and are not provided with medullary sheaths. Further, the nerve-fibres of different strands assume the medullary sheaths at different periods. By examining the foetal central nervous system at different stages of its development, it is a comparatively easy matter to locate the different tracts of fibres by evidence of this kind. Speaking broadly, the tracts which myelinate first are those which bring the central nervous system into relation with the peripheral parts (skin, muscles, etc.); then those fibres which bind the various segments of the central nervous system together; next, those which connect the spinal medulla with the cerebellum; and, lastly, the tracts which connect the spinal medulla with the cerebral hemispheres. The nervous apparatus for the performance of automatic movements is fully

provided, therefore, before this is put under the control and direction of the higher centres. It by no means follows that in all the higher animals corresponding strands myelinate at relatively corresponding periods. Take the case of a young animal which from the time of its birth is able to move about and perform voluntary movements of various kinds in a more or less perfect manner, and compare it with the helpless new-born infant which is only capable of exhibiting automatic movements. In the former the cerebro-spinal tracts, or motor tracts, which descend from the cerebrum into the spinal medulla, and which are the paths along which the mandates of the will travel, myelinate at an early period; whilst in the infant the corresponding fibres do not obtain their medullary sheaths until after birth. The study of the dates, therefore, at which the various strands of nerve-fibres myelinate not only gives the anatomist a means of locating their position in the white matter of the central nervous system, but it also affords the physiologist most important information regarding their functions, and also the periods at which these functions are called into play.

It is a matter of interest to note that influences which either accelerate or retard the periods at which nerve-fibres are brought into functional activity have also an effect in determining the dates at which these fibres assume their sheaths of myelin. Thus, when a child is prematurely born the whole process of myelination is, as it were, hurried up; and further, when in new-born animals light is freely admitted to one eye whilst it is carefully excluded from the other, the fibres of the optic nerve of the former myelinate more rapidly than those of the opposite nerve.

Study of the minute structure (Anatomical method) of the central nervous system, especially of material that has been stained by the methods of Golgi and Ramon y Cajal or by the use of methylene blue, completes the results attained by these other methods, by demonstrating the precise mode of origin and termination of the various fasciculi.

Posterior Funiculus and the Posterior Roots of the Spinal Nerves.—In the cervical and upper thoracic regions of the spinal medulla the posterior funiculus is divided by the posterior intermediate sulcus and septum into the *fasciculus cuneatus*, which lies lateral and next to the posterior column of gray matter, and the *fasciculus gracilis*, which lies medially and next to the posterior-median septum. The *fasciculus cuneatus* is composed of nerve-fibres, which are for the most part larger than those entering into the formation of the *fasciculus gracilis*, and both tracts have a most intimate relation to the posterior nerve-roots; indeed, they are both composed almost entirely of fibres which enter the medulla by these roots, and then pursue a longitudinal course.

The nerve-fibres which form the posterior nerve-roots, on entering the medulla along the sulcus lateralis posterior, divide within the *fasciculus cuneatus* into ascending and descending branches. These branches diverge abruptly from each other; and the former take an upward course, whilst the latter proceed downwards. The **descending fibres** are, as a rule, short, and soon end in the gray matter of the spinal medulla. These descending fibres occupy an area in the posterior funiculus along the line of separation of the *fasciculus gracilis* and the *fasciculus cuneatus*, and, hence, may be called the *fasciculus interfascicularis* (comma tract of Schultze). This area, when the spinal medulla is divided, undergoes descending degeneration and then presents a comma-shaped outline. (Fig. 473).

The **ascending fibres** vary greatly in length, and at differing distances from the point where the parent fibres enter the medulla they end in the gray matter. A small contribution, however, of ascending fibres, from each posterior nerve-root, extends upwards to the upper end of the spinal medulla, to end in the medulla oblongata (Figs. 474 and 475).

As each posterior nerve-root enters, its fibres range themselves in the lateral part of the *fasciculus cuneatus* close up against the posterior column of gray matter. The nerve-fibres of the nerve-root next above take the same position, and consequently those which entered from the nerve immediately below are displaced medially, and come to lie in the *fasciculus cuneatus* nearer to the median plane. This process goes on as each nerve-root enters, and the result is that the fibres of the lower nerves are gradually pushed nearer and nearer to the posterior median septum in a successive series of lamellar tracts. Of course, the greater proportion of the fibres which are thus carried upwards from the posterior nerve-roots sooner or later leave the posterior funiculus and enter the gray matter, to end there in relation to some of its cells; but, as we have said, every posterior nerve-root sends a few fibres up the whole length of that portion of the spinal medulla which lies above, and thus the posterior funiculus gradually increases in bulk as it is traced upwards, and in all except the lowest part of the spinal medulla a *fasciculus gracilis* is present. The *fasciculus gracilis* is composed of the long ascending fibres of the posterior nerve-roots, which have entered the lower segments of the spinal medulla. To put the matter differently, the fibres of the sacral roots are displaced medially by the entering lumbar fibres, while the fibres of the lumbar roots are in their turn pushed medially

by the entering thoracic fibres, and, lastly, the fibres of the cervical roots displace the thoracic fibres. The difference between the fasciculus gracilis and the fasciculus cuneatus consists simply in this, that the former is composed of the fibres of posterior nerve-roots which have entered the medulla at a lower level than those which enter into the formation of the fasciculus cuneatus. The fibres of the fasciculus gracilis, taking them as a whole, must therefore necessarily run a very much longer course.

Our knowledge of the constitution of the posterior columns of the spinal medulla is largely derived from studying the course of degeneration in monkeys, after the medulla has been cut across—either partially or completely. But we also have a direct knowledge of the lamination of the posterior columns of the human spinal medulla (Fig. 473), that has been acquired from the examination of cases in which the medulla or its nerve-roots had been injured during life.

Numerous collateral fibrils stream into the gray matter of the posterior column both from the ascending and descending branches of the entering fibres of the posterior nerve-roots. These are classified into long and short collaterals. The **long**

FIG. 473.—A DIAGRAM TO ILLUSTRATE THE GROUPING OF THE VARIOUS FASCICULI IN THE SPINAL MEDULLA (in transverse section).

collaterals extend forwards into the anterior column of gray matter and end in relation to the ventral nerve-cells. The **short collaterals** end in relation to the nerve-cells in the substantia gelatinosa, and other nerve-cells of the posterior column of gray matter.

The majority of the fibres of the posterior nerve-root enter the spinal medulla on the medial side of the apex of the posterior column of gray matter. The manner in which these are related to the fasciculus cuneatus and the fasciculus gracilis has been noticed; but a certain number of those fibres which lie most laterally take a curved course forwards on the medial side of the posterior column of gray matter and then pass into it. In the thoracic region these curved fibres end in connexion with the cells of the nucleus dorsalis (Fig. 467, B, p. 525, and Fig. 473).

Fasciculus Posterolateralis (O.T. Tract of Lissauer).—This is a small tract of nerve-fibres of minute calibre which assume their medullary sheaths at a comparatively late period. It is placed at the surface of the medulla close to the sulcus lateralis posterior. It is formed by some of the lateral fibres of the posterior nerve-roots which do not enter the fasciculus cuneatus, but pass upwards in the medulla close to the substantia gelatinosa, in which they ultimately end.

It must now be evident that the fibres which enter the medulla spinalis through each

posterior nerve-root have three main modes of distribution: (1) the majority take part in the formation of the fasciculus cuneatus, and pass upwards or downwards to end in the gray matter at some other level in the central nervous system; (2) some fibres, and many collaterals of fibres in the fasciculus cuneatus, lie close to the posterior column and describe a series of graceful curves as they pass forwards, prior to turning laterally into all regions of the gray matter to end at the same level as they enter the medulla spinalis; (3) a third series form the postero-lateral fasciculus and end in connexion with the cells of the substantia gelatinosa and other cells in the posterior and anterior columns of gray matter (Fig. 473).

The fibres derived from the posterior nerve-roots which ascend in the posterior funiculi of the medulla spinalis to the medulla oblongata of the brain constitute a direct sensory tract; other fibres are described which give rise to a crossed sensory tract termed the **fasciculus spino-thalamicus**. These latter fibres arise as the axons of certain of the cells in the posterior column in connexion with which fibres from the posterior nerve-roots have ended, and crossing to the opposite side of the medulla spinalis through the anterior commissure they ascend in the antero-lateral funiculus to the brain, where they ultimately reach the thalamus. As the spino-thalamic tract ascends in the spinal medulla its fibres are not gathered into a compact strand, but are more or less loosely scattered in the lateral funiculus (Fig. 473).

Association Fibres in the Posterior Funiculus.—But the whole of the fibres of the posterior funiculus are not derived from the posterior nerve-roots. A few fibres exist in this funiculus which have a different origin. They are derived from certain of the cells of the gray matter, and, entering the posterior funiculus, they divide into ascending and descending branches which pass upwards and downwards in the funiculus for a varying distance, before they finally turn in to end in the gray matter at a higher and a lower level. These fibres, therefore, constitute links of connexion between different segments of the spinal medulla, and they constitute the **fasciculus posterior proprius**. Our information regarding these fibres at present is somewhat defective; but it is believed that the deepest part of the funiculus, *i.e.* the part next the posterior gray commissure, and the **fasciculus septo-marginalis** of Bruce, placed in apposition with the posterior-median septum and in the adjoining part of the surface, belong mainly to this category.

Funiculus Lateralis and Funiculus Anterior.

—It is convenient to consider the anterior along with the lateral funiculus and to call the whole mass of white substance that is left, after eliminating the posterior funiculus, the **antero-lateral funiculus**. In contact with the surface of the gray columns there is a broad band of white matter the parts of which are known respectively as the **fasciculus proprius anterior** and **lateralis** (O.T. the ground bundles of the antero-lateral funiculus). It is composed wholly of fibres which spring from nerve-cells in the gray columns, and, after passing for varying distances upwards or downwards, end in the gray matter of the spinal medulla. Thus they constitute an intrinsic system of fibres linking together different levels of the spinal medulla. They become medullated before any other fibres, except the root-fibres and their continuations in the posterior funiculus. When cut across some of the fibres degenerate above, others below, the injury, and the degeneration extends for varying distances upwards and downwards respectively.

FIG. 474.—DIAGRAM TO SHOW THE MANNER IN WHICH THE FIBRES OF THE POSTERIOR NERVE-ROOTS ENTER AND ASCEND IN THE POSTERIOR FUNICULUS OF THE SPINAL MEDULLA. (From Edinger.)

The best-known long or extrinsic systems of fibres in the antero-lateral funiculus are those known as the *fasciculus cerebrospinalis lateralis* (O.T. crossed pyramidal tract), the *fasciculus cerebrospinalis anterior* (O.T. direct pyramidal tract), the *fasciculus cerebellospinalis* (O.T. direct cerebellar tract) (*which goes from the spinal medulla to the cerebellum, and ought therefore to be called spinocerebellaris, as it will be subsequently named in this account*), and the *fasciculus anterolateralis superficialis* (O.T. Gowers' tract).

There are, however, many other fasciculi at least as important as these, but there is as yet no close agreement as to their precise limits or connexions. One reason for this is that some of the elements of one tract may become intermingled with those of another; moreover, the position and relations of certain of them

FIG. 475.—DIAGRAM REPRESENTING THE CONNEXIONS OF SOME IMPORTANT SENSORY AND MOTOR TRACTS IN THE BRAIN.

vary considerably at different levels of the spinal medulla. In Fig. 473 an attempt has been made to present the present state of our knowledge of these great strands of white fibres. This diagram is not intended to represent any definite level of the spinal medulla, though certain features are shown which occur only in the cervical region; and in respect of other features, the arrangement found in lower regions of the spinal medulla has been introduced to render the diagram more serviceable.

Much of the apparent complexity of this chart will disappear if the reader recalls some general statements (p. 512) made with regard to the outstanding features of the brain. It was then explained that when sensory nerves, coming from the skin and muscles, enter the spinal medulla, they not only establish relations with the motor nuclei and other spinal structures in the neighbourhood of their insertion, but also give rise, directly or indirectly (see Fig. 475) to many

fasciculi, which pass upwards in the spinal medulla to reach the medulla oblongata, the pons and cerebellum, the mesencephalon (corpora quadrigemina), the thalamus, and the cerebral hemisphere. In the neighbourhood of each level where these ascending sensory tracts end, such as for example the region of the vestibular nucleus and cerebellum, the tectum mesencephali, the corpus striatum, and the cerebral hemisphere, great descending tracts originate and pass downwards in the spinal medulla (Fig. 475—the *red lines*). Thus we have cerebro-spinal, rubro-spinal, tecto-spinal, vestibulo-spinal, and bulbo-spinal fasciculi passing down the spinal medulla; and each system eventually ends around the series of motor nuclei (Fig. 475), many of them in the spinal medulla.

In the anterolateral funiculus the various fasciculi will be found to be grouped roughly into three bands:—Next to the gray columns is the fasciculus proprius, then comes a band of descending (motor) fasciculi, and then upon the surface a series of ascending (sensory) fasciculi. This arrangement, however, is not maintained with any degree of exactitude in the anterior funiculus, where the sharp demarcation between ascending and descending fasciculi is in great part destroyed by the intermingling of fibres passing in opposite directions.

The fibres of the posterior nerve-root have already been studied so far as their relation to the posterior funiculus is concerned. No clear conception of the nature and significance of the ascending fasciculi in the anterolateral funiculus can be obtained unless they also are studied in relationship with the fibres of the posterior root.

It has already been explained that of the fibres which enter the spinal medulla in the posterior root the great majority enter the fasciculus cuneatus, most of which (Fig. 473, *a*) bifurcate, one branch passing upward as a constituent of the fasciculus cuneatus and perhaps, if it ascends far enough, passing into the fasciculus gracilis, the other descending in the fasciculus interfascicularis (O.T. comma tract). Other fibres perhaps enter the posterolateral fasciculus (O.T. Lissauer's bundle). But all the other fibres of the posterior root, together with the majority of the fibres of the fasciculus cuneatus, sooner or later enter the gray matter (Fig. 473, *b* to *h*) of the spinal medulla.

Some of them (*b*) pass directly to end in the nucleus dorsalis of their own side, and from its cells fresh fibres arise, which pass laterally through the posterior column and lateral funiculus to reach the surface, where they bend upwards as constituent fibres of the spino-cerebellar fasciculus. These pass upwards throughout the whole length of the spinal medulla (above their place of origin), into the medulla oblongata, thence into the cerebellum through the restiform body.

Other fibres on the same (*c*), and perhaps also on the other side (*d*), end amidst cells of the gray matter, the axis-cylinder processes of which pass into the anterolateral superficial fasciculus (O.T. Gowers' tract). In this they ascend throughout the spinal medulla, medulla oblongata, and pons, to enter the cerebellum alongside the brachium conjunctivum (superior peduncle). This element in the anterolateral fasciculus is sometimes designated the *fasciculus spinocerebellaris anterior*, to distinguish it both from the non-cerebellar fibres of the parent fasciculus and from the *fasciculus spinocerebellaris [posterior]* (O.T. the direct cerebellar tract). These two spino-cerebellar tracts convey to the cerebellum information from the muscles and overlying skin which assists it to co-ordinate the muscles for carrying on precisely adjusted movements.

Other fibres of the posterior nerve-root (*e, f, g*, and *h*) terminate in relationship with cells in the gray columns of their own side of the spinal medulla, the axons of which cross the median plane in the anterior commissure to pass respectively (*e*) into the anterolateral superficial fasciculus [not to be confused with the cerebellar constituents of this bundle]; (*f*) into the real *fasciculus spinothalamicus*, of which the last-mentioned fibres are merely outlying members; (*g*) into the *fasciculus spinotectalis*, to ascend to the mesencephalon; and (*h*) into the marginal area of the anterior funiculus to form a group which may be called the *fasciculus spinothalamicus anterior*.

The careful investigations of the late Dr. Page May led him to attach a definite physiological significance to this grouping of the ascending paths. The *fasciculus spinothalamicus [posterior]* is supposed to convey upwards to the thalamus (for

transmission to the cerebral cortex, which is concerned with the conscious appreciation of sensations) all impulses of *pain, heat, and cold* coming from the skin upon the opposite side of the body. The *fasciculus spinothalamicus anterior* conveys impulses of *touch* and *pressure* from the opposite side.

The *spino-cerebellar fasciculi* [*anterior* and *posterior*] convey to the cerebellum respectively homolateral and bilateral unconscious afferent impulses underlying muscular co-ordination and reflex tone.

Among the descending tracts that establish connexions between various parts of the brain (see Fig. 475) and the motor nerve-cells in the anterior column may be mentioned the *cerebrospinal*, the *rubro-spinal* (from the red nucleus), the *tecto-spinal* (from the corpora quadrigemina), the *vestibulo-spinal* (from the terminal nucleus of the vestibular nerve), and the *bulbo-spinal tracts*. The last-mentioned forms a peculiar triangular area upon the surface immediately to the lateral side of the anterior nerve-roots (Fig. 473), but there is great uncertainty as to its mode of origin: it is often called the *fasciculus olivospinalis*, from the fact that its discoverer, Helweg, believed it to originate from the olivary nucleus in the bulb or medulla oblongata. It may be regarded as an outlying part of the vestibular (or cerebellar) tract to the motor nuclei of the spinal medulla.

The *fasciculus cerebrospinalis lateralis* (O.T. crossed pyramidal tract) is a large well-defined descending tract which lies immediately in front of the posterior column of gray matter, and subjacent to the spinocerebellar fasciculus, which shuts it out from the surface. Below the point where the spino-cerebellar fasciculus begins the cerebrospinal fasciculus becomes superficial, and in this position it can be traced as low as the fourth sacral nerve, at which level it ceases to exist as a distinct strand. The cerebro-spinal fasciculus is composed of an admixture of both large and small fibres. These arise in the brain from the large pyramidal cells of the motor or precentral area of the cerebral cortex, and pass downwards through various subdivisions of the brain to gain the spinal medulla. As they enter the spinal medulla they cross the median plane from one side to the other, and it thus happens that the cerebro-spinal tract in the right lateral column of the spinal medulla has its origin in the cortex of the left cerebral hemisphere, and *vice versa*. As the tract descends in the spinal medulla it gradually diminishes in size; and this is due to the fact that, as it traverses each spinal segment, numerous fibres leave it to enter the anterior column of gray matter, and end in connexion with the anterior motor cells from which the fibres of the anterior nerve-roots arise. The entire strand is ultimately exhausted in this way. Numerous collateral fibrils spring from the cerebro-spinal fibres, and, entering the gray matter, end in a similar manner. In this way a single cerebro-spinal fibre may be connected with several spinal segments before it finally ends. The lateral cerebro-spinal fasciculus must be regarded as a great motor strand which brings the spinal motor apparatus under the control of the will.

Schäfer believes that many of the fibres of the cerebro-spinal fasciculus end in connexion with the cells of the nucleus dorsalis.

In many marsupials, rodents, and ungulates the lateral cerebro-spinal fasciculus lies in the posterior funiculus of the spinal medulla.

The *fasciculus lateralis proprius* represents the remainder of the lateral funiculus. Its fibres are largely derived from the cells situated in all parts of the gray matter, and also from the nerve-cells of the opposite side of the spinal medulla. After a course of very varying length in the fasciculus lateralis, these fibres turn medially and re-enter the gray matter. Such fibres may thus be regarded as *inter-segmental association fibres* binding two or more segments of the spinal medulla together. It may be mentioned that the association fibres which link together segments of the spinal medulla which are near to each other lie close to the gray matter, whilst those which connect the more distant segments are situated further out in the lateral funiculus.

Funiculus Anterior.—One well-defined tract is situated in the funiculus anterior. This is termed the *fasciculus cerebrospinalis anterior*. The remainder of the funiculus receives the name of the *fasciculus anterior proprius*.

The *fasciculus cerebrospinalis anterior* (O.T. *direct pyramidal tract*) is usually a nerve-strand of small size which lies near the anterior median fissure. As a rule it cannot be traced lower than the middle of the thoracic region of the spinal medulla. It is a descending tract and must be associated with the lateral cerebro-spinal fasciculus of the opposite side, seeing that both of these strands arise from the motor area of the cortex of the same cerebral hemisphere. From this it must be clear that the anterior cerebro-spinal fasciculus does not cross the median plane as it enters the spinal medulla, but descends on the side of the spinal medulla corresponding to the cerebral hemisphere in which it arises. Nevertheless, its fibres do not end in the same side of the spinal medulla, but at every step along the path of the strand they make use of the anterior commissure, and cross to the opposite side of the spinal medulla, to terminate in relation to the opposite ventral motor cells in the same manner as the lateral cerebro-spinal fibres.

From this crossing of the cerebro-spinal fasciculi, it follows that the destruction of the fibres which compose them as they descend in one side of the brain must result in paralysis of the muscles supplied by the efferent nerves of the opposite side of the spinal medulla.

In cases of old brain lesion it is sometimes possible to detect some degenerated fibres in the lateral cerebro-spinal fasciculus of the sound side of the spinal medulla, and from this it is supposed that this tract contains a few uncrossed fibres. If this is the case, each side of the spinal medulla stands in connexion with the motor area of both cerebral hemispheres.

It is well to note that the fibres of both lateral cerebro-spinal fasciculi are not medullated until the time of birth. They are the latest of all the fasciculi of the spinal medulla to myelinate.

Commissura Anterior Alba.—The anterior white commissure is composed of medullated nerve-fibres passing from one side of the spinal medulla to the other and entering the anterior column of gray matter, and also the anterior funiculus of white matter. It is to be regarded more as a decussation than as a commissure, and its width, which varies somewhat in different regions, fluctuates in correspondence with the diameter of the spinal medulla.

Amongst the fibres which cross in the anterior commissure may be mentioned: (1) The fibres of the *fasciculus cerebrospinalis anterior*; (2) collaterals from both the anterior and lateral funiculi; (3) axons of many of the cells of the gray matter; (4) the dendritic processes of some of the medial anterior cells.

Commissura Grisea.—Although this is composed of gray matter with a large admixture of neuroglia, numerous nerve-fibres pass transversely through it, so as to establish relations between the cells in the gray matter on the two sides of the spinal medulla.

THE ENCEPHALON OR BRAIN.

The **brain** is the enlarged and greatly modified upper part of the cerebro-spinal nervous axis. It is surrounded by the same membranes that envelop the medulla spinalis (viz., the dura mater, the arachnoid, and the pia mater), and it almost completely fills up the cavity of the cranium. So closely, indeed, is the skull capsule moulded upon the brain that the impress of the latter is almost everywhere evident upon the inner surface of the cranial wall. The relations, therefore, of cranium to brain are totally different from those presented by the vertebral canal to the spinal medulla. As we have noted, the medulla spinalis occupies only a part of its bony case; and there is not only a wide and roomy space between the arachnoid and the pia mater, but also an interval of some width between the dura mater and the walls of the vertebral canal.

General Appearance of the Brain.—When viewed from above the brain presents an ovoid figure, the broad end of which is directed backwards. Its greatest transverse diameter is usually found in the neighbourhood of that part which lies between the two parietal tuberosities of the cranium. The only parts which are visible when the brain is inspected from this point of view are the two convoluted **cerebral hemispheres**. These present an extensive convex surface, which

is closely applied to the internal aspect of the cranial vault, and are separated from each other by a deep median cleft, termed the *fissura longitudinalis cerebri*, which extends from the front to the back of the brain.

The inferior aspect of the brain is usually termed the *basis cerebri*. It presents an uneven and irregular surface, which is more or less accurately adapted to the inequalities on the floor of the cranial cavity. Upon this aspect of the brain some of its main subdivisions may be recognised. Thus, posteriorly, is seen the short cylindrical portion, called the *medulla oblongata*, through which, at the foramen magnum, the brain becomes continuous with the medulla spinalis. The medulla oblongata lies on the ventral aspect of the cerebellum, and occupies the vallecula or hollow which intervenes between the two cerebellar hemispheres. The *cerebellum*

FIG. 476.—THE BASE OF THE BRAIN WITH THE CEREBRAL NERVES ATTACHED.

is a mass of considerable size which is placed below the posterior portions of the two cerebral hemispheres. It is easily recognised on account of the closely set, curved, and parallel fissures which traverse its surface and give it a foliated appearance. Above the medulla oblongata, and in close connexion with it, is a prominent white elevation called the *pons*. Immediately in front of the pons there is a deep hollow or recess. This is bounded behind by the pons, on each side by the projecting temporal lobe of the cerebral hemisphere, and in front by the orbital portions of the frontal lobes of the cerebral hemispheres. Passing out from each side of the anterior part of this recess is the deep lateral fissure of the brain which intervenes between the pointed and projecting extremity of the temporal lobe and the frontal lobe of the cerebrum, whilst, in the median plane in front, the longitudinal fissure, which separates the frontal portions of the cerebral hemispheres, opens into it.

Within the limits of this deep hollow, on the base of the brain, two large rope-

like strands, the **pedunculi cerebri**, may be seen issuing from the under surface of the cerebral hemispheres. As they pass downwards these peduncles are inclined obliquely towards the median plane, so that when they plunge into the pons they are situated in close apposition the one to the other (Fig. 478). Turning round the lateral side of each peduncle, where it emerges from the cerebrum, a flattened band termed the **optic tract** may be observed. These bands come from the anterior part of the hollow, where they are joined together by a short connecting piece termed the **optic chiasma**. The **optic nerve** is inserted, on each side, into the chiasma.

The pedunculi cerebri, the optic tracts, and the optic chiasma enclose a deep rhomboidal or lozenge-shaped interval on the base of the brain, which is termed the **fossa interpeduncularis**. Within the limits of this area the following parts may be seen as we pass from behind forwards: (1) the **substantia perforata posterior**; (2) the **corpora mamillaria**; (3) the **tuber cinereum** and the stalk of the **hypophysis cerebri** (O.T. pituitary body).

At its posterior angle, immediately in front of the pons, the interpeduncular fossa is very deep and is floored by a layer of gray matter, which is perforated by numerous small apertures. This is the **substantia perforata posterior**. Through the apertures which are dotted over its surface the small postero-medial basal branches of the posterior cerebral artery enter the brain.

The **corpora mamillaria** are two small white pea-like eminences placed side by side in front of the **substantia perforata posterior**.

The **tuber cinereum** is a slightly-raised field of gray matter, which occupies the interval between the anterior portions of the optic tracts in front of the **corpora mamillaria**. Springing from the anterior part of the **tuber cinereum**, immediately behind the optic chiasma, is the **infundibulum**, or the stalk which connects the **hypophysis cerebri** with the base of the brain (Fig. 478).

Lateral to the limits of the anterior part of the interpeduncular space there is, on each side, a small depressed triangular field of gray matter, which leads laterally into the lateral cerebral fissure. It is perforated by the antero-medial and the antero-lateral groups of basal arteries, and receives the name of the **substantia perforata anterior**.

General Connexions of the Several Parts of the Brain.—The **medulla oblongata**, the pons, and the **cerebellum** occupy the posterior cranial fossa, and they are separated from the cerebral hemispheres, which lie above them, by a partition of **dura mater**, termed the **tentorium cerebelli**. Further, they surround a cavity, a portion of the primitive cavity of the early neural tube, which is termed the **fourth ventricle** of the brain, and they all stand in intimate connexion, one with the other. The **medulla oblongata** is for the most part carried upwards into the pons; but at the same time two large strands from its dorsal aspect, termed the **restiform bodies**, are prolonged into the **cerebellum**, and constitute its **inferior peduncles**, or the chief bonds of union between the **medulla (oblongata and spinalis)** and the **cerebellum**. The pons has large numbers of transverse fibres entering into its composition, and the great majority of these are gathered together on each side in the form of a large rope-like strand. This plunges into the corresponding hemisphere of the **cerebellum**, and constitutes its **middle peduncle**, which is known as the **brachium pontis**.

The **cerebrum**, which forms the great mass of the brain, occupies the anterior and middle cranial fossæ, and extends backwards into the occipital region above the **tentorium** and the **cerebellum**. The greater part of the **cerebrum** is formed by the cerebral hemispheres, which are separated from each other in the median plane by the longitudinal fissure. At the bottom of this fissure is the **corpus callosum**, a broad commissural band which connects the two hemispheres with each other. Each hemisphere is hollow, the cavity in its interior being termed the **lateral ventricle** of the brain. Between and below the cerebral hemispheres, and almost completely concealed by them, is the **inter-brain** or **diencephalon**. The principal parts forming this portion of the brain are two large masses of gray matter, termed the **thalami**. Between these is the **third ventricle** of the brain—a deep narrow cavity occupying the median plane. The third ventricle communicates

with the lateral ventricles by two small apertures, called the **foramina inter-ventricularia**.

The cerebrum is connected with the parts in the posterior cranial fossa (pons, cerebellum, and medulla oblongata) by a narrow stalk called the **mesencephalon**. The mid-brain is built up of the **pedunculi cerebri**, passing from the pons to the cerebrum; the **corpora quadrigemina**, forming its dorsal part; and the **brachia conjunctiva** (O.T. superior cerebellar peduncles), proceeding from the cerebellum to the cerebrum. It is tunnelled by a narrow passage, the **aquæductus cerebri**, which extends between the fourth and third ventricles.

In a view of the intact brain the greater part of the mesencephalon and diencephalon is hidden by the cerebral hemispheres; but a precise idea will be obtained of the inter-relationships of the various parts of the brain, if we study

FIG. 477.—THE PARTS OF THE BRAIN CUT THROUGH IN A MEDIAN SAGITTAL SECTION.
The lateral walls of the ventricular cavities are also shown.

the relationship of these structures to the series of cavities in the interior of the brain as they are displayed in a median sagittal section (Fig. 477).

The central canal which tunnels the spinal medulla is seen to extend into the medulla oblongata for a short distance; then it expands into the irregular cavity of the fourth ventricle, the floor (anterior wall) of which is formed partly by the medulla oblongata and partly by its continuation upwards, the **pars dorsalis pontis**. Behind the fourth ventricle lies the cerebellum, but it forms only a small part of the roof (**tegmen**). This consists mainly of the **velum medullare anterius** above and the thin epithelial lamina (**lamina chorioidea epithelialis**) below.

The fourth ventricle is continued upwards into the **aquæductus cerebri**, which tunnels the mesencephalon, of which the thick mass of the **tegmentum** is placed in front of it and the **lamina quadrigemina** behind.

The aqueduct opens in front into the third ventricle, the major portion of each lateral wall of which is formed by the **thalamus**. Near the antero-superior

corner of each lateral wall of the third ventricle the small **foramen interventriculare** (O.T. **foramen of Monro**) leads into the cavity of the corresponding cerebral hemisphere, which is known as the lateral ventricle.

MEDULLA OBLONGATA.

The **medulla oblongata** is the continuation upwards of the medulla spinalis. It is not more than 25 mm. (one inch) in length, and it may be regarded as beginning immediately above the uppermost root of the first cervical nerve, or, roughly,

FIG. 478.—FRONT VIEW OF THE MEDULLA OBLONGATA, PONS, AND MESENCEPHALON OF A FULL-TIME HUMAN FETUS.

about the level of the foramen magnum. From this it proceeds upwards in a very nearly vertical direction, and ends at the lower border of the pons. At first its girth is similar to that of the spinal medulla, but it rapidly expands as it approaches the pons, and consequently it presents a more or less conical form. Its anterior surface lies behind the grooved surface of the basilar portion of the occipital bone, whilst its posterior surface is sunk into the vallecule of the cerebellum. The medulla oblongata is a bilateral structure, and this is indicated on the surface by the presence of anterior and posterior median fissures, on the ventral and dorsal surfaces respectively.

The **fissura mediana anterior**, as it passes from the spinal medulla on to the medulla oblongata, is interrupted at the level of the foramen magnum by several strands of fibres which cross the median plane from one side to the other. This intercrossing is termed the **decussation of the pyramids**. Above this level the fissure

is carried upwards to the lower border of the pons, but is often rendered very shallow by numerous external arcuate fibres which emerge upon the surface

FIG. 479.—POSTERIOR VIEW OF THE MEDULLA, PONS, AND MESENCEPHALON OF A FULL-TERM HUMAN FÆTUS.

a triangular field, which is thus opened up on the dorsal surface. This triangular field is the lower part of the *fossa rhomboidea*, or the floor of the fourth ventricle of the brain. The lower half of the medulla oblongata, containing as it does the continuation of the central canal of the spinal medulla, is frequently termed the **closed part of the medulla oblongata**; the upper half, above the opening of the canal, which by its dorsal surface forms the lower part of the floor of the fourth ventricle, is then called the **open part**.

Deferring for the present the examination of the floor of the fourth ventricle, the appearance presented by the real surface of the medulla oblongata may now engage our attention. In the spinal medulla the corresponding surface area is divided into three districts or funiculi by the emerging motor roots and the entering sensory roots of the spinal nerves. Of these the sensory enter along the bottom of the sulcus lateralis posterior, whilst the motor fila are spread over a relatively broad surface area and have no groove in connexion with their emergence from the spinal medulla. In the case of the medulla oblongata corresponding rows of fila enter and emerge from the surface of each side. The fila of the hypoglossal nerve carry up the line of the anterior nerve-roots of the spinal medulla. In one respect, however, they differ: they emerge in linear order and along the bottom of a distinct furrow, termed the *sulcus lateralis anterior*, which proceeds upwards on the surface of the medulla oblongata. The fila which carry up the line of the posterior nerve-roots on the surface of the medulla oblongata are the root-bundles of the accessory, the glosso-pharyngeal, and the vagus nerves. These are attached along the bottom of a furrow which is the direct continuation upwards of the sulcus lateralis posterior of the spinal medulla, and therefore receives the name of the *sulcus lateralis posterior* of the medulla oblongata. The root-bundles of these nerves differ, however, in so far that they are not all composed of afferent fibres which spring from ganglionic cells placed without and enter the medulla. Certain of them are purely efferent (roots of accessory), whilst others contain a considerable number of efferent fibres also, and are therefore to be regarded as mixed roots.

By the sulci laterales, and also by the two rows of fila attached along the

between its lips and then curve laterally to reach the posterior part of the medulla oblongata. At the lower margin of the pons it expands slightly and ends in a blind pit, which receives the name of the *foramen cæcum* of Vieq d'Azyr.

The *fissura mediana posterior* is present only on the lower half of the medulla oblongata. As it ascends it rapidly becomes shallower. Half-way up, the central canal opens on the dorsal surface of the medulla oblongata, and at this point the lips of the posterior median fissure are thrust apart from each other and constitute the boundaries of

bottom of these furrows, the surface of the medulla oblongata on each side is divided into three districts, viz., an anterior, a lateral, and a posterior, similar to the surface areas of the three funiculi on the side of the spinal medulla. Indeed, at first sight, they appear to be direct continuations upwards of these three portions of the spinal medulla; this, however, is not the case, because the fibres of the three funiculi of the spinal medulla undergo a rearrangement as they proceed upwards into the medulla oblongata.

Anterior Area of the Medulla Oblongata.—Pyramis.—The district between the anterior median fissure, and the sulcus lateralis anterior, along the bottom of which the root-fascicles of the hypoglossal nerve issue from the medulla oblongata, receives the name of the pyramid. An inspection of the surface is sufficient to show that the pyramid is composed of a compact strand of longitudinally directed nerve-fibres. It represents, in fact, the portion of the great cerebro-spinal fasciculus which is destined to carry fibres from the cerebral hemisphere to all the motor nuclei on the other side of the medulla oblongata and medulla spinalis. Somewhat constricted at the place where it emerges from the pons (Fig. 478) it swells immediately to form a prominent rounded column, which passes vertically downward, separated from the pyramid of the other side by the fissura mediana anterior. Towards the lower part of the medulla oblongata it gradually tapers.

Although the pyramid at first sight appears to be continuous with the anterior funiculus of the medulla spinalis, only a very small proportion of the fibres contained in the latter are derived from the pyramid. This at once becomes manifest when the lips of the anterior median fissure are thrust apart at the place of junction between the medulla oblongata and spinal medulla. The pyramid is then seen to divide at this level into two parts, viz., a small portion composed of a variable number of the most lateral fibres of the pyramid, termed the *fasciculus cerebrospinalis anterior* (O.T. *direct pyramidal tract*), and a much larger portion situated next the median fissure, called the *fasciculus cerebrospinalis lateralis* (O.T. *crossed pyramidal tract*). The anterior cerebro-spinal fasciculus is continued down into the anterior funiculus of the medulla spinalis, and in this it takes up a medial position next the median fissure. The lateral cerebro-spinal fasciculus is broken up into three or more coarse bundles, which sink backwards and at the same time cross the median plane, to take up a position in the posterior part of the opposite lateral funiculus of the spinal medulla. The term *decussatio pyramidum* (*decussation of the pyramids*) is applied to the intercrossing of the corresponding bundles of the lateral cerebro-spinal fasciculi of opposite sides.

The anterior cerebro-spinal fasciculus is, therefore, the only part of the pyramid which has a place in the anterior funiculus of the spinal medulla. The much larger part of this funiculus, termed the *fasciculus anterior proprius*, as it is traced up into the medulla oblongata, is seen to be thrust aside by the decussating bundles of the lateral cerebro-spinal fasciculus. It thus comes to occupy a deep position in the substance of the medulla oblongata, behind and to the lateral side of the pyramid.

Lateral Area of the Medulla Oblongata.

—This is the district on the surface of the medulla oblongata which is included between the two rows of nerve-roots, viz., the hypoglossal roots in front, and the root-bundles of the accessory, the vagus, and the

FIG. 480.—DIAGRAM OF THE DECUSSATION OF THE PYRAMIDS (modified from van Gehuchten).

NH, Nucleus hypoglossi; NV, Vago-glossopharyngeal nucleus; FS, Tractus solitarius; NA, Nucleus ambiguus.

glossopharyngeal nerves behind. It presents a very different appearance in its upper and lower parts. In its lower portion it simply appears to be a continuation upwards of the lateral area of the spinal medulla; in its upper part a striking oval prominence bulges out on the surface of the medulla, and receives the name of *oliva* (O.T. *olivary eminence*).

The lower part of this district, however, is very far from being an exact counterpart of the lateral funiculus of the spinal medulla. The large lateral cerebro-spinal tract is no longer present, seeing that it forms, in the medulla oblongata,

FIG. 481.—LEFT LATERAL ASPECT OF A BRAIN FROM WHICH THE CEREBRAL HEMISPHERE (WITH THE EXCEPTION OF THE CORPUS STRIATUM) AND THE CEREBELLUM (EXCEPTING ITS NUCLEUS DENTATUS) HAVE BEEN REMOVED.

the greater part of the pyramid of the opposite side. Another strand of fibres, viz., the fasciculus spinocerebellaris, prolonged upwards in the lateral funiculus of the medulla spinalis, gradually leaves this portion of the medulla oblongata. This tract lies on the surface, and is frequently visible to the naked eye as a white band (Fig. 481), which inclines obliquely backwards into the posterior district of the medulla oblongata to join its upper part, or, in other words, the restiform body. The remainder of the fibres of the lateral funiculus, comprising the fasciculus lateralis proprius and the fasciculus anterolateralis superficialis, is continued upwards in the lateral area of the medulla oblongata, and at the inferior border of the olive the majority of these fibres disappear from the surface by dipping into

the substance of the medulla oblongata under cover of that projection. A small proportion of the fibres, however, are retained on the surface and travel upwards towards the pons in the interval, which exists between the posterior border of the olive and the roots of the vagus and glossopharyngeal nerves.

The **olive** is a smooth oval projection which bulges out from the upper part of the lateral area of the medulla oblongata. Its long axis is vertical and is about half an inch long. It marks the position of the subjacent **nucleus olivaris inferior**, a crumpled thin-walled sac of gray matter, which is separated from the surface only by a very thin layer of superficial white matter.

Posterior Area of the Medulla Oblongata.—In its inferior half, this district is bounded behind by the posterior median fissure, and in its superior half by the lateral margin of the medullary part of the floor of the fourth ventricle of the brain. In front it is separated from the lateral area by the row of root-fascicles belonging to the accessory, glossopharyngeal and vagus nerves. As in the lateral area, we recognise an inferior portion and a superior portion, which appear continuous but in reality are almost quite distinct the one from the other.

The inferior part of the posterior area corresponds more or less closely with the posterior funiculus of the spinal medulla. In the cervical region the posterior funiculus is divided by a septum of pia mater into a medial fasciculus gracilis and a lateral fasciculus cuneatus. These are prolonged upwards into the medulla oblongata, and in the lower part of the posterior area they stand out distinctly, and are separated one from the other by a continuation upwards from the spinal medulla of the sulcus intermedius posterior. In the medulla oblongata the medial of these strands is called the **funiculus gracilis**, whilst the lateral one is designated the **funiculus cuneatus**. When they reach the level of the inferior part of the floor of the fourth ventricle, each ends in a slightly expanded bulbous prominence. The swollen extremity of the funiculus gracilis is called the **clava**. This is thrust aside from its fellow of the opposite side by the opening up of the medulla oblongata to form the floor of the fourth ventricle, and the central canal opens on the surface in the angle between the two clavae.

The elongated prominences formed on the surface of the medulla oblongata by these two strands and their enlarged extremities are due to the presence of two elongated nuclei or collections of gray matter which make their appearance subjacent to the strands, and represent the termini of these uppermost extensions of the spinal posterior root-fibres. These are termed respectively the **nucleus gracilis** and **nucleus cuneatus**. [*As it is the slenderness of the one nucleus and the wedge-shape of the other in transverse section which gave rise to the terms gracilis and cuneatus respectively, it is clearly wrong to introduce the word funiculi into the terminology. The funiculi were named from the nuclei and not the nuclei from the funiculi.*]

But a third longitudinal elevation is also apparent on the surface of the inferior part of the posterior area of the medulla oblongata. This is placed on the lateral side of the funiculus cuneatus—between it and the posterior row of nerve-roots—and it has no counterpart in the posterior funiculus of the medulla spinalis. It is called the **tuberculum cinereum**. It is produced by a mass of substantia gelatinosa coming close to the surface and forming a bulging in this situation. Extremely narrow below, it widens as it is traced upwards, and finally ends in an expanded extremity. A thin layer of white matter, composed of longitudinally arranged fibres, is spread over this district, and separates the substantia gelatinosa from the surface. These fibres constitute the **tractus spinalis** of the **trigeminal nerve**, which here assumes a superficial position as it descends in the medulla oblongata.

The **corpus restiforme** (restiform body) forms the upper part of the posterior area of the medulla oblongata. It lies between the floor of the fourth ventricle and the roots of the vagus and glossopharyngeal nerves. It is a large and prominent rope-like strand, which inclines upwards and laterally, and then finally takes a turn backwards and enters the cerebellum. It forms the great link of connexion between the cerebellum on the one hand and the medulla oblongata and spinal medulla on the other, and consequently it is also called the **inferior cerebellar peduncle**. A study of the surface of the medulla oblongata yields some important

information regarding the constitution of the restiform body. Thus the spino-cerebellar tract (Fig. 481) from the lateral column of the spinal medulla can be traced into it, and large numbers of fibres which take a curved course on the surface of the medulla oblongata may likewise be followed into it. These are the external arcuate fibres. Numerous other fibres enter the restiform body on its deep aspect, but these will be studied at a later stage.

Fibræ Arcuatæ Externæ.—The external arcuate fibres enter into the constitution of the restiform body, after pursuing a longer or shorter course on the surface of the medulla (Fig. 481).

They are more particularly seen in the neighbourhood of the olive, over the surface of which they may be observed coursing in the form of a number of fine curved bundles or as a continuous sheet of fibres. They vary greatly in number and in distinctness, and they are sometimes so numerous that they cover the olive almost entirely. An attentive examination will show that the majority of them come to the surface in the median fissure between the pyramids, and also not infrequently in the groove between the pyramid and olive, or through the substance of the pyramid itself. The anterior median fissure in its upper part is often almost completely blocked up by these emerging fibres. The arcuate fibres, reaching the surface of the medulla in this manner, turn backwards, and the great majority enter the restiform body and form a considerable part of its outer portion.

Other arcuate fibres arise in the cuneate and gracile nuclei, and enter the restiform body of the same side. Van Gehuchten, however, denies this.

There is frequently present, especially upon the left side, a bundle of fibres that is usually mistaken for a group of arcuate fibres. It is the *fasciculus circum-olivaris pyramidis* (Fig. 481). It consists of a bundle of varying size which emerges from the pyramid, bends backwards, curving round the inferior border of the olive, and then passes obliquely upward and backwards to end in a fusiform ridge of gray matter, the *corpus ponto-bulbare* (Essick), which crosses the restiform body very obliquely (Fig. 481, the ridge immediately posterior to the fila of the vagus nerve).

These structures are of great morphological interest, and will be referred to again in the succeeding pages (see Fig. 499, p. 566).

PONS.

The **pons** (O.T. **pons Varolii**) is a marked white prominence on the basal aspect of the brain which is interposed between the medulla oblongata and the pedunculi cerebri, and lies in front of the cerebellum. It is convex from side to side, and from above downwards, and transverse streaks on its surface show that, superficially at least, it is composed of bundles of nerve-fibres, most of which course transversely. On each side these transverse fibres are collected together in the form of a large compact strand, which sinks in a backward and lateral direction into the white matter of the corresponding hemisphere of the cerebellum. This strand is termed the *brachium pontis*, and the term "pons," applied to the entire structure, expresses in an admirable way the arch-like manner in which this portion of the brain bridges across the interval between the two cerebellar hemispheres.

The *ventral surface* of the pons is in relation to the basilar part of the occipital bone and the dorsum sellæ of the sphenoid bone. It presents a median groove (*sulcus basilaris*), which gradually widens as it is traced upwards: it lodges the basilar artery. This median depression is produced by the prominence which is caused on each side by the passage of the cerebro-spinal fasciculus downwards through the pons. The **trigeminal nerve**, with its large entering sensory root and its small emerging motor root, is attached to the side of the anterior aspect of the pons, nearer its superior than its inferior border (Fig. 481). It is usual to restrict the term "pons" to that portion of the structure which lies between the two trigeminal nerves, and to apply the designation of *brachium pontis* to the part which extends beyond the nerve into the hemisphere of the cerebellum. The **abducens nerve**, the **facial nerve**, and **acoustic nerve** are attached to the brain at the inferior border of the pons. The abducens nerve emerges at the inferior border of the pons

opposite the lateral border of the pyramid; the facial and acoustic are also attached to the inferior edge of the pons, but far away from the median plane. The acoustic nerve is in contact with the cerebellum and the facial is on its medial side, with its sensory root (the *nervus intermedius*) between them (Figs. 478, 481). A large bundle of fibres upon the front of the pons departs from the transverse course pursued by most of the pontine fibres, and starting at the medial side of the trigeminal nerve, passes almost vertically downwards between the facial and acoustic nerves (Fig. 526, p. 593) and reaches the lateral aspect of the medulla oblongata, where it passes into the corpus ponto-bulbare (Fig. 481). This bundle is known as the *fasciculus obliquus [pontis]*. It is curious to observe that while the facial nerve lies upon the medial side of this oblique bundle, its sensory root (the *nervus intermedius*) is placed on its lateral aspect alongside the acoustic nerve (Fig. 527, p. 594).

Immediately below the insertion of the acoustic nerve at the inferior margin of the pons a little calyx-like appendage of the epithelial roof of the fourth ventricle (*recessus lateralis*) projects laterally partly behind the glossopharyngeal nerve. Through an elliptical aperture in this epithelial process (*apertura lateralis ventriculi quarti*) a little cauliflower-like mass of chorioid plexus becomes extruded between the acoustic and the glossopharyngeal nerves (Fig. 527, p. 594).

The *posterior surface* of the pons looks backwards towards the cerebellum, and presents a triangular area covered with gray matter, which forms the superior part of the anterior wall or floor of the fourth ventricle. This area is directly continuous inferiorly with the medullary part of the floor of the fourth ventricle, and is bounded on each side by a band of white matter termed the *brachium conjunctivum* (Fig. 482).

Brachia Conjunctiva (O.T. Superior Peduncles of the Cerebellum).—These are hidden from view by the superior part of the cerebellum, under cover of which they lie. They emerge from the lateral hemispheres of the cerebellum, and, as they proceed upwards on the dorsal aspect of the pons, they converge towards each other until, at the inferior level of the corpora quadrigemina, the medial margins of the two brachia become almost contiguous (Fig. 482, p. 550). At first they form the lateral boundaries of the superior part of the fourth ventricle; but, as they ascend and approach closer to each other, they gradually come to overhang that cavity, and thus enter into the formation of its roof. They disappear from the surface by dipping under cover of the quadrigeminal bodies and entering the substance of the mesencephalon.

Velum Medullare Anterius.—Filling up the triangular interval between the two brachia conjunctiva, and stretching across from the medial and free margin of the one to the corresponding margin of the other, is a thin layer of white matter which completes the roof or dorsal wall of the upper part of the fourth ventricle, and receives the name of the *anterior medullary velum*. When traced downwards, the velum is seen to be carried, with the brachia conjunctiva, into the white matter of the cerebellum. Spread out on its posterior surface is a small, thin, tongue-shaped prolongation of gray matter from the cortex of the cerebellum, which is termed the *lingula*, whilst issuing from its substance close to the inferior quadrigeminal bodies are the two *trochlear nerves*.

VENTRICULUS QUARTUS.

Fourth Ventricle.—The fourth ventricle of the brain is somewhat rhomboidal in form. Below, it tapers to a point and becomes continuous with the central canal of the lower half of the medulla oblongata; above, it narrows in a similar manner and is continued into the *aquæductus cerebri*, which tunnels the mesencephalon. The posterior wall is termed the *tectum* or *roof* and is concealed by the cerebellum. The anterior wall is called the *floor* and is formed by the dorsal surfaces of the medulla oblongata and pons. On each side a long, curved and narrow prolongation of the ventricular cavity is carried laterally from its widest part and curves round the upper part of the corresponding restiform body. This is termed the *recessus lateralis*. The roof of the cavity is very thin and is intimately connected with the cerebellum. It is better, therefore, to defer its description until that part of the brain has been studied.

Fossa Rhomboidea (floor of the fourth ventricle).—In its inferior part the floor of the fourth ventricle is formed by the dorsal surface of the open part of the medulla oblongata, whilst in its superior part it is formed by the dorsal surface of the pons (Fig. 482). The area thus constituted is lozenge-shaped, its widest part being opposite the superior ends of the restiform bodies or inferior peduncles of the cerebellum. A thick layer of gray matter, continuous with that which surrounds the central canal, is spread out like a carpet over the ventricular floor, and covering this is the usual ependymal layer, which lines all the ventricles of the brain. The area is circumscribed by definite lateral boundaries. Thus, *below*, it is bounded on each side by the clava, the cuneate tubercle, and the restiform body; whilst *above*, the lateral limits are formed by the brachia conjunctiva.

The fossa rhomboidea is divided into two lateral and symmetrical portions by a median groove. Its lower narrow pointed portion between the two clavae receives the name of the **pars inferior**, or, from its fancied resemblance to the point of a pen,

FIG. 482.—FLOOR OF THE FOURTH VENTRICLE. On the right side the right half of the cerebellum has been removed by cutting through its three peduncles and dividing it in the median plane. On the left side the left half of the cerebellum is drawn over to the left so as to expose the floor of the ventricle fully.

the **calamus scriptorius**. Crossing each half of the floor, at its widest part, are several more or less conspicuous bundles of fibres termed the **striæ medullares**. They begin upon the lateral and posterior aspects of the restiform body, where they spring from the cochlear nuclei, pass transversely medially, and disappear from view in the median furrow. The striæ medullares exhibit a large amount of variation in different specimens, both in their degree of prominence and also in the direction which they pursue. It is not uncommon to find that no trace of them is visible upon the surface.

On the inferior (bulbar) district of the ventricular floor a small triangular depression, placed immediately below the striæ medullares, catches the eye. This is termed the **fovea inferior**. It is shaped somewhat like an arrow-head. The apex or point looks towards the striæ, whilst the lateral angles of the base are prolonged downwards in the form of diverging grooves (Fig. 482). Of these, the medial groove runs towards the opening of the central canal at the calamus scriptorius, whilst the lateral groove runs towards the lateral boundary of the floor. In this

manner the portion of the floor which lies below the striæ medullares is mapped out into three triangular areas. The medial subdivision is slightly elevated and is termed the **trigonum nervi hypoglossi**, because subjacent to the medial part of this area is the nucleus of origin of the hypoglossal nerve. The intermediate area between the two diverging grooves which proceed from the base of the fovea inferior is the **ala cinerea**. It is sometimes called the **trigonum n. vagi** because the nucleus of the vagus and the glossopharyngeal nerves lies subjacent to it. Near the lateral angle is the **area acustica**. The base of this area is directed upwards and runs continuously into an eminence over which the striæ medullares pass. Subjacent to this district of the floor of the ventricle lies the large terminal chief nucleus of the vestibular division of the acoustic nerve. A more accurate name for the area acustica would be **area vestibularis**.

A close inspection of the pars inferior fossæ rhomboideæ will show that the base of the trigonum vagi is separated from the medial margin of the clava by a narrow lanceolate strip of the ventricular floor, to which Retzius has given the name of **area postrema**. Beneath this area is some vascular tissue (Streeter), and marking it off on its superior and medial aspect from the base of the trigonum vagi there is a translucent cord-like ridge called the **funiculus separans**.

When the floor of the ventricle is examined under water with a magnifying glass, the trigonum hypoglossi is seen to consist of a narrow medial strip which corresponds to the hypoglossal nucleus, and a wider lateral part which has been shown to be the surface representation of another nucleus termed the **nucleus intercalatus** (Streeter).

On the part of the floor of the ventricle which lies above the striæ medullares, and corresponds to the dorsal surface of the pons, there is also a slight depression, termed the **fovea superior**. Between it and the median groove is a marked prominence called the **eminentia medialis**. Inferiorly this elevation passes downwards and becomes continuous with the trigonum hypoglossi, whilst superiorly it is carried upwards towards the opening of the aquæductus cerebri. In both directions it gradually becomes less prominent, but still it forms a distinct elongated elevation, which stretches alongside the whole length of the median groove. As already stated, the **area acustica** extends upwards into the pontine part of the ventricular floor and forms an elevated region in the most lateral part of its widest portion, below and to the lateral side of the fovea superior. Proceeding upwards from the fovea superior to the opening of the aquæductus cerebri there is a shallow depression termed the **locus cœruleus**, seeing that it usually presents a faint slate-blue colour. When the ependyma is scraped away from the surface of this part of the floor, the colour is seen to be due to the **substantia ferruginea**,—a name applied to a linear group of strongly pigmented cells, which lies in the lateral part of the gray matter covering this portion of the ventricular floor. When transverse sections are made through the superior part of the pons, the substantia ferruginea appears on the cut surface as a small black spot or dot.

INTERNAL STRUCTURE OF MEDULLA OBLONGATA AND PONS.

The structure of the medulla oblongata and pons differs in a marked degree from that of the spinal medulla: indeed in its superior part it presents very little in common with the latter. Some of the largest fasciculi which come up from the spinal medulla (such as the funiculus posterior) end in the lower part of the medulla oblongata; others leave the medulla oblongata and pass into the cerebellum; and of the bundles of fibres which pass upwards or downwards, from or to the spinal medulla respectively, most of them come to occupy very different positions in the medulla oblongata and pons.

The gray matter instead of being moulded into one compact column, as is the case in the spinal medulla, becomes broken up into a series of discrete nuclei. Thus, there are developed from the basal lamina of the rhombencephalon not one compact mass like the spinal anterior column, but three distinct broken columns of efferent nuclei (Fig. 526, p. 593):—(1) a **medial somatic column**, which in turn is broken up into two parts, a bulbar nucleus (*the hypoglossal*) which supplies the motor fibres to the tongue muscles, and a pontine nucleus (*the abducens*) which supplies the lateral rectus of the eye; (2) a **lateral somatic column** broken up into separate nuclei, viz., *accessorius*, *ambiguus*, *facial*, and *trigeminal* supplying the

sterno-mastoid and trapezius muscles and the striated muscles of the larynx, pharynx and face and those concerned with mastication; and (3) a **splanchnic column** of nuclei giving efferent fibres, which pass out in the vagus, glossopharyngeal and facial nerves to be widely distributed to unstriated muscle, glands and other tissues in the head, neck, thorax and abdomen.

The terminal nuclei of the sensory nerves which are developed in the alar lamina of the rhombencephalon again do not unite to form a definite posterior column, as happens in the spinal medulla, but form discrete masses; and as these act as receptive organs for a much greater variety of sensory nerves than are represented in the spinal nerves there is a much greater number of nuclei than would be formed if the various components of the posterior column in the spinal medulla were dissociated. Thus, there are terminal nuclei in the medulla oblongata not only for the ordinary cutaneous nerves, but also for nerves coming from the mucous membranes of the alimentary and respiratory organs, as well as from other visceral structures; and there are also special nerves of taste (*nervus intermedius* and glossopharyngeal), hearing (cochlear part of the acoustic) and equilibration (vestibular part of the acoustic). But this does not exhaust the peculiar features of the terminal sensory nuclei of the rhombencephalon. In the description of the spinal medulla attention was called to the fact that certain of the fibres of the posterior nerve-root did not end in the gray matter of the spinal medulla, but passed upwards throughout the whole length (above their points of entry) of the funiculus posterior to reach the medulla oblongata. Special terminal nuclei are developed from the alar lamina to receive these fibres. They are the *nucleus gracilis* and *nucleus cuneatus*.

Then again, part of the terminal vestibular nucleus receives accessions of fibres from these (*gracile* and *cuneate*) nuclei as well as from other sensory terminal nuclei in the spinal medulla and develops into that great mass of tissue, the cerebellum, to which vast numbers of other fibres come and go, adding considerably to the complexity of the region of the pons and medulla oblongata. Moreover, there is developed from the alar lamina a whole series of other masses of gray matter—the *nucleus olivaris inferior*, *nuclei arcuati*, *nucleus pontobulbaris* and *nuclei pontis*—as links in the complex chains that bind all parts of the central nervous system to the great co-ordinating mechanism of the cerebellum.

Thus it comes about that, instead of having, as in the spinal medulla, a definite column of gray matter ensheathed in a thick mass of white substance, the rhombencephalon is composed of many scattered masses of gray matter; and its white substance is represented partly by great longitudinal strands, but also by many great systems of fibres passing transversely through its substance or, as in the pons and many of the arcuate fibres, upon its surface.

From what has already been said concerning the external form of the medulla oblongata and pons it will be apparent that the curious distortion of the neural tube which occurred as the result of the pontine flexure has also been largely responsible for the distinctive features of this region of the brain.

As the pontine flexure develops, a strain is thrown upon the thin roof-plate, which yields and becomes stretched so as to permit the thick lateral walls of the neural tube to fall laterally (Figs. 483 and 484). One result of this process is the great lateral expansion of the cavity of the hind-brain, which assumes the characteristic rhomboid form. If the thin and greatly attenuated epithelial roof is torn away from the rhombencephalon of an embryo of the third month the fourth ventricle will present the appearance (viewed from behind) shown in Fig. 483. The ventricle is seen to be prolonged laterally, on each side, to form a little recess upon the lateral aspect of the rhombencephalon. This is called the *recessus lateralis*.

This thin epithelial roof becomes invaginated towards the cavity of the fourth ventricle, on each side of the median plane, in the whole length of the epithelial roof, *i.e.* from the cerebellar attachment above almost as far as the closed part of the medulla oblongata below (Fig. 519). The upper end of this invaginated fold becomes prolonged laterally as far as the extremity of the *recessus lateralis* (Fig. 527). Pia mater and blood-vessels extend into these folds, which are then known as the *chorioid plexuses* of the fourth ventricle. At the extremities of these two

plexuses, which are situated at the three corners of the epithelial roof of the ventricle, oval or elliptical perforations develop in the roof at about the fifth month of foetal life. These are known as the *apertura medialis ventriculi quarti* (O.T. *foramen of Magendie*), which opens between the clavæ on the posterior surface and the *apertura laterales* upon the anterior (Fig. 527), behind the insertion of the glossopharyngeal nerve on each side. Through each of these lateral openings the great swollen cauliflower-like extremity of the chorioid plexus becomes extruded from the ventricle. The inferior extremities of the two plexuses lying side by side present an analogous relationship to the *apertura medialis*, but they are exceedingly attenuated and the epithelial lamella from which they spring becomes dragged backwards into contact with the cerebellum (Fig. 477), so that, when seen from below, the *apertura medialis* is a great funnel-shaped tube leading into the fourth ventricle and the chorioid plexuses look like two delicate vascular fringes on the cerebellum.

These three apertures are the only means provided for the escape of the fluid contained in the ventricles of the central nervous system. The fluid is poured into a space, enclosed by the arachnoid, which is called the subarachnoid space.

As a result of the pontine flexure the lateral walls of the neural tube in the neighbourhood of the bend fall away the one from the other and eventually come to be placed in the same transverse plane,

FIG. 483. — TRANSVERSE SECTIONS ACROSS THE MEDULLA OBLONGATA IN TWO HUMAN EMBRYOS, REPRESENTING DIFFERENT STAGES IN THE EXPANSION OF THE ROOF AND THE FALLING LATERALLY OF THE LATERAL WALLS. (From His, slightly modified.)

FIG. 484.—THE BRAIN OF AN EMBRYO OF ELEVEN WEEKS, viewed from behind. The epithelial roof of the fourth ventricle has been removed. At this stage the cerebellum is in the form of a simple band or plate which arches over the posterior aspect of the anterior part of the cavity of the hind-brain. (From His.)

one with the other and also with the floor-plate. At the time this process is in operation (see Fig. 483) the alar and basal laminae are particularly well defined, and the limiting sulci are accentuated by the bending of the lateral wall; but this sharp distinction is soon lost as the result of the great expansion of the basal lamina (Fig. 485). This is due not only to growth of its intrinsic elements, but even more to its invasion by large numbers of neuroblasts which migrate from the alar into the basal lamina.

Later still the development of the great sensory and motor tracts contributes largely to the dimensions of the basal lamina.

As the two basal laminae (one on each side of the median plane) increase in thickness the epithelial cells in the intervening floor-plate become stretched and lengthened (Fig. 483), so that a definite septum or *raphe* is formed between the two halves of the rhombencephalon.

The fate of the extreme posterior edge of the alar lamina is a very curious one. The nervus acusticus is inserted into this edge in the region of the recessus lateralis, and from it masses of neuroblasts develop to form receptive nuclei for the two parts of this nerve, these being the cochlear and vestibular. These are the **nucleus cochlearis** and **nucleus vestibularis** respectively. Sensory fasciculi, bringing impulses from muscles, skin and related structures in all parts of the body, make their way into the superior part of the vestibular nucleus, and it grows and forms a large thickening of the posterior edge above the recessus lateralis. Eventually as it extends medially (Fig. 484) it reaches and invades the roof-plate and fuses with the corresponding rudiment of the other side. Thus a semilunar band, the primitive cerebellum, is formed, arching across the posterior aspect of the metencephalon. The part of the dorsal edge which lies below the vestibular nucleus becomes bent over (forwards) to form what is known as the **rhombic lip** (Fig. 483). It is destined to be transformed into a series of masses of gray matter, the chief

FIG. 485.—TRANSVERSE SECTION OF THE HUMAN EMBRYO AT A LATER STAGE THAN THOSE SHOWN IN FIG. 483. (After His.)

function of which is to emit fibres to carry impulses into the cerebellum. But most of these fibres pass not so much to the part of the cerebellum derived from their own side but to that of the opposite side. Thus, from above downwards, the thickened margin of the fossa rhomboidea on each side develops into the following structures:—cerebellum, the rest of the vestibular nucleus, the cochlear nucleus, the nuclei pontis (and arcuate nuclei), the olivary nucleus, the nucleus gracilis and nucleus cuneatus. At an early stage of development most of the neuroblasts that form the rudiments of the nuclei pontis, nuclei arcuati, and nucleus

olivaris inferior begin a curious process of migration, the course of which is determined by the source and direction of the afferent tracts passing into each nucleus. Such migrations are of common occurrence throughout the brain, and attempts to explain them have given rise to much discussion. The attractive force which appears to lead certain nerve-cells away from the place where they originally developed has been called *neurobiotaxis* by Ariens-Kappers. But the solution of the problems of these migrations is quite a simple one. If we take the case of a nerve-cell (*A*) at an early stage of development, which collects afferent impulses through its dendrites from the cell *B*, and emits an efferent impulse through its axon to the cell *C*, as the whole nervous system is very small at the stage under consideration, the three cells necessarily will be comparatively close the one to the other—a fact which may be represented by the positions of the letters thus:—

B—A—C.

In the course of subsequent growth it must inevitably happen that the points *B* and *C* will become removed further and further apart. If we suppose that the cell *B* remains constant the cell *A* will be faced with two alternatives if it is to continue to link together the elements *B* and *C*: either its dendrites or its axon must elongate. Now the axon is specially modified in structure for conducting impulses for long distances, and the dendrites are not so specialised. Therefore it invariably happens that it is the axon that becomes lengthened. In other words the cell-body *A*, considered in its relations to *C*, appears to migrate towards the direction *B* from which its chief supply of afferent impulses comes. This may be represented thus:—

B—A ————— C.

In the specific case we are considering the vestibular nucleus and the cerebellum receive their chief supply of afferent fibres from the incoming vestibular nerve: hence there is no reason for migration. Similarly the nucleus gracilis and nucleus cuneatus receive the fibres which come up through the funiculus posterior and remain where they are. But the nuclei pontis, the olivary nucleus, and the arcuate nuclei are "fed" with impulses passing downwards (and some perhaps upwards) in the basal lamina, close to the median plane, and they "migrate" towards the direction from which their afferent paths are approaching; the nuclei pontis towards the peduncles of the cerebrum bringing cerebro-pontine fibres from the cerebral cortex, and the olivary nucleus to the neighbourhood of certain descending tegmental tracts and ascending spinal sensory tracts that seem to supply the attractive force, which leads them to forsake the rhombic lip of the alar lamina and migrate into the basal lamina.

The majority of the cells destined to form the nuclei pontis wander obliquely upwards and forwards between the facial and acoustic nerves to reach the basal

FIG. 486.—TRANSVERSE SECTION THROUGH THE MIDDLE OF THE OLIVARY REGION OF THE HUMAN MEDULLA OBLONGATA.

The floor of the fourth ventricle is seen, and it will be noticed that the restiform body, on each side, has now taken definite shape. Some of the descending tracts in red; ascending tracts in blue.

lamina of the metencephalon. But strewn along this pathway from the edge of the fossa rhomboidea to the front of the pons are scattered nerve-cells which have, so to speak, fallen by the way, and remain to indicate in the adult brain the path taken by the majority of their sister cells. This remnant forms the **corpus ponto-bulbare**: the pontine fibres that spring from its cells and are making their way upwards to fall in line (Fig. 499, p. 566) with the other transverse fibres of the pons form the **fasciculus obliquus** [pontis], and the cerebro-pontine fibres that pass below the pons in order to reach this outlying part (corpus ponto-bulbare) of the nuclei constitute the **fasciculus circumolivaris pyramidis** (Fig. 517, p. 583).

But not all of the elements of the nuclei pontis that migrate pass into the metencephalon; a certain proportion of them invariably pass into the myelencephalon. These collect upon the anterior surface of the pyramids to form small irregular patches of gray matter which have received the name **nuclei arcuati**. Their afferent fibres (probably cerebro-pontine) come from the pyramids; and their efferent fibres (which proceed to the cerebellum) form some of the **fibræ arcuatae externæ**, which are visible upon the surface of the medulla oblongata (Fig. 486).

Olivary Nuclei.—The most conspicuous of the isolated clumps of gray matter

in the medulla are the inferior olivary nucleus and the two accessory olivary nuclei. The **nucleus olivaris inferior** is the mass of gray substance which produces the swelling known as the olive, and constitutes a very striking object in transverse sections through this region. It presents the appearance of a thick wavy or undulating line of gray matter, folded on itself, so as to enclose a space filled with white matter. It is in reality a crumpled lamina arranged in a purse-like manner, with an open mouth or slit, which is called the **hilus** (*hilus nuclei olivaris*), directed towards the median plane. The hilus does not reach either extremity, so that in transverse sections through either end of the nucleus the gray lamina is seen in the form of a completely closed capsule. Into and out of the open mouth of the olivary capsule streams a dense crowd of fibres. These constitute what is called the **olivary peduncle**.

The **accessory olivary nuclei** are two band-like laminae of gray matter, which are respectively placed on the dorsal and medial aspects of the main nucleus. In transverse section each of these nuclei presents a rod-like appearance (Fig. 486).

The **medial accessory olivary nucleus** (*medialis*) extends lower down in the medulla oblongata than the main nucleus, and it is much larger in its lower than its upper part. It begins immediately above the decussation of the pyramids, where it is seen lying on the lateral side of the cerebro-spinal fasciculus and the lemniscus medialis (Fig. 486). Higher up it lies across the mouth of the main nucleus and on the lateral side of the medial lemniscus. The **dorsal accessory olivary nucleus** is placed close to the dorsal aspect of the main nucleus. The two accessory nuclei fuse together before they finally disappear.

The nerve-cells of the inferior olivary nucleus are small and round, and emit a large series of short radiating, complexly branched dendrites, so that the cell-body seems to lie

FIG. 487.—THE INFERIOR OLIVARY NUCLEUS, as reconstructed and figured by Florence R. Sabin.

View of the dorso-lateral and lateral surfaces.

in the centre of a spherical mass formed by its own dendrites and an almost equally complex mass of intertwined end branches of the axons, which bring impulses into these cells. There is no definite information as to the place of origin of these afferent fibres. Flechsig and Bechterew, using different methods of investigation, have demonstrated the presence of a large descending tract in the mesencephalon and rhombencephalon, which ends amidst the cells of the lateral pole of the olivary nucleus. This has been called the *fasciculus thalamo-olivaris*, but it is not quite certain that it arises

in the thalamus, although its origin must be somewhere in the neighbourhood of it. Flechsig denies that any fibres reach the olivary nucleus from the spinal medulla, but the proximity of the spino-thalamic and bulbo-thalamic (*lemniscus medialis*) fibres and the demonstration of Ramon y Cajal that fibres enter the nucleus olivaris from adjoining fasciculi in these regions suggest that there may be a spinal afferent path.

There seems to be a direct relationship between the size of the inferior olivary nucleus and the extent of the cortical area that presides over highly skilled movements.

The axons emitted by the cells of the olivary nucleus cross the median raphe and pass through the opposite side of the medulla oblongata as internal arcuate fibres, which enter the restiform body and pass into the cerebellum.¹

These fibres are seen only in the superior part of the medulla oblongata. They form the deep part of the restiform body and constitute its chief bulk. Streaming out from the hilus of the inferior olivary nucleus, they cross the median plane, and in the opposite side of the medulla oblongata they either pass through the inferior

¹ These fibres should be called the *fasciculus olivocerebellaris*, by which designation they will be referred to in this account, but in the recognised nomenclature (which most writers do not follow in this instance) the tract is called "*cerebello-olivaris*."

olivary nucleus of that side or sweep round it. Ultimately, on the dorsal aspect of the olivary nucleus, they are gathered together in the form of a conspicuous group of arcuate fibres, which curve backwards to take up a position in the deep part of the restiform body. In passing back, they traverse the tractus spinalis of the trigeminal nerve and break it up into several separate bundles. The cerebello-olivary fibres thus connect the inferior olivary nucleus of one side with the opposite side of the cerebellum. Each part of the inferior olivary nucleus is connected with a definite part of the cerebellum.

Decussation of the Pyramids and the Changes produced thereby.—As we examine, under the microscope, a series of successive transverse sections through the inferior end of the medulla oblongata and the upper end of the spinal medulla, the most striking change which meets the eye is the decussation of the lateral cerebro-spinal tracts. From their position alongside the anterior median fissure of the medulla oblongata most of the fibres of the pyramid cross the median plane and,

FIG. 488.—DIAGRAM OF THE FASCICULUS OLIVOCEREBELLARIS (CEREBELLO-OLIVARY FIBRES).

N.XII., Hypoglossal nucleus.

after passing right through the anterior column of gray matter, bend downwards in the lateral funiculus of the opposite side of the spinal medulla. Strands from the right lateral cerebro-spinal tract alternate with corresponding strands from the left side, and the interval between the bottom of the anterior median furrow and the gray matter surrounding the central canal becomes filled up with a great mass of intercrossing bundles of fibres.

As a rule the medial three-fourths of the pyramid are composed of fibres which, lower down in the opposite lateral funiculus of the spinal medulla, form the fasciculus cerebro-spinalis, whilst the lateral fourth of the pyramid proceeds downwards in the anterior funiculus of the spinal medulla of the same side, as the fasciculus cerebrospinalis anterior. A considerable amount of variation, however, occurs in the proportion of fibres which is allotted to the formation of these two tracts. Sometimes the lateral cerebro-spinal tract is much larger than usual, and then the anterior cerebro-spinal tract suffers a corresponding diminution in size. Cases, indeed, occur in which the entire pyramid enters into the decussation, and in these there is no anterior cerebro-spinal tract. Further, it is not uncommon to meet with variations of an opposite kind which lead to an increase of the anterior cerebro-spinal tract at the expense of the lateral cerebro-spinal tract. Sometimes the decussation is asymmetrical, and the corresponding cerebro-spinal tracts on opposite sides of the spinal medulla are then unequal in size. One factor that often comes into play and causes asymmetry is the prolongation downwards into the pyramid on one side (usually the left) of some of the cerebro-pontine fibres. In such cases these fibres soon leave the pyramid and form the *fasciculus circumolivaris*.

The variations indicated above receive an additional interest when viewed in the light of comparative anatomy. It would appear that only in man and the anthropoid apes is the decussation of the pyramids in the inferior part of the medulla oblongata incomplete.

According to Sherrington, an anterior cerebro-spinal tract in the spinal medulla of the anthropoid apes stands in connexion with the arm-centre in the cerebral cortex. If this is the case in man it must have other connexions as well, seeing that it is carried down the spinal medulla for a considerable distance beyond the level of the spinal segments which give motor fibres to the upper limb. In the lower apes an anterior cerebro-spinal tract

does not seem to exist: the whole pyramid crosses over to the opposite side of the spinal medulla in the shape of the lateral cerebro-spinal tract.

As we have noted, the decussating pyramidal bundles pass through the anterior column of gray matter, and cut it into two portions (Figs. 489 and 490). The basal part remains in position on the anterior and lateral aspect of the central canal, and forms part of the thick layer of gray matter which surrounds it. The

FIG. 489.—SECTION THROUGH THE INFERIOR END OF THE MEDULLA OBLONGATA OF A CHIMPANZEE.

detached head of the anterior column is set free; and from the large multipolar cells which lie in its midst some of the fibres of the anterior root of the first cervical nerve, and also some of the root fibres of the accessory nerve, take origin.

As we proceed into the medulla oblongata another effect of the decussation of the pyramids is seen in the submergence from the surface of the strand of fibres which, in the anterior funiculus of the spinal medulla, lies to the lateral side of the anterior cerebro-spinal tract, and which receives the name of the fasciculus anterior proprius. While the decussation is going on the fasciculus proprius is thrust aside, and in the medulla oblongata, it takes up its position as a flattened band-like strand on the lateral side of the pyramid (Fig. 489). When the decussation is completed, this strand is seen to lie close to the median plane on the dorsal aspect of the pyramid, where it is separated from its fellow of the opposite side by the median raphe alone (Fig. 491). In the upper part of the medulla oblongata it approaches still nearer to the dorsal surface and appears to form the greater part of a strand, which is termed the **medial longitudinal bundle** (Figs. 494 and 495). The detached head of the anterior column of gray matter of the spinal medulla,

FIG. 490.—TRANSVERSE SECTION THROUGH THE INFERIOR END OF THE MEDULLA OBLONGATA OF A FULL-TIME FŒTUS,

Treated by the Weigert-Pal method. The gray matter is bleached white, and the medullated tracts of fibres are black.

as it is traced upwards, is observed to cling closely to its original relationship with the fasciculus anterior proprius. It is applied to the lateral side of this strand, and, gradually becoming smaller, finally disappears at the level of the inferior part of the inferior olivary nucleus.

Cuneate and Gracile Fasciculi, with their Nuclei.—As the fasciculus gracilis and the fasciculus cuneatus of the posterior funiculus of the spinal medulla are traced up into the medulla oblongata they seem to increase in bulk, and in transverse sections they assume the form of massive wedge-shaped strands, quite distinct from each other. They increase in width and lose considerably in depth, and consequently the transverse diameter of the area which they occupy becomes greater. As a result of this, and also owing to the removal of the lateral cerebro-spinal tract from the lateral funiculus of the spinal medulla immediately in front, the posterior column of gray matter is gradually rotated forwards and comes to lie transversely and in the same straight line with its fellow of the

FIG. 491.—SECTION THROUGH THE CLOSED PART OF THE HUMAN MEDULLA OBLONGATA IMMEDIATELY ABOVE THE DECUSSATION OF THE PYRAMIDS (Weigert-Pal specimen).

opposite side (Figs. 490 and 491). The substantia gelatinosa, at the same time, becomes increased in quantity and presents a horseshoe-shaped outline in transverse section. It clasps within its concavity the somewhat reduced head of the posterior column, and forms with it a conspicuous circular mass of gray matter which lies close to the surface, and produces upon it the bulging termed the tuberculum cinereum. The basal portion of the posterior column of gray matter remains upon the dorsal and lateral aspect of the central canal, and forms a portion of the central gray mass of the closed part of the medulla oblongata; but very soon the neck of the column, which at this level is greatly reduced owing to the absence of entering posterior nerve-roots, is invaded by bundles of fibres which traverse it in different directions and convert it into a formatio reticularis. By this means the rounded head of the posterior column becomes cut off from the central gray matter, and from this point upwards it remains as an isolated gray column intimately associated with the spinal root of the trigeminal nerve. It has, in fact, become the *nucleus tractus spinalis nervi trigemini*.

The *gracile* and *cuneate* nuclei are seen in their most typical form in sections at the level of the decussation of the pyramids (Figs. 489 and 490). The *gracile*

nucleus appears in the form of a relatively slender mass of gray matter in the interior of the funiculus gracilis.

The **cuneate nucleus** is a direct offshoot from that part of the base of the posterior column of gray matter which is preserved as a portion of the central gray mass. In transverse section it is seen to invade the funiculus cuneatus upon its deep aspect, and it gradually grows backwards into its substance. It presents

FIG. 492.—SECTION THROUGH THE INFERIOR PART OF THE MEDULLA OBLONGATA OF THE ORANG.

a very different appearance from the gracile nucleus, because throughout its whole length the gray nucleus and the fibres of the strand are separated from each other by a sharp line of demarcation. A little higher up a second and much smaller mass of gray matter appears in the funiculus cuneatus, superficial to the main nucleus. This is termed the **accessory** or the **lateral cuneate nucleus** (Fig. 491).

As a series of sections is studied from below upwards, it will be noticed that the number of fibres in the gracile and

cuneate funiculi rapidly decreases, until, at the level of the clava and cuneate tubercles, it is seen that these eminences are composed almost entirely of the gray nuclei, covered by a thin layer of the few remaining fibres of the two fasciculi involved. It would appear that no fibres belonging to the funiculus gracilis and funiculus cuneatus get beyond these nuclei. They all end in fine terminal ramifications around the cells of the nuclei. In the case of the funiculus cuneatus the bundles of fibres, as they pass from the surface into the subjacent gray nucleus, are very distinctly seen in transverse sections through the bulb.

When the medulla oblongata opens up into the fourth ventricle the gracile and cuneate nuclei are pushed laterally by the expanding ventricular floor, and the gracile nucleus soon comes to an end; but the cuneate nucleus extends upwards for a short distance farther, and terminates only when the restiform body begins to take definite shape on its lateral aspect.

Decussatio

Lemniscorum.

Immediately above the level of the decussation of the pyramids another decussation of fibres takes place in the substance of the medulla oblongata in the median plane, and upon the dorsal aspect of the pyramids. This is the decussation of the **lemniscus medialis**, or the **sensory decussation**, so-called in contradistinction to the term "motor decussation," which is sometimes applied to the decussation of the pyramids. The fibres which take part in this decussation are called **internal arcuate fibres**, and they are derived from the cells of the gracile and cuneate nuclei. From the deep aspects of these nuclei these fibres

FIG. 493.—TRANSVERSE SECTION THROUGH THE CLOSED PART OF A FETAL MEDULLA, IMMEDIATELY ABOVE THE DECUSSATION OF THE PYRAMIDS.

Treated by Weigert-Pal method.

stream forwards and medially towards the median raphe, forming a series of concentric curves in the substance of the medulla oblongata. They cross the median plane and decussate with the corresponding fibres of the opposite side, upon the dorsal aspect of the pyramids. Having thus gained the opposite side of the medulla oblongata, they immediately turn upwards and form a conspicuous strand of longitudinal fibres, which ascends close to the median plane and is separated from its fellow of the opposite side by the median raphe alone. This strand is termed the **lemniscus medialis**.

FIG. 494.—TRANSVERSE SECTION THROUGH THE HUMAN MEDULLA OBLONGATA IN THE INFERIOR OLIVARY REGION.

As we proceed up the medulla the internal arcuate fibres which first come into sight appear as coarse bundles which curve

FIG. 495.—TRANSVERSE SECTION THROUGH THE MIDDLE OF THE OLIVARY REGION OF THE HUMAN MEDULLA OBLONGATA.

The floor of the fourth ventricle is seen, and it will be noticed that the restiform body on each side has now taken definite shape. Some of the descending tracts in red; ascending tracts in blue.

forwards in a narrow group round the central gray matter (Figs. 494 and 495). Soon, other finer bundles appear, which describe wider curves on the lateral side of the coarser group,

until a very large part of each lateral half of the medulla is seen to be traversed by these arcuate fasciculi (Fig. 495). The internal arcuate fibres decussate in the median plane with the internal arcuate fibres of the opposite side. They then change their direction and turn upwards, and the lemniscus, as already stated, takes form and gradually increases in volume as it ascends. This great and important tract is thus laid down between the pyramid and the **fasciculus longitudinalis medialis**; and the consequence of this is that the latter tract is pushed still farther backwards, and, when the lemniscus is fully established, it comes to lie immediately beneath the gray matter of the floor of the fourth ventricle (Fig. 495). But the lemniscus is not in direct contact with the fasciculus longitudinalis, for a bundle of fibres, the continuation of which has been seen in the anterior funiculus of the medulla spinalis, the **fasciculus tectospinalis**, separates them as well as fibres coming from sensory nuclei of the cerebral nerves which are crossing the raphe to join the medial lemniscus (Fig. 495).

It is important that we should realise at this stage the full significance of the decussation of the lemniscus and have a clear conception of the connexions of the fibres which take part in it. The funiculus posterior, which ends in the cuneate and gracile nuclei, is derived from the posterior roots of the spinal nerves. The lemniscus fibres therefore carry on the continuity of part of the posterior funiculus, the gracile and cuneate nuclei, which are thrown across its path in the lower part of the medulla oblongata, merely constituting a nodal interruption. At this point the lemniscus is transferred to the opposite side of the medulla oblongata. But it will be remembered that a large proportion of the fibres of the entering posterior nerve-roots of the spinal nerves end in connexion with the cells of the posterior column of gray matter of the spinal medulla. It must not be supposed that the path represented by these latter fibres comes to a termination thereby; from these posterior column cells other fibres arise which cross, in the anterior white commissure, to the opposite side of the spinal medulla and proceed up the spinal medulla to the lateral part of the medulla oblongata. These fibres constitute the **spino-thalamic tract** already referred to. *The practical bearing of this is that, owing to the crossing of the lemniscus medialis and lower down of the spino-thalamic tract, unilateral lesions of the medulla oblongata are apt to produce complete hemi-anaesthesia; whilst unilateral lesions of the spinal medulla produce only partial hemi-anaesthesia.*

The pyramid forms a massive tract in front of and quite distinct from the lemniscus medialis. The lemniscus medialis, the tecto-spinal bundle, and the medial longitudinal bundle are, in the first instance, not marked off from each other. They appear as a broad flattened band applied to the raphe. One edge of this band is directed backwards and reaches the gray matter on the floor of the fourth ventricle, while the other edge looks forwards, and is in contact with the pyramid. In the upper part of the medulla oblongata the lemniscus and the medial longitudinal fasciculus begin to draw asunder from each other. The intermediate longitudinal fibres become reduced in number and the two strands grow denser—the one on the dorsal aspect of the pyramid, and the other immediately beneath the gray matter of the floor of the fourth ventricle (Fig. 495).

The **fasciculus longitudinalis medialis** is largely formed of fibres homologous with those which in the spinal medulla constitute the fasciculus anterior proprius. As they are followed upwards these fibres are thrust back by the two decussations: the lower decussation pushing them behind the pyramids, and the upper decussation displacing them still farther backwards to a position behind the lemniscus medialis.

Corpus Restiforme.—The gracile and cuneate nuclei gradually give place to the **restiform body** in the superior part of the posterior district of the medulla oblongata. Fibres from various quarters converge to form this great strand. It first takes shape as a thin superficial layer of longitudinal fibres, which are gathered together on the lateral aspect of the cuneate nucleus; but after that nucleus has come to an end, and as the superior part of the medulla oblongata is reached, the restiform body is seen to have grown into a massive strand, which presents a kidney-shaped or oval outline on transverse section (Fig. 495); and it ultimately enters the white central core of the cerebellum as its inferior peduncle. The fibres which build up the restiform body are the following: (1) the fasciculus spino-cerebellaris; (2) arcuate fibres coming from the nucleus gracilis and nucleus cuneatus of both

sides of the medulla oblongata; (3) external arcuate fibres coming from the arcuate nuclei; and (4) olivo-cerebellar fibres.

The *fasciculus spinocerebellaris* extends upwards from the lateral funiculus of the medulla spinalis. In the lateral district of the medulla oblongata it occupies a similar position; but before the olive is reached it inclines backwards, crosses the posterior lateral furrow and passes obliquely upwards into the restiform body. As its fibres diverge backwards, they pass over and cover up the tractus spinalis of the trigeminal nerve and its nucleus, thus shutting them out from the surface. The fibres of the *fasciculus spinocerebellaris*, in the first instance, enter into the lateral or superficial part of the restiform body.

Bruce has shown that the fibres of the spino-cerebellar tract ultimately lie in the centre of the restiform body, forming as it were its central core, and that, in the cerebellum, they can be traced to the superior vermis.

The **posterior external arcuate fibres** take origin from the gracile and cuneate nuclei, and enter the superficial part of the restiform body of the same side.

The **anterior external arcuate fibres** proceed from the inferior portions of the gracile and cuneate nuclei of the opposite side. It can easily be determined that, after decussating in the median plane, all the internal arcuate fibres which arise from these nuclei do not enter the lemniscus medialis. A large proportion of them gain the surface by sweeping round the medial aspect of the pyramid in the anterior median fissure. Many of them gain the surface by piercing the pyramid or by passing out between it and the olive. These fibres constitute the anterior external arcuate group, and on the surface of the medulla oblongata they sweep

FIG. 496.—DIAGRAM,

Which shows in part the fibres which enter into the constitution of the restiform body.

FIG. 497.—SECTION THROUGH THE JUNCTION BETWEEN THE SPINAL MEDULLA AND MEDULLA OBLONGATA OF THE ORANG. The spino-cerebellar tract is well seen, especially on the right side.

conveys to the cerebellum (1) fibres conveying impulses from the posterior spinal roots of the same and also from the opposite side of the medulla spinalis, the former after being interrupted in the nucleus dorsalis and the nucleus gracilis and nucleus cuneatus of the same side, the latter in the nucleus gracilis and nucleus cuneatus of the other side; and (2) fibres from the olivary and arcuate nuclei, which convey impulses from the higher regions of the brain, directly or indirectly (probably the latter) from the motor area of the cerebral cortex.

backwards around it, forming a thin layer over the olive and ultimately reaching the restiform body. The anterior external arcuate fibres, as well as the spino-cerebellar tract-fibres, cover over the tractus spinalis of the trigeminal nerve, which thus comes to take up a deeper position in the substance of the medulla oblongata (Figs. 495 and 496).

The other elements in the restiform body, viz., those derived from the nucleus olivaris inferior and the nuclei arcuati, have already been described.

Thus, the restiform body

Formatio Reticularis.—Behind the olive and the pyramid is the **formatio reticularis**. In the medulla oblongata it occupies a position which, to a large extent, corresponds with that of the lateral funiculus in the spinal medulla. In transverse section it appears as an extensive area, which is divided into a lateral and a medial field by the fila of the hypoglossal nerve as they traverse the substance of the medulla oblongata to reach the surface. In the lateral portion, which lies behind the olive, a considerable quantity of gray matter, continuous with that in the spinal medulla, is present in the reticular formation; it is, therefore, called the **formatio reticularis grisea**. In the medial part, which lies behind the pyramid, the gray matter is extremely scanty, and the reticular matter here is termed the **formatio reticularis alba**.

The nerve-fibres which traverse the **formatio reticularis** run both in a transverse and in a longitudinal direction. The **transverse fibres** are the internal arcuate fibres. The **longitudinal fibres** are derived from different sources in the two fields. In the **formatio grisea** they represent to a large extent the fibres of the lateral funiculus of the spinal medulla, after the removal of the spino-cerebellar and the lateral cerebro-spinal tracts. They consist, therefore, of the fibres of the fasciculi rubro-spinalis, thalamo-olivaris, spinothalamicus, and spinocerebellaris anterior (antero-lateralis superficialis) of the spinal medulla. In the **formatio alba** the longitudinal fibres are the tract of the lemniscus medialis, fasciculus tectospinalis, and the medial longitudinal bundle, all of which have already been described.

Central Canal and the Gray Matter which surrounds it.—The central canal, as it proceeds upwards through the closed part of the medulla, is gradually forced to assume a more dorsal position, owing to the accumulation of fibres on its ventral aspect. (Moreover, the posterior cleft-like part of the cavity of the foetal neural tube, which becomes obliterated in the spinal medulla by the fusion of its walls, remains patent in the medulla oblongata. Hence the central canal in the closed part of the medulla oblongata extends backwards to the roof-plate.) First the decussation of the pyramids, and then the decussation of the medial lemniscus, both of which take place in front of the canal, tend to push it backwards; and the formation of the longitudinal strands in which these intercrossings result (viz., the pyramid and the medial lemniscus), together with the continuation upwards of the funiculus anterior proprius, leads to a great increase in the amount of tissue which separates it from the anterior surface of the medulla oblongata. In the closed part of the medulla oblongata the canal is surrounded by a thick layer of gray matter, which is continuous with the basal portions of the anterior and posterior columns of gray matter of the spinal medulla. This central gray matter is sharply defined on each side by the internal arcuate fibres, which curve forwards and medially around it. Finally, the central canal opens on the dorsal aspect of the medulla oblongata into the cavity of the fourth ventricle. The central mass of gray matter which surrounds the canal in the closed part of the medulla oblongata is now spread out in a thick layer on the floor of the fourth ventricle, and in such a manner that the portion which corresponds to the basal part of the anterior column of the spinal medulla is situated close to the median plane, whilst the part which represents the base of the posterior column occupies a more lateral position. This is important, because the nucleus of origin of the hypoglossal nerve is placed in the medial part of the floor, whilst the nuclei of termination of the afferent fibres of the vagus, glossopharyngeal, and acoustic nerves lie in the lateral part of the floor. The gray matter of the ventricular floor is covered with ependyma.

Three Areas of Flechsig.—In transverse sections, through the upper, open part of the medulla oblongata, the fila of the hypoglossal and vagus nerves are seen traversing the substance of the medulla oblongata. The nucleus of origin of the hypoglossal is placed in the gray matter of the floor of the fourth ventricle close to the median plane; the nucleus of the vagus is situated in the gray matter of the ventricular floor immediately to the lateral side of the hypoglossal nucleus. From these nuclei the root-bundles of the two nerves diverge from each other as they are traced to the surface and subdivide the substance of the medulla, as seen in transverse section, into the three areas of Flechsig, viz., an anterior, a lateral, and a posterior.

The **anterior area**, which is bounded medially by the median raphe and laterally by the hypoglossal roots, presents within its limits: (*a*) the substantia alba; (*b*) the pyramid; (*c*) the lemniscus medialis; (*d*) the medial longitudinal fasciculus; (*e*) the medial accessory olivary nucleus; (*f*) the arcuate nucleus.

The **lateral area** lies between the root fibres of the hypoglossal and those of the vagus. It contains: (a) the inferior olivary nucleus; (b) the dorsal accessory olivary nucleus; (c) the nucleus lateralis; (d) the nucleus ambiguus; (e) the splanchnic efferent nucleus of the vagus and glossopharyngeal nerves; (f) the *formatio reticularis grisea*.

The **posterior area** is situated behind the vagus roots, and within its limits are seen: (1) the restiform body; (2) the superior part of the cuneate nucleus; (3) to the medial side of this a crowd of transversely cut bundles of fibres, loosely arranged and forming the descending root of the vestibular part of the acoustic nerve; (4) close to these, but placed more deeply, a round, compact, and very conspicuous bundle of transversely cut fibres, viz., the *tractus solitarius*, or descending root of the vagus and glossopharyngeal nerves; (5) the large *tractus spinalis* of the trigeminal nerve close to the lateral side of its nucleus composed of *substantia gelatinosa*.

INTERNAL STRUCTURE OF THE PONTS.

When transverse sections are made through the pons, it is seen to be composed of a basilar part and a dorsal or tegmental part. The latter may be regarded as

FIG. 498.—SECTION THROUGH THE LOWER PART OF THE HUMAN PONTS IMMEDIATELY ABOVE THE MEDULLA OBLONGATA.

the upward prolongation of the medulla oblongata, exclusive of the pyramids which are drawn forward into the basilar part.

Pars Basilaris Pontis.—This constitutes the chief bulk of the pons. It is composed of: (1) transverse fibres arranged in coarse bundles, *fibræ pontis*; (2) longitudinal fibres, gathered together in massive bundles; and (3) a large amount of gray matter, termed the *nuclei pontis*, which fills up the interstices between the intersecting bundles of fibres.

The *fasciculi longitudinales*, to a large extent, consist of the same fibres which, lower down, are gathered together in the two solid pyramidal tracts of the medulla oblongata. When the pyramids are traced upwards into the pons they are seen to

present the form of two compact bundles. Superiorly, however, they are broken up into smaller bundles by the transverse fibres of the pons, and are spread out over a wider area. At the upper border of the pons they again come together and form two solid strands, each of which is continuous with the central part of the corresponding basis of the cerebral peduncle. Added to these there are twice as many other fibres entering the pons from the basis pedunculi to terminate in the nuclei pontis.

The **fibræ pontis** at the inferior border of the pons are placed on the superficial or ventral aspect of the pyramidal bundles. As we proceed upwards they increase in number, and many are seen breaking through the pyramids and even passing across upon their dorsal aspect. Laterally, these transverse fibres are collected together into one compact mass, which enters the white central core of the cerebellum and constitutes the **brachium pontis** (O.T. **middle cerebellar peduncle**). At the median plane the transverse fibres of the two sides of the basilar portion of the pons intercross and form a coarse decussation.

The **nuclei pontis** form a considerable part of the bulk of the basilar portion of the pons. The gray matter is packed into the intervals between the intersecting transverse and longitudinal bundles.

There is some analogy between the pyramidal portions of the medulla oblongata and the ventral part of the pons. In the medulla oblongata fine arcuate fibres, on their way to the surface, pass through the pyramids. Other external arcuate fibres sweep over the surface of the pyramids. These present a strong resemblance to the transverse fibres of

the pons. They likewise reach the cerebellum, although by a different route, viz., the restiform body. The nuclei pontis are represented also in the pyramidal part of the medulla oblongata by the arcuate nuclei, which are covered over by the external arcuate fibres, and even tend to penetrate, to a slight extent, into the pyramidal tracts. These arcuate nuclei, as already pointed out, are continuous with the nuclei pontis.

Connexions of the Longitudinal and Transverse Fibres.

When a transverse section through the superior part of the pons is compared with one close to its inferior border, it becomes at

FIG. 499.—DIAGRAM OF THE LEFT LATERAL ASPECT OF THE FŒTAL RHOMBENCEPHALON REPRESENTING SOME OF THE CELL GROUPS AND FIBRE TRACTS.

once apparent that the numerous scattered bundles of longitudinal fibres which enter the ventral part of the pons from above, if brought together into one tract, would form a strand very much larger than the two pyramids which leave its lower aspect and enter the medulla oblongata. It is clear, therefore, that many of the longitudinal fibres which pass into the pons from above do not pass out from it below into the medulla oblongata. What becomes of these fibres that are thus absorbed in the pons? It is known that the pyramidal bundles suffer a small loss by the fibres which they send to the nuclei of origin of the efferent nerves which arise within the pons (viz., the motor root of the trigeminal, abducens, and facial nerve nuclei); but this loss is, comparatively speaking, trifling. It is clear, therefore, that other longitudinal bundles enter the pons from above apart from those which form the pyramidal tracts. These bundles occupy a lateral and dorsal position in the ventral part of the pons, and may be termed the **cerebro-pontine fibres**, seeing that they come from the cerebral cortex and end in fine ramifications around the cells of the nuclei pontis (Fig. 498).

The transverse fibres take origin as axons of the cells of the nuclei pontis. Crossing the median plane, they enter the brachium pontis of the opposite side, and thus reach the cerebellar cortex, where they end in ramifications round certain of the cortical cells. Some authorities believe that there are also fibres passing in the opposite direction, *i.e.*

from the cerebellum to the nuclei pontis; but there is some doubt concerning the existence of any such fibres. The brachium pontis thus may contain both efferent and afferent cerebellar fibres; but no fibres pass continuously through the pons from one brachium pontis into the other.

Certain of the transverse fibres of the pons turn backwards and enter the dorsal or tegmental part of the pons, but the precise connexions of these are doubtful.

Corpus Trapezoideum.—This name is applied to a group of transverse fibres which traverse the lower part of the pons (Fig. 498). They are quite distinct from those which have been just described as entering the brachium pontis, and they lie in the boundary between the dorsal and basilar parts of the pons, but encroaching considerably into the ground of the former. They arise from the cells of the terminal nucleus of the cochlear division of the acoustic nerve, and constitute a tract which establishes certain central connexions for that nerve. They will be more fully described when we treat of the cerebral connexions of the acoustic nerve.

Pars Dorsalis Pontis (Dorsal or Tegmental Part of the Pons).—On the dorsal surface of the tegmental part of the pons there is spread a thick layer of gray matter, covered with ependyma, which forms the floor of the upper or pontine part of the fourth ventricle. Beneath this the median raphe of the medulla oblongata is continued up into the pons, so as to divide its tegmental part into two symmetrical halves.

In the *inferior part of the pons*, immediately beyond the medulla oblongata, the restiform body is placed on the outer side of the dorsal part (Fig. 498). In transverse sections through the pons it appears as a large, massive oval strand of fibres which gradually inclines backwards into the cerebellum, and thus leaves the pons. Between the restiform body and the median raphe the tegmental part of the pons is composed of substantia reticularis, continuous with the same material in the medulla oblongata. Thus arcuate or transverse fibres, curving in towards the raphe, and also longitudinal fibres, are seen breaking through a mass of gray matter which occupies the interstices of the intersecting fibres. To the naked eye the formatio reticularis presents a uniform gray appearance, but its constituent parts are revealed by low powers of the microscope in properly stained and prepared specimens. Embedded in this substantia reticularis are various clumps of compact gray matter and certain definite strands of fibres. These we shall describe as we pass from the restiform body medially towards the median raphe.

(1) **Spinal Root of the Trigeminal Nerve and its Nucleus.**—Close to the medial side of the restiform body, but separated from it by the vestibular root of the acoustic nerve as it proceeds backwards through the pons, is seen a large crescentic group of coarse transversely divided bundles of fibres. This is the tractus spinalis (O.T. spinal root) of the trigeminal nerve, and applied to its medial concave side is a small mass of gray matter, which is the direct continuation upwards of the substantia gelatinosa.

(2) The nucleus of the facial nerve comes next. It is sunk deeply in the dorsal part of the pons and lies close to the transverse fibres of the corpus trapezoideum. It is a conspicuous, obliquely placed, ovoid clump of gray matter. From its lateral and dorsal aspect the root-fibres of the facial nerve stream backwards and medially towards the gray matter on the floor of the fourth ventricle. Passing forwards between this nucleus and the trigeminal sensory nucleus a solid nerve-bundle may be observed. This is the facial nerve, traversing the pons towards its place of emergence from the brain.

(3) Immediately medial to the facial nucleus, but placed more deeply in the tegmental part of the pons, is the **superior olivary nucleus**. It lies in a bay formed for it by the transverse fibres of the corpus trapezoideum. These fibres curve round its ventral aspect, and many of them may be observed penetrating into its substance. In man, it is a very small mass of gray matter, and presents little resemblance to the inferior olivary nucleus, except in the size and shape of its constituent cells. In sections through the part of the pons where it attains its greatest size, it appears in the form of two, or it may be three, small isolated masses of gray matter. It is intimately connected with the acoustic fibres, and establishes manifold connexions between them and the nuclei of other nerves.

Upon the medial and dorsal aspect of the superior olive there is a dense group of longitudinal fibres. These constitute the **fasciculus thalamo-olivaris** or **central tegmental tract**, to which we have already referred in discussing the inferior olivary nucleus (Fig. 498). It is uncertain whether this tract arises in the thalamus.

(4) The **medial longitudinal bundle** and the **lemniscus medialis** come next. As they proceed upwards through the tegmental part of the pons, these longitudinal tracts occupy the same relative position as in the medulla oblongata. They are placed close to the median raphe; but they have drawn further apart from each other, and their fibres are more distinctly concentrated into separate strands, with an interval of some little width between them, which is occupied by the **tecto-spinal tract**. The **medial longitudinal bundle** lies immediately under cover of the gray

FIG. 500.—TRANSVERSE SECTION THROUGH THE PONS AT THE LEVEL OF THE NUCLEI OF THE TRIGEMINAL NERVE (Orange).

matter of the floor of the fourth ventricle. The **lemniscus medialis** is placed close to the trapezial fibres, many of which traverse it as they pass towards the median plane.

(5) The **nucleus of the abducens nerve** also forms a conspicuous object in sections through the lower part of the pons. It is a round mass of gray matter, which is situated close to the lateral side of the medial longitudinal bundle, and immediately under cover of the gray matter of the floor of the fourth ventricle. From its medial side numerous root-bundles of the abducens nerve pass out and proceed forwards between the lemniscus medialis and the superior olivary nucleus. They occupy in the pons, therefore, a position similar to that occupied by the hypoglossal root-fibres in the medulla oblongata.

Up to the present only the inferior part of the dorsal portion of the pons has been described, *i.e.* the portion immediately adjoining the medulla oblongata. As we proceed upwards and gain a point *above the level of the trapezial fibres*, many of the structures which have attracted attention lower down gradually disappear from the formatio reticularis. The lemniscus medialis becomes markedly

increased in size by the addition of the fibres of the spino-thalamic tract. Further, the floor of the fourth ventricle becomes narrower, and other objects appear in the tegmental substance.

The **brachium conjunctivum** (O.T. **superior cerebellar peduncle**) is a very conspicuous object, in sections, through the middle and upper parts of the pons. In transverse section it presents a semilunar outline, and as it emerges from the cerebellum it lies immediately on the lateral side of the fourth ventricle, towards which its concave aspect is turned (Fig. 500). Its dorsal border is joined with the corresponding brachium of the opposite side by the thin lamina of white matter, termed the *anterior medullary velum*, whilst its ventral border is sunk to a small extent in the dorsal part of the pons. As it is traced upwards it sinks deeper and deeper into the pons until it becomes completely submerged, with the exception of the dorsal border to which the anterior medullary velum is attached. It now lies on the lateral side of the tegmental or reticular substance of the pons, and this position it maintains until the mesencephalon is reached (Fig. 501).

About *half-way up the pons* the nuclei of the trigeminal nerve mark a very

FIG. 501.—SECTION THROUGH THE SUPERIOR PART OF THE PONTS OF THE ORANG, ABOVE THE LEVEL OF THE TRIGEMINAL NUCLEI.

important stage in its tegmental portion. These nuclei are two in number on each side, viz., a large oval terminal nucleus for certain of the sensory fibres of the nerve and a nucleus of origin, equally conspicuous, for certain of the motor fibres (Fig. 500). The **sensory nucleus** lies close to the lateral surface of the pons, deeply sunk in its tegmental part, and in the interval between the submerged anterior border of the brachium conjunctivum and the ventral part of the pons. The **motor nucleus** is placed on the medial side of the sensory nucleus, but somewhat nearer the dorsal surface of the pons. At this level the tractus spinalis of the trigeminal nerve begins by the bending downward of the fibres of the sensory portion. The sensory and motor roots of the fifth nerve traverse the ventral part of the pons on their way to and from the region of the nuclei.

Above the level of the nuclei of the trigeminal nerve a new tract of fibres comes into view. This is the **mesencephalic root** of the trigeminal nerve, as it descends towards the rest of the nerve. It is a small bundle of nerve-fibres, semilunar in cross section, which lies close to the medial side of the brachium conjunctivum and on the lateral and deep aspect of the gray matter on the floor of the fourth ventricle (Figs. 500 and 501).

On a slightly deeper plane than the mesencephalic root of the fifth nerve, between it and the medial longitudinal bundle, and in close relation to the gray

matter of the floor of the ventricle, is the collection of pigmented cells which constitutes the *substantia ferruginea*.

The **medial longitudinal bundle**, as it is traced upwards through the tegmental part of the pons, maintains the same position throughout, and as it ascends it becomes more clearly mapped out as a definite and distinct tract. It lies close to the median raphe, and immediately subjacent to the gray matter of the floor of the fourth ventricle.

The **lemniscus medialis**, as it ascends through the tegmental part of the pons, undergoes striking changes in shape. In the lower portion of the pons its fibres, which in the medulla oblongata are spread out along the side of the median raphe, are collected together in the form of a loose bundle, which occupies a wide field, somewhat triangular in shape, on either side of the median raphe and immediately behind the basilar portion of the pons. As it proceeds up, the fibres spread out laterally until a compact ribbon-like layer is formed in the interval between the tegmental and basilar portions of the pons (Figs. 501 and 502).

Above the level of the trigeminal nuclei another flattened layer of fibres comes

FIG. 502.—TWO SECTIONS THROUGH THE DORSAL PORTION OF THE PONS AT ITS SUPERIOR PART, CLOSE TO THE MESENCEPHALON.

A is at a slightly lower level than B.

into view to the lateral side of the lemniscus medialis. To this the name of **lemniscus lateralis** is given. These fibres spread laterally and backwards, and finally take up a position on the lateral surface of the brachium conjunctivum. In the angle between the medial and lateral lemnisci a little knot of compact gray matter, termed the **nucleus lemnisci lateralis**, comes into view (Fig. 501). This appears to be in more or less direct continuity with the superior olivary nucleus. Many of the fibres of the lemniscus lateralis take origin in this nucleus. Bruce called attention to the continuity between the superior olive and the nucleus of the lateral lemniscus in man, and Cunningham confirmed the observation in so far as the orang brain is concerned. In many other mammals the nuclei are quite distinct.

THE CEREBELLUM.

In the foregoing account it has been seen that the cerebellum is formed from two distinct rudiments, each derived from the posterior edge of the alar lamina immediately above the pontine flexure and the insertion of the vestibular nerve. As development proceeds during the second month there is a rapid proliferation of cells in the mantle layer of the cerebellar rudiments, and they become considerably thickened. But at first this thickening manifests itself not so much as a swelling of the superficial aspect of the cerebellum but as a bulging inwards into the cavity of the fourth ventricle (Fig. 503).

The accentuation of the pontine flexure at this stage brings the two cerebellar rudiments into the transverse direction and in line one with the other and the roof-plate, which is now being thickened by immigrant neuroblasts from the medial extremities of the two cerebellar rudiments. When one organ is thus formed by the union in the roof-plate of the originally separate rudiments, it presents the form of a dumb-bell shaped mass (Fig. 503). Upon the inferior aspect of this mass there is a slight ridge, to which the *tela chorioidea ventriculi quarti* is attached. Opposite the lateral cerebellar rudiments (but not in the median plane) the attachment of the tela becomes thickened to form the posterior medullary vela.

Early in the third month the growth of the cerebellar rudiment begins to manifest itself by lateral bulgings of its surface.

The rhombic lip, the inferior part of which has been seen to play an important part in the development of the nuclei pontis and nucleus olivaris inferior, is also continued upwards beyond the pontine flexure on to the cerebellar rudiment, where it forms a marginal fringe. Thus even in the second month a groove can be detected upon the cerebellum separating off a band which is continuous with the tuberculum acusticum. The part nearest to the latter represents the rudiment of the *flocculus* and the medial extremity the *nodulus* (Fig. 503). During the third month the cerebellum appears as a rounded bar transversely placed across the upper part of the roof of the fourth ventricle, and as the lateral extremities of this bar expand (Fig. 504), it assumes a dumb-bell shape not unlike that presented a few weeks earlier (Fig. 503) on its ventricular aspect. As these lateral bosses (*lobi laterales*) develop, a mass of transverse fibres in connexion with them also becomes apparent. It represents the fibres transverse of the pons. They arise from the cells (*nuclei pontis*) which have wandered into the basal lamina of the metencephalon from the rhombic lip of the myelencephalon (Fig. 499); and the fibres which enter each cerebellar boss come mainly from the nuclei pontis of the other side. Towards the end of the fourth month, or even a month earlier in some cases, a little bud grows out from the cerebellum on each side immediately above the flocculus. It is the *paraflocculus* or *flocculus secundarius*. In man it never attains a large size, but in most mammals it develops into a large lobe, even as big as one-third the size of a cerebellar hemisphere (in the manatee), and in many animals a deep fossa is formed in the temporal bone to lodge this part of the cerebellum.

FIG. 504.—THE POSTERIOR ASPECT OF A FETAL (FOURTH MONTH) CEREBELLUM, MEDULLA OBLONGATA AND FOSSA RHOMBOIDEA.

FIG. 503.—DORSAL ASPECT OF THE RHOMBOENCEPHALON IN A HUMAN EMBRYO.

third month. Earlier in that month the median part of the cerebellum presents in sagittal section almost a semicircular outline (Fig. 507, A) with a slight notch near its inferior margin (*fissura postnodularis*) demarcating the *nodulus*. As development proceeds during the third month the nodular region becomes bent forwards upon the rest of the cerebellum (Fig. 507, B), thus starting the posterior diverticulum of the fourth ventricle, which ultimately assumes a tent-like outline (Fig. 519).

At the close of the third month the irregular growth of the surface of the

median bridge, which can now be called the **vermis**, leads to the appearance of

FIG. 505.—INFERIOR SURFACE OF THE CEREBELLUM OF A HUMAN FÆTUS WHICH HAS REACHED THE END OF THE FIFTH MONTH OF DEVELOPMENT.

FIG. 506.—CEREBELLUM OF A HUMAN FÆTUS WHICH HAS REACHED THE END OF THE FIFTH MONTH OF DEVELOPMENT. Viewed from above and behind.

a transverse depression upon the superior surface. This is the **fissura prima** (Fig. 507, B, C, and D), which becomes the deepest and most complex of all the multitude of fissures that ultimately cut into the cerebellum (Fig. 519). Soon afterwards the **fissura secunda** makes its appearance (Fig. 507, C) and with the **fissura prima** subdivides the vermis into *anterior*, *medial*, and *posterior lobes*.¹

Other transverse fissures appear in rapid succession until the vermis becomes cut up into the following parts, named from above (at the *velum medullare anterius*) downwards: **lingula**, **lobulus centralis**, **culmen**, **declive**, **pyramid**, **uvula**, and **nodule**.

Quite unnecessary importance is usually attached to the subdivisions of the part here called

FIG. 507.—MEDIAN SAGITTAL SECTIONS OF FÆTAL CEREBELLA IN FOUR STAGES OF DEVELOPMENT. A and B, third month; C, fourth month; D, fifth month.

declive which is described as consisting of three parts (**declive**, **folium vermis**, and **tuber vermis**).

¹ The term *medial* is used advisedly because, the anterior and posterior lobes having quite insignificant lateral connexions, the rest of the vermis is virtually the medial continuation of (or bridge between) the lateral lobes.

There is no justification for such a subdivision, nor is any useful purpose served by linking together two parts so distinct, morphologically and physiologically, as the **culmen** and **declive** and calling the complex **monticulus**.

Only some of the fissures of the vermis become prolonged laterally beyond the limits of the vermis, but as the boss-like lateral lobes begin to expand their surface becomes folded and a series of independent lateral fissures are formed. [*The anterior lobe, however, is prolonged laterally upon each side into tapering wings and all the fissures in them are merely prolongations of the fissures of the vermis.*]

After the limiting fissures of the flocculus and paraflocculus, the first independent fissure to make its appearance is one which develops behind and almost parallel to the lateral prolongations of the *fissura prima*. Kölliker called the intervening strip of cerebellum *lobulus lunatus posterior* and the fissure may be called *fissura postlunaris*. These postlunar fissures begin far out on the lateral swelling in the fourth month and gradually approach the median plane, where they may meet and become confluent on the vermis. But it often happens that they do not meet, in which case no *folium vermis* is cut off the declive.

At the end of the fourth or beginning of the fifth month an oval swelling makes its appearance upon each side of the uvula upon the inferior surface of each lateral lobe (Fig. 505). This is called the **tonsilla cerebelli** or **tonsil**, and the fissure which develops behind it and delimits it is called **post-tonsillar**. As a rule the

two post-tonsillar fissures become confluent with the *fissura secunda* upon the vermis and the whole furrow in the adult may be called *fissura secunda*. At the middle of the fifth month a lateral fissure called **parapyramidal** makes its appearance some distance behind the post-tonsillar, from which it is separated by an area called the **lobulus biventer**. As a rule these parapyramidal fissures become confluent with the *supra-pyramidal fissure*. The whole furrow is known in the adult by the latter name. The fissure to which most importance is usually attached develops quite late in the human cerebellum, and not at all in that of the great majority of other animals. It is called the *fissura horizontalis cerebelli*. In the adult it begins upon the front, where the brachium pontis plunges into the cerebellum, and the furrow is formed in a more or less mechanical way by the bulging forwards (above and below the cerebellar peduncles) of the exuberant mass of the cerebellar hemispheres. The actual infolding is preceded by the appearance of several irregular depressions (Fig. 508) in the place where the horizontal fissure will develop. This fissure begins in front and

FIG. 508.—THE LEFT LATERAL ASPECT OF THE FETAL RHOMBENCEPHALON AT THE FOURTH (A) AND FIFTH (B) MONTHS.

The cerebellum is stippled.

passes continuously round the circumference of the organ, cutting deeply into its lateral and posterior margins. In front, its lips diverge to enclose the three cerebellar peduncles as they pass into the interior of the cerebellum. The horizontal fissure divides the organ into a superior and an inferior part, which may be studied separately.

In some cases it meets the corresponding fissure of the other side upon the vermis, but very often such a confluence does not occur. The folium vermis in such cases is not distinguished from the tuber vermis.

The cerebellum is subdivided somewhat arbitrarily into a median portion termed the **vermis**, and two much larger lateral portions, called the **lateral hemispheres**. The demarcation between these main subdivisions of the organ is not very evident from every point of view. In front, and also behind, there is a marked deficiency or notch. The **incisura cerebelli posterior** (O.T. **marsupial notch**) is smaller and narrower than the anterior notch. It is bounded laterally by the lateral hemispheres, whilst its bottom is formed by the axial lobe or vermis. It is occupied by a fold of dura mater, called the **falx cerebelli**. The **incisura cerebelli anterior** (O.T. **semilunar notch**) is wide, and, when viewed from above, it is seen to be occupied by the inferior quadrigeminal bodies and by the brachia

FIG. 509.—SUPERIOR SURFACE OF THE CEREBELLUM.

conjunctiva. As in the case of the posterior notch, its sides are formed by the lateral hemispheres and the bottom by the vermis.

On the superior surface of the cerebellum there is little distinction to be noted between the median lobe and the superior surface of each lateral hemisphere. On this aspect the median lobe receives the name of **superior vermis**, and it forms a high median elevation, from which the surface slopes gradually downwards on each side to the margin of the hemisphere. The superior vermis is highest in front, immediately behind the anterior notch, and from this it shows a somewhat sharp descent towards the posterior notch. This elevation of the superior vermis is frequently called the **monticulus**. The folia on the surface of the superior vermis are thicker and fewer in number than those on the upper surface of the lateral hemisphere. It is this which gives it the worm-like appearance from which it derives its name.

On the inferior surface of the cerebellum the distinction between the three main constituent parts of the organ is much better marked (Fig. 510). On this aspect the lateral hemispheres are full, prominent, and convex, and occupy the cerebellar fossæ in the floor of the cranium. They are separated by a deep median hollow, which is continued forwards from the posterior notch. This hollow is termed the **vallecula cerebelli**, and in its fore part is lodged the medulla oblongata. When the medulla oblongata is raised and the lateral hemispheres are pulled apart, so as to expose the bottom of the vallecula, it will be seen that this is formed by the **vermis**

inferior, or inferior aspect of the median lobe, and, further, that the latter is separated on each side from the corresponding lateral hemisphere by a distinct furrow, termed the *sulcus valleculæ*.

Lobes on the Superior Surface of the Cerebellum.—When examined from before backwards, the superior vermis presents the following subdivisions: (1) the *lingula cerebelli*; (2) the *lobulus centralis*; (3) the *culmen*; (4) and the *declive*. With the exception of the *lingula*, each of these is continuous on either side, with a corresponding district on the upper surface of the hemisphere. Thus the central lobule is prolonged laterally on either side in the form of a small, flattened, wing-like expansion called the *ala lobuli centralis*. The *culmen* together with its lateral prolongations can be called the *lobulus culminis* of the hemispheres; the *declive* stands in the same relation to the *lobulus lunatus*; and the *postero-superior lobules* of the hemispheres may be linked by a *folium vermis*.

The *lingula* can be seen only when the part of the cerebellum which forms the bottom of the anterior notch is pushed backwards. It consists of four or five small flat *folia* continuous with the gray matter of the vermis superior, which are prolonged forwards on the superior surface of the anterior medullary velum in the interval between the two *brachia conjunctiva*.

The *lobulus centralis* lies at the bottom of the anterior cerebellar notch, and is only seen to a very small extent on the superior surface of the organ. It is a little median mass which is prolonged laterally for a short distance round the anterior notch in the form of two expansions, termed the *alæ lobuli centralis*.

The *culmen* constitutes the highest part or summit of the *monticulus* of the vermis superior. It is bounded behind by a deep and strongly marked *fissura prima*, and is prolonged laterally on either side into the lateral hemisphere. This is the most anterior subdivision on the superior surface of the hemisphere.

The *declive* lies behind the *culmen*, from which it is separated by the *fissura prima*, and it forms the sloping part or descent of the *monticulus* of the vermis superior. On each side it is continuous with the lateral hemisphere, and the three parts are included under the one name of *lobulus lunatus* (Fig. 509).

Lobes on the Inferior Surface of the Cerebellum.—The connexion between the several parts of the inferior vermis and the corresponding districts on the inferior surface of the two hemispheres is not so distinct as in the case of the vermis superior and the lobules on the superior surface of the hemispheres. A groove, the *sulcus valleculæ*, intervenes between the vermis inferior and the hemisphere on each side.

From behind forwards the following subdivisions of the vermis inferior may be recognised: (1) the *tuber vermis*; (2) the *pyramis*; (3) the *uvula*; (4) the *nodulus*.

On the inferior surface of the hemisphere there are four main lobules mapped out by intervening fissures. From behind forwards these are: (1) the *postero-inferior lobule*, a large subdivision which bounds the horizontal fissure on its inferior aspect; (2) the *biventral lobule*, which lies in front of the *postero-inferior lobule*, and is partially divided into two parts by a curved fissure which traverses its surface; (3) the *tonsil*, a small rounded lobule which bounds the fore part of the *vallecula*, and is lodged in a deep concavity on the medial aspect of the *biventral lobule*; (4) the *flocculus*, a minute lobule situated on the *brachium pontis* of the cerebellum in front of, and partially overlapped by, the anterior border of the *biventral lobule*.

These lobules, with the corresponding portions of the vermis inferior, constitute the lobes on the inferior surface of the cerebellum. Still, it should be noted that, just as in the case of the superior surface of the organ, this subdivision is to some extent artificial, and is not in every particular provided with a sound morphological basis.

The *tuber vermis* (usually not definitely marked off from the *declive*) forms the most posterior part of the vermis inferior, and is composed of several transversely arranged *folia* which, on either side, run directly into the *postero-inferior lobule*.

The *postero-inferior lobule*, which is wider towards the *vallecula* than it is more

laterally, is traversed by two or it may be three curved fissures. The most anterior of these cuts off a narrow, curved strip of cerebellar surface, which presents a more or less uniform width throughout its whole length. This is the so-called **lobulus gracilis**.

The **pyramid** is connected with the biventral lobule on each side by an elevated ridge which crosses the sulcus vallecule. The term **lobus pyramidis** is applied to the three lobules, which are thus associated with each other.

The **uvula** is a triangular elevation of the vermis inferior. It lies between the two tonsils, and is connected with each of these by a low-lying band-like ridge of gray matter scored by a few shallow furrows, and in consequence termed the **furrowed band**. The two tonsils and the uvula form the lobus uvulae.

FIG. 510.—INFERIOR SURFACE OF THE CEREBELLUM.

The tonsil on the right side has been removed so as to display more fully the posterior medullary velum and the furrowed band.

The nodule and the flocculus of each side are linked by a delicate connecting lamina which is formed by the **posterior medullary velum**.

THE STRUCTURE AND CONNEXIONS OF THE CEREBELLUM.

Arrangement of the Gray and White Matter of the Cerebellum.—The white matter of the cerebellum forms a solid compact mass in the interior, and over this is spread a continuous and uniform layer of gray matter. In each lateral hemisphere the white central core is more bulky than in the vermis, in which the central white matter is reduced to a relatively thin bridge thrown across between the two lateral hemispheres. When sagittal sections are made through the cerebellum, the gray matter on the surface stands out clearly from the white matter in the interior. Further, from all parts of the surface of the central core stout stems of white matter are seen projecting into the lobes of the cerebellum. From the sides of these white stems secondary branches proceed at various angles, and from these again tertiary branches are given off. Over the various lamellæ of white matter thus formed the gray cortex is spread, and the fissures on the surface show a corresponding arrangement, dividing up the organ into lobes, lobules, and folia. When the cerebellum is divided at right angles to the general direction of its fissures and folia, a highly arborescent appearance is thus presented by the cut surface. To this the term *arbor vitæ* is applied.

Nucleus Dentatus and other Gray Nuclei in the White Matter of the Cerebellum.—Embedded in the midst of the mass of white matter which forms the central core of each lateral hemisphere there is an isolated nucleus of gray matter, which presents a strong resemblance to the inferior olivary nucleus of the medulla. It is called the **nucleus dentatus**, and it consists of a corrugated or plicated lamina

of gray matter, which is folded on itself so as to enclose, in a flask-like manner, a portion of the central white matter (Figs. 511 and 512). This gray capsule is not completely closed. It presents an open mouth, termed the hilus, which is directed medially and upwards, and out of this stream the fibres of the brachium conjunctivum.

Three small additional masses of gray matter are also present on each side of the median plane in the central white matter of the cerebellum. These are termed the nucleus emboliformis, the nucleus globosus, and the nucleus fastigii. The nucleus emboliformis or embolus is a small lamina of gray matter which lies just medial to the hilus of the nucleus dentatus, being thus related to it somewhat in the same manner that the medial accessory olivary nucleus is related to the main inferior olivary nucleus. The nucleus globosus lies medial to the nucleus emboliformis and on a somewhat deeper horizontal plane. The nucleus fastigii or roof nucleus is placed in the white substance of the vermis close to the median plane and its fellow of the opposite side. It is, therefore, situated on the medial aspect of the nucleus globosus.

FIG. 511.—SAGITTAL SECTION THROUGH THE LEFT LATERAL HEMISPHERE OF THE CEREBELLUM.

Showing the "arbor vitæ" and the nucleus dentatus.

FIG. 512.—From a dissection by Dr. Edward B. Jamieson in the Anatomical Department of the University of Edinburgh. The nucleus dentatus is displayed from above and the brachium conjunctivum has been traced from it to the mesencephalon.

The nucleus dentatus and the emboliform nucleus present a structure very similar to that of the inferior olivary nucleus. In the nucleus globosus and the nucleus fastigii the cells are somewhat larger in size.

Cerebellar Peduncles.—These are three in number on each side, viz., the

middle, the inferior, and the superior (Fig. 519, p. 585). The fibres of which they are composed all enter or emerge from the white medullary centre of the cerebellum.

The **middle peduncle** or **brachium pontis** is much the largest of the three, and has already been described on pp. 565 and 566. It is formed by the transverse fibres of the pons, and it enters the cerebellar hemisphere on the lateral aspect of the other two peduncles. The lips of the anterior part of the horizontal fissure are separated widely from each other to give it admission (Fig. 510). Within the cerebellar hemisphere its fibres are distributed in two great bundles. Of these, one, composed of the superior transverse fibres of the pons, radiates out in the inferior part of the hemisphere; whilst the other, consisting of the inferior transverse fibres of the pons, spreads out in the superior part of the hemisphere.

The **inferior peduncle** is simply the **restiform body** of the medulla oblongata. After leaving the bulb it ascends for a short distance on the dorsal surface of the pons and then turns sharply backwards, to enter the cerebellum between the other two peduncles.

The **superior peduncle** or **brachium conjunctivum**, as it issues from the cerebellum, lies close to the medial side of the middle peduncle (Fig. 512). Its further course upwards on the dorsum of the pons to the inferior quadrigeminal body has been previously described (pp. 548 and 569).

Connexions established by the Peduncular Fibres.—The fibres of the **brachium pontis** represent the second stage of the connexion between the cerebral hemisphere of one side and the opposite cerebellar hemisphere. The connexions which they establish in the pons are described on p. 566.

The **restiform body** is also composed of afferent fibres (see p. 563); only the more important connexions which these establish in the cerebellum can be touched on here. The principal afferent strand is the *fasciculus spinocerebellaris*. The fibres of this strand end in the cortex of the *superior vermis* on both sides of the median plane, but chiefly on the opposite side. The olivo-cerebellar tract (*fasciculus olivocerebellaris*) are also afferent. It appears that they end in connexion with cells in the cortex of both the vermis and hemisphere, and also cells in the nucleus dentatus. The numerous *arcuate fibres* which enter the restiform body establish connexions with cells in the cortex of the lateral hemisphere and of the vermis.

The **brachium conjunctivum** is an efferent tract: its fibres come from the cells of the nucleus dentatus, and pass to the red nucleus and thalamus of the opposite side. According to Ramon y Cajal collateral branches springing from these fibres descend to the motor nuclei in the medulla oblongata and spinal medulla.

There is, however, a bundle of fibres passing *downwards* alongside the **brachium conjunctivum** from the tegmentum of the mesencephalon and possibly from the thalamus: these fibres cross in the mid-brain and pass inferiorly to the cerebellum in contact with the lateral margin of (or intermingled with) the fibres of the **brachium**. They probably convey to the cerebellum fibres from the visual centres of the opposite side.

The **fasciculus anterolateralis superficialis** of the spinal medulla (O.T. Gowers' tract), for which the better name **fasciculus spinocerebellaris anterior** is now in common use, also enters the cerebellum alongside the emerging **brachium conjunctivum**. It has been noticed in connexion with the lateral funiculus of the spinal medulla (p. 537). The fibres which compose it are carried upwards through the formatio reticularis grisea of the medulla oblongata and the corresponding part of the tegmental portion of the pons. In this part of its course the fibres are scattered and do not form a compact strand. Reaching the superior end of the pons the tract turns backwards across the **brachium conjunctivum**, enters the anterior medullary velum, and proceeds downwards in it into the cerebellum.

Roof of the Fourth Ventricle.—In its superior part the roof of the fourth ventricle is formed by the anterior medullary velum as it stretches across between the two **brachia conjunctiva**, and also, to some extent, by the approximation of these **brachia** themselves as they approach the mesencephalon.

In its inferior part the roof of the ventricle is exceedingly thin and is not all formed of nervous matter. The posterior medullary velum is a mere ridge which can hardly be said to enter into its formation: the epithelial lining of the cavity, supported by pia mater, is carried downwards towards the inferior boundaries of the floor of the ventricle. At the lowest part of the calamus scriptorius, and also along each lateral boundary of the floor, the epithelial roof becomes thickened at its attachment to the parts of the medulla oblongata. The small semilunar lamina which stretches across between the inferior parts of the two clavæ at the calamus scriptorius and overhangs the opening of the central canal is termed the **obex** (Fig. 482, p. 550). A downwardly directed protrusion of the epithelial roof is often found behind the obex.

FIG. 513.—THE POSTERIOR ASPECT OF A FŒTAL CEREBELLUM AND MEDULLA OBLONGATA.

THE HISTOGENESIS AND MINUTE STRUCTURE OF THE CEREBELLUM.

The developmental history of the cerebellum presents certain peculiar features which seem quite enigmatic unless considered from the point of view of the evolution of the connexions and functions of the organ. The cerebellum is derived from part of the alar lamina of the rhombencephalon, and at an early stage of its development the rudiment shows the regular lamination into ependyma, mantle layer, and

FIG. 514.—SECTION THROUGH THE MOLECULAR AND GRANULAR LAYERS IN THE LONG AXIS OF A CEREBELLAR FOLIUM (after Kölliker).

N¹. Axons of granule cells in molecular layer.

cerebral cortex) to which the co-ordinating influence of the cerebellum is essential for the properly adjusted performance of complex actions.

The neuroblasts which receive all these extrinsic sensory impulses, visual, tactile, musculo-sensory, et cetera, collect at the threshold of what was originally the vestibular cerebellar rudiment; and they can be seen during the latter part of the second month migrating from the rhombic lip into the marginal layer of the cerebellum, until eventually its whole surface has been invaded by these alien neuroblasts, so

that the originally non-nucleated marginal layer becomes a densely packed granular layer (*stratum marginale embryonale*). When this stage is reached the cerebellum consists of an inner ependymal layer, a mantle layer crowded with locally developed neuroblasts, a clear layer (the inner part of the original marginal layer), and the superficial layer of neuroblasts which have invaded the outer part of the marginal layer. As development proceeds in the mantle layer the axons of its neuroblasts are directed mainly towards the ventricular surface—the reverse of what happens in the spinal medulla; and as these fibre-masses increase in quantity the main part of the mantle layer becomes pushed farther and farther away from the ependyma by the accumulation of their own (and other) axons. Some of the neuroblasts, however, do not become pushed out into the line of the embryonic cerebellar cortex, but remain behind amidst the fibre-mass and receive the axons that come from the cortical cells. These neuroblasts left amidst the fibres gradually assume the form of the dentate, fastigial, globose, and emboliform nuclei already described; and their axons pass out (as the *brachia conjunctiva*) to the thalamus, mesencephalon, and pons. In the meantime many of the neuroblasts of the mantle layer have been converted into the large pear-shaped **Purkinje-cells**.

While these events have been occurring in the true mantle layer a peculiar process has been taking place in the superficial layer of immigrant cells. One by one they begin to leave their places upon the surface and dip into the mantle layer; many of them pass between the Purkinje-cells to a deeper plane, where they cease their wanderings and form a densely packed layer of granule cells (Fig. 514), the axons of which indicate the course of these migrations.

MINUTE STRUCTURE OF A CEREBELLAR FOLIUM.

A cerebellar folium is composed of a central core of white matter, covered with a layer of gray matter. The gray cortex is arranged in two very evident layers, viz., a superficial **molecular layer** and a subjacent rust-coloured **granular layer**. Between these strata a single layer of large cells, termed the **cells of Purkinje**, are disposed in the form of a very nearly continuous sheet. The cells of Purkinje constitute the most characteristic, and probably the most essential, constituents of the cerebellar cortex.

The **cells of Purkinje** are most numerous on the summit of the folium. At the bottom of the sulci which intervene between the folia they become fewer in number, and, therefore, looser in their arrangement. Each consists of a large flask-shaped or piriform cell body, the narrow end of which projects into the molecular layer, whilst the thicker, deeper end rests on the granular layer. From the latter arises a **single axon**, which passes into the granular layer and presents the peculiarity of almost immediately assuming its medullary sheath. From this axon a few collateral branches soon arise, which, taking a recurrent course, enter the molecular layer, to end in connexion with certain of the adjoining cells of Purkinje. They would seem to have the function of binding together adjacent cells, and thus enabling them to carry on their operations in harmony with each other.

The **dendritic processes** spring from the narrow end of the cell in the form of either one or perhaps two stout stalks. These ascend into the molecular layer, branching and rebranching until an aborescent arrangement of extraordinary richness and extent results. The dendritic branches extend throughout the entire thickness of the molecular layer, and the branching takes place in one plane only, viz., in a plane which is transverse to the long axis of the folium. Consequently, it is only when transverse sections through a folium are made that the full dendritic effect is obtained (Fig. 515); in sections made parallel to the long axis of the folium the cells are seen in profile, and are observed to occupy quite a narrow area (Fig. 514). The branching of the dendrites of a cell of Purkinje may, therefore, be compared to that which takes place in the case of a fruit-tree which is trained against a wall.

In the **molecular layer** the cells are not very numerous, and of these the most characteristic are the **basket-cells** which lie in the deeper part of the layer. In addition to numerous dendrites the basket-cell gives off an axon which runs transversely, as regards the long axis of the folium, between the planes of adjacent dendritic arborisations of the cells of Purkinje. At first very fine, these axons gradually become coarse and thick, and at intervals they give off collaterals which run towards the bodies of the cells of Purkinje. Reaching these, they break up into an enormous number of fine terminal

branches, which enclose the cells of Purkinje, as well as the short non-medullated portions of their axons, in a close basket-work of fine filaments.

The **granular layer** is, for the most part, composed of large numbers of small granule-like bodies closely packed together. Each of these possesses a somewhat large nucleus, with a very small amount of surrounding protoplasm. From the cell body three or four, or perhaps five, dendrites and one axon proceed. The **dendrites** are short and radiate out from different aspects of the cell body. They end in tufts of claw-like twigs, which either embrace or are otherwise in contact with neighbouring granule cells. The whole multitude of granule cells, therefore, are brought into intimate connexion with each other. The **axon** passes into the molecular layer, in which it ends, at a varying distance from the surface, by dividing into two branches. These diverge so sharply from each other that they form almost a right-angle with the parent stem, and they run parallel to the long axis of the folium, threading their way among the branches of the cells of Purkinje and entering into contact association with them. When it is borne in mind that the number of granule cells is very great, and that each sends an axon into the molecular layer, the important part which these fibres, with their longitudinal branches, take in building up the molecular layer will be understood. They are found pervading its entire thickness—from the surface down to the bodies of the cells of Purkinje.

THE MESENCEPHALON.

The **mesencephalon** or **mid-brain** is the short, narrow part of the brain-stem which occupies the aperture of the tentorium cerebelli (*incisura tentorii*), and connects the cerebrum, which lies above, with the parts which occupy the posterior cranial fossa. It is about three-quarters of an inch in length, and it consists of a dorsal part, composed of the **corpora quadrigemina**, and a much larger ventral part, which is formed by the two **pedunculi cerebri**.

The **pedunculi cerebri** can be seen to some extent on the base of the brain, where they bound the posterior part of the interpeduncular fossa. Encircling the upper end of each cerebral peduncle, where it emerges from the cerebrum, is the optic tract (Fig. 527, p. 594).

The mesencephalon is tunnelled from below upwards by a narrow passage, called the **aquæductus cerebri**, which connects the fourth ventricle with the third

ventricle (Fig. 519, p. 585). This channel lies much nearer the dorsal aspect than the ventral aspect of the mesencephalon.

Corpora Quadrigemina.—This name is applied to four rounded eminences or colliculi on the dorsal aspect of the mesencephalon (Figs. 516 and 517). The superior pair are larger and broader than the inferior pair, but they are not so well defined nor are they so prominent. A longitudinal and a transverse groove separate the colliculi from each other. The longitudinal groove occupies the median plane and extends upwards to the posterior commissure of the brain. The superior end of this groove widens out into a shallow depression, in which the **pineal body**, a small conical structure which belongs to the diencephalon, rests. From the lower end of the same groove a short but well-defined and projecting band, the **frenulum**

veli, passes to the anterior medullary velum, which lies immediately below the inferior colliculi. The transverse groove curves round below each of the superior pair of colliculi and separates them from the inferior pair. It is also continued in an upward and ventral direction on the lateral aspect of the mesencephalon.

The quadrigeminal bodies are not marked off laterally from the sides of the mesencephalon, but each has in connexion with it, on this aspect, a prominent strand, which is

FIG. 516.—THE CORPORA QUADRIGEMINA AND THE NEIGHBOURING PARTS.

prolonged superiorly and ventrally towards the thalamic region. These strands are called the **brachia of the corpora quadrigemina**, and they are separated from each other by a continuation, on the side of the mesencephalon, of the transverse groove which intervenes between the two pairs of bodies.

The **corpus geniculatum mediale** is closely associated with the brachia, although it does not form part of the mesencephalon, but belongs to the prosencephalon. It is a small, sharply defined oval eminence, which lies on the lateral side of the superior part of the mesencephalon under shelter of the posterior end of the thalamus.

The **brachium quadrigeminum inferius**, proceeding upwards from the colliculus inferior, advances towards the corpus geniculatum mediale and disappears from view under cover of this prominence.

The **brachium quadrigeminum superius** is carried superiorly and ventrally between the overhanging thalamus and the corpus geniculatum mediale. A superficial examination of the mesencephalon is sufficient to show that, while a large part of this strand enters the corpus geniculatum laterale, a considerable portion is a continuation of the lateral root of the optic tract.

Pedunculi Cerebri.—The cerebral peduncles (Figs. 517 and 527) appear upon the ventral or basal aspect of the mesencephalon as two large rope-like strands which emerge from the cerebral hemispheres and disappear below by plunging into the pars basilaris of the pons. At the place where each peduncle emerges from the corresponding side of the cerebrum it is encircled by the optic tract.

Each pedunculus cerebri is composed of two parts, viz., a dorsal tegmental part (**tegmentum**), which is prolonged upwards into the region below the thalamus (hypothalamus), and a ventral portion (**basis pedunculi**), which, when traced upwards into the cerebrum, is seen to take up a position on the lateral side of

FIG. 517.—THE LEFT LATERAL ASPECT OF THE BRAIN-STEM AFTER THE CEREBRAL HEMISPHERE (EXCEPT THE CORPUS STRIATUM) AND THE CEREBELLUM (EXCEPT THE NUCLEUS DENTATUS) HAVE BEEN REMOVED.

the thalamus and to be continuous with the internal capsule of the brain. When the base of the brain is examined, it is the basis pedunculi which is seen, and it is observed to be white in colour and streaked in the longitudinal direction. In the tegmentum the longitudinally-arranged fibres are, in large part, *corticipetal*, or, in other words, fibres which are ascending towards the cortex of the cerebrum; the basis pedunculi, on the other hand, is entirely composed of longitudinal strands of fibres which are *corticifugal*, or fibres which descend from the cerebral hemisphere.

On the surface of the mesencephalon the separation between the tegmental and basal portions of the pedunculus cerebri is clearly indicated by a medial and a lateral groove. The medial furrow is the more distinct of the two. It looks into the interpeduncular fossa, and from it emerge the fila of the oculo-motor

nerve. It is termed, therefore, the **sulcus n. oculomotorii**. The lateral groove, which is placed on the lateral aspect of the mesencephalon, receives the name of the **sulcus lateralis** [**mesencephali**]. When traced downwards, it is observed to become continuous with the furrow which intervenes between the brachium pontis and brachium conjunctivum of the cerebellum.

A close inspection of the lateral surface of the tegmental part of the pedunculi cerebri, below the level of the brachia, will reveal some faintly-marked bundles of fibres curving obliquely upwards and backwards to reach the inferior colliculus (Fig. 517, p. 583). These are fibres of the **lateral lemniscus**, coming to the surface at the sulcus lateralis and sweeping over the subjacent brachium conjunctivum to gain the inferior colliculus, inferior brachium, and medial geniculate body.

INTERNAL STRUCTURE OF THE MESENCEPHALON.

When transverse sections are made through the mesencephalon the aquæductus cerebri is seen to be surrounded by a thick layer of gray matter, which receives the name of the **stratum griseum centrale** or the **central gray matter of the aqueduct**. On the dorsal aspect of this gray matter the corpora quadrigemina form a layer which

FIG. 518.—DIAGRAMMATIC VIEW OF THE CUT SURFACE OF A TRANSVERSE SECTION THROUGH THE SUPERIOR PART OF THE MESENCEPHALON.

separates it from the surface, and to which the term **lamina quadrigemina** is applied. On the anterior and lateral aspects of the central gray matter are the tegmental portions of the cerebral peduncles; whilst, intervening between each of the tementa and the corresponding basis pedunculi, there is a conspicuous mass of dark pigmented matter, termed the **substantia nigra**.

Aquæductus Cerebri and Stratum Griseum Centrale.—The aqueduct is the canal which leads from the fourth ventricle below, upwards through the mesencephalon,

to the third ventricle above. It is not quite three-quarters of an inch in length, and it lies much nearer the dorsal than the ventral surface of the mesencephalon. When examined in transverse section, it presents a triangular outline as it passes into the fourth ventricle and a T-shaped outline close to the third ventricle. In the intermediate part of its course it assumes different outlines, and not always the same form at the same level in different specimens.

The aqueduct is lined with ciliated epithelium, and outside this is the thick layer of central gray matter, which is directly continuous below with the gray matter spread out on the floor of the fourth ventricle, and above with gray matter on the floor and sides of the third ventricle. Scattered more or less irregularly throughout the central gray matter are numerous nerve-cells of varying forms and sizes, whilst in addition to these there are three definite collections or clusters of cells, which constitute the nuclei of origin of the trochlear nerve, the oculomotor nerve, and the mesencephalic root of the trigeminal nerve. The position and relations of these will be given at a later stage.

Substantia Nigra.—When seen in transverse section, the **substantia nigra** presents a semilunar outline. It consists of a mass of gray matter, in the midst of which are large numbers of deeply pigmented nerve-cells. It is only when this substance is examined in bulk that it appears dark; in thin sections it does not differ much in colour from ordinary gray matter, although, under the microscope, the brown-coloured cells stand out very conspicuously, even under low powers. The substantia nigra is disposed in the form of a thick layer, interposed between the tegmental and basal portions of the cerebral peduncle. It begins below at the superior border of the pons and extends upwards into the hypothalamus. The margins of this layer of dark-coloured substance come to the surface at the

oculomotor and the lateral sulci of the mesencephalon, and its medial part is traversed by the emerging fila of the oculomotor nerve. It is not equally thick throughout. Towards the lateral sulcus it becomes thin, whilst it thickens considerably near the medial aspect of the pedunculus cerebri. The surface of the substantia nigra, which is turned towards the tegmentum, is concave and uniform; the opposite surface is convex and rendered irregular by the presence of numerous slender prolongations of the substance into the basis pedunculi.

The morphological and physiological significance of the substantia nigra is not fully understood, and the connexions established by its cells are imperfectly known.

Bechterew, however, is of the opinion that fibres arising in the motor area of the cerebral cortex end in relationship with the cells of the substantia nigra, the axons of which proceed to the motor trigeminal nucleus for the purpose of co-ordinating the muscles of mastication.

Colliculi Inferiores (or inferior quadrigeminal bodies).—Each inferior colliculus

FIG. 519.—THE MEDIAL ASPECT OF THE RIGHT HALF OF THE BRAIN EXPOSED BY A MEDIAN SAGITTAL SECTION.

is composed largely of a mass of gray matter which, in transverse section, presents an oval outline (Fig. 520, p. 587). This central nucleus is, to a large extent, encapsulated by white matter. Numerous cells of various sizes are scattered throughout it, and the whole mass is pervaded by an intricate interlacement of fine fibres, which are derived, to a large extent, from the lateral lemniscus.

In transverse sections through this region, the lateral lemniscus is seen to abut against the lateral margin of the central nucleus. Many of the fibres of this tract enter it at once and become dispersed amongst its cells; others sweep over its dorsal surface, so as to give it a superficial covering; whilst a third group is carried medially, in the form of a thin layer, on its ventral aspect, so as to mark it off from the subjacent central gray matter of the aqueduct (Fig. 520, p. 587). In this manner, therefore, the inferior colliculus becomes partially circumscribed by the fibres of the lateral lemniscus. Several of the lateral lemniscus fibres, which proceed over the superficial or dorsal aspect of the nucleus, reach the median plane and form a loose decussation with the corresponding fibres of the opposite side.

The intimate connexion which is thus exhibited between the fibres of the lateral lemniscus

and the nucleus of the inferior colliculus is very significant. The lateral lemniscus, to a large extent, comes from the nuclei of termination of the cochlear nerve of the opposite side. We must associate, therefore, the inferior colliculus, and also the corpus geniculatum mediale, which likewise receives fibres from the lateral lemniscus, with the organ of hearing.

This view regarding the inferior colliculi is supported both by experimental and by morphological evidence. Speaking broadly, it may be stated that the inferior colliculi become prominent only in mammals, and then they are invariably correlated with a spirally wound and well-developed cochlea. That they have nothing to do with sight is shown by the fact that, when the eye-balls are extirpated in a young animal, the inferior colliculi remain unaffected, whilst the superior colliculi after a time atrophy (Gudden). When, on the other hand, the cochlear terminal nuclei are destroyed, fibres which have undergone atrophy may be followed to the inferior colliculi of both sides, but particularly to that of the opposite side (Baginski, Bumm, and Ferrier and Turner). A very considerable tract of ascending fibres takes origin within the inferior colliculus and passes upwards, in the inferior brachium, into the tegmentum subjacent to the medial geniculate body. Within the tegmentum they proceed up to the thalamus (Ferrier and Turner).

Colliculi Superiores (or superior quadrigeminal bodies).—The superior colliculus presents a more complicated structure (Fig. 521). Superficially, it is coated with a very thin layer of white matter, which is termed the *stratum zonale*. Underneath this there is a gray nucleus, called the *stratum griseum*, which, in transverse section, exhibits a crescentic outline and rests in a cap-like manner upon the subjacent part of the eminence. The succeeding two strata, which respectively receive the names of *stratum opticum* and the *stratum lemnisci*, present this feature in common, that they are composed of gray matter, traversed by numerous fibres. The source from which the fibres are derived is different, however, in each case.

Nerve-fibres reach the superior colliculus through—(1) the lemnisci and (2) the superior brachium.

The fibres of the lemnisci constitute the *stratum lemnisci*. The superior brachium contains fibres of two different kinds, viz., fibres from the optic tract and fibres from the cortex of the occipital lobe of the cerebrum. By the former it is connected with both retinae, and by the latter with the visual centre in the occipital region of the cerebral cortex. The great majority of these fibres pass into the margin of the colliculus superior and form a layer—*stratum opticum*—underneath the *stratum griseum*, in which they ultimately terminate.

Tegmentum.—The tegmentum of the pedunculus cerebri may be regarded as the continuation upwards of the formatio reticularis of the medulla oblongata and the dorsal or tegmental portion of the pons into the mesencephalon. It consists, therefore, of fine bundles of longitudinal fibres intersected by arching fibres, which take a transverse and curved course. The interstices between these nerve-bundles is occupied by gray matter containing irregularly scattered nerve-cells. On its dorsal aspect the tegmentum is continuous, at the side of the central gray matter, with the bases of the corpora quadrigemina, whilst, ventrally, it is separated from the basis pedunculi by the substantia nigra. The tegmenta of opposite sides are, to some extent, marked off from each other in the median plane by a prolongation upwards of the median raphe of the pons and medulla oblongata, although, in the inferior part of the mesencephalon, this is much obscured by the decussation of the brachia conjunctiva. The two longitudinal strands, termed the *medial longitudinal bundle* and the *medial lemniscus*, are prolonged upwards throughout the entire length of the mesencephalon; and they present the same relations to the tegmentum as in the inferior parts of the brain. The medial longitudinal fasciculus is placed in relation to its dorsal aspect, whilst the lemniscus is carried up in its ventral part.

The tegmentum of the mesencephalon may be considered as presenting two parts: viz., (1) an inferior part, which is placed subjacent to the inferior colliculi and is largely occupied by the decussation of the brachia conjunctiva (Fig. 520); and (2) a superior part, subjacent to the superior colliculi which is traversed by the emerging bundles of the oculomotor nerve. The superior part contains a large and striking nuclear mass, termed the *nucleus ruber* or the red tegmental nucleus (Fig. 521). In the inferior part of the central gray matter of the mesencephalon is the nucleus of the trochlear nerve; in the superior part, the nucleus of the oculomotor nerve.

Brachia Conjunctiva.—As the brachia conjunctiva leave the pons and sink into the tegmentum of the mesencephalon, they undergo a complete decussation, subjacent to the inferior colliculi and the central gray matter (Figs. 520, 521, p. 587; and 522, p. 588). In this manner each brachium is transferred from one side, across the median plane, to the opposite side. The decussation is completed at the level of the superior borders of the inferior colliculi, and then each brachium proceeds upwards into the superior part of the tegmentum, where it encounters the red nucleus. Into this a large proportion of its fibres plunge, and come to an end in connexion with the nuclear cells. Many of the fibres, however, are carried around the nucleus so as to form for it a

FIG. 520.—TRANSVERSE SECTION THROUGH THE HUMAN MESENCEPHALON AT THE LEVEL OF THE INFERIOR COLICULUS.

FIG. 521.—TRANSVERSE SECTION THROUGH THE HUMAN MESENCEPHALON AT THE LEVEL OF THE SUPERIOR COLICULUS.

capsule, which is thicker on the medial than on the lateral side (Fig. 521). These are prolonged into the thalamus, and end ultimately in connexion with the ventral thalamic cells. The brachium conjunctivum is, therefore, a great efferent tract which issues from the nucleus dentatus of the cerebellum, crosses the median plane in the inferior part of the mesencephalon, and ends in the red nucleus and the ventral part of the thalamus.

Nucleus Ruber.—The red nucleus is a rounded nuclear mass, of a reddish tint in the fresh brain, which lies in the superior part of the tegmentum, and in the path of the brachium conjunctivum. In transverse section it presents a circular outline. It begins at the level of the inferior border of the superior colliculus and it extends upwards into the hypothalamus. At first it is small and is placed at a little distance from the median plane; but, as it proceeds upwards, it increases in bulk and approaches more nearly to the median raphe, and to its

fellow of the opposite side. The curved emerging bundles of the oculomotor nerve pass through it on their way to the surface. The relation which the fibres of the opposite brachium conjunctivum present to it has been described. These fibres traverse its inferior part in such numbers that in Weigert-Pal specimens it presents a very dark colour; but higher up, as the fibres gradually end in nuclear mass, they become less numerous in its midst, and the nucleus assumes a paler tint.

Numerous fibres which descend from the cerebral cortex, and others from the corpus striatum, enter the red nucleus. It also sends out fibres which proceed in two directions: (1) upwards into the thalamus; (2) downwards to the spinal medulla. The thalamic fibres may be regarded as carrying on the

FIG. 522.—SECTION THROUGH THE INFERIOR COLLICULUS AND THE TEGMENTUM OF THE MESENCEPHALON BELOW THE LEVEL OF THE NUCLEUS OF THE TROCHLEAR NERVE IN THE ORANG. (The decussation of the brachia conjunctiva and the course of the trochlear nerve in the central gray matter are seen.)

continuity of the path of the brachium conjunctivum after its nodal interruption in the red nucleus. The fibres to the spinal medulla, called the **rubro-spinal tract** and first described by Monakow, cross to the opposite side and then descend in the tegmentum to reach the lateral funiculus of the spinal medulla (Fig. 473, p. 534).

Fasciculus Longitudinalis Medialis.—The medial longitudinal fasciculus is a very conspicuous tract of longitudinal fibres which extends throughout the whole length of the medulla oblongata, pons, and mesencephalon, in the formatio reticularis or tegmental part of each. Below, at the level of the decussation of the pyramids, it becomes continuous with the fasciculus anterior proprius of the spinal medulla (p. 562), whilst, by its opposite or superior end, it establishes intricate connexions in the region immediately above the mesencephalon. Throughout its whole length it lies close to the median plane and its fellow of the opposite side. In the mesencephalon it is applied to the ventral aspect of the central gray matter, whilst in the pons and medulla oblongata it is situated immediately subjacent to the gray matter of the floor of the fourth ventricle. One of its most salient features is the intimate association which it presents with the three motor nuclei from which the nerves for the supply of the muscles of the eyeball take origin, viz., the oculomotor nucleus, the trochlear nucleus, and the abducent nucleus. The first two of these are closely applied to its medial and dorsal aspect, whilst the abducent nucleus is placed on its lateral side. Into each of these nuclei it sends many collaterals, and probably also some of its constituent fibres, and these end around the nuclear cells. It would appear, therefore, that one of the most

important functions of this strand is to bind together these nuclei, and thus enable them to act in harmony one with the other. Fibres also enter the medial longitudinal fasciculus from the vestibular nucleus of the acoustic nerve system. The results obtained by degeneration would seem to indicate that, to a large extent, it is formed of fibres which run a short course within it.

That it is a brain tract of high importance, is evident from the fact that it is present in all vertebrates, and, further, that its fibres assume their medullary sheaths at an extremely early period. In fishes, amphibians, and reptiles, it is one of the largest bundles of the medulla oblongata. In man, its fibres medullate between the sixth and seventh months of foetal life, and at the same time as the fibres of the fasciculus anterior proprius of the spinal medulla, with which it stands in connexion.

According to van Gehuchten and Edinger, it extends upwards beyond the level of the oculomotor nucleus, and in the thalamic region its fibres take origin from a special nucleus of its own in the gray matter of the third ventricle, immediately behind the level of the corpora mamillaria. Fibres also enter the medial longitudinal bundle from a nucleus common to it and the posterior commissure of the brain. This nucleus is placed in the fore part of the central gray matter of the mid-brain. Held asserts that numerous fibres, arising from cells in the superior colliculus, curve in an arcuate manner in the tegmentum outside the central gray matter, to take part on the ventral aspect of this in what is called the **fountain decussation**. Reaching the opposite side, these fibres turn downwards and join the medial longitudinal bundle. The same authority considers that fibres from the ventral part of the posterior commissure can also be traced downwards into the medial longitudinal bundle. Edinger, on the other hand, places these fibres as a distinct tract on the ventral and lateral aspect of the medial longitudinal bundle, although in apposition with it.

Mendel believed that fibres from the oculomotor nucleus are carried down in the medial longitudinal bundle, and, from this, into the facial nerve for the supply of the orbicularis oculi and the corrugator supercilii, bringing these muscles, therefore, under the control of the same nucleus as the levator palpebrae superioris muscle. This view was adopted by many clinicians because this upper group of facial muscles is often spared in cases of facial paralysis; but Harman has adduced reasons in support of the view that there is a superior prolongation of the facial nucleus which innervates these muscles. It has been suggested further that fibres from the hypoglossal nucleus may, by the medial longitudinal bundle, reach the facial nerve, and through it the orbicularis oris. In this manner the same nucleus would hold sway over the tongue and the sphincter muscle of the lips. The close relation which exists between the ascending part of the intrapontine portion of the facial nerve and the medial longitudinal bundle would render the passage of fibres from one to the other a circumstance which could easily be understood. But the balance of evidence now available inclines us to regard the facial nucleus as the origin of the fibres innervating all the facial muscles. Another interchange of fibres through the medial longitudinal bundle has been described by Duval and Laborde. According to these authorities, fibres from the abducens nucleus ascend in the medial longitudinal bundle into the mesencephalon, and establish connexions

FIG. 523.—SECTION THROUGH THE INFERIOR COLLICULUS AND THE TEGMENTUM OF THE MESENCEPHALON, AT A SLIGHTLY LOWER LEVEL THAN FIG. 522.

with that part of the oculomotor nucleus from which the nerve for the medial rectus of the opposite side derives its fibres. If this view is correct, it affords a ready and simple anatomical explanation of the harmonious action of the lateral and medial recti muscles in producing movements of the two eyeballs simultaneously to the right and to the left. From the investigations of E. H. Fraser it would appear that no fibres from the abducens nucleus go directly into the oculomotor nerve. The same observer has shown that many fibres from Deiters' nucleus, a part of the vestibular nucleus of the acoustic nerve to be described later in this account, enter the oculomotor and the trochlear nuclei through the path afforded by the medial longitudinal bundle.

FIG. 524.—DIAGRAM REPRESENTING SOME OF THE CONSTITUENT ELEMENTS OF THE FASCICULUS LONGITUDINALIS MEDIALIS.

FIG. 525.—DIAGRAM OF THE CONNEXIONS OF THE MEDIAL LEMNISCUS AND ALSO OF CERTAIN OF THE THALAMO-CORTICAL FIBRES.

Lemniscus Lateralis.—The lateral lemniscus is a definite tract of longitudinal fibres, which extends upwards through the lateral part of the tegmental substance of the superior portion of the pons and the mesencephalon. It is formed by the fibres of the corpus trapezoideum and striæ medullares in the inferior part of the pons, turning abruptly upwards and taking a course towards the quadrigeminal region. But the details of the arrangement and connexions of this important fasciculus must be left for fuller consideration when we are discussing the central connexions of the acoustic nerve.

Lemniscus Medialis.—The medial lemniscus has already been followed through the medulla oblongata and pons, and its position in each of these portions of the brain-stem has been defined (pp. 561 and 562). In the tegmentum of the inferior part of the mesencephalon it is carried up in the form of a more or less flattened

band on the ventral aspect of the decussating brachia conjunctiva. To its lateral side, and forming an angle with it (as seen in transverse section), is the lateral lemniscus (Figs. 522 and 523), and at this level there is no clear demarcation between these two tracts. In the superior part of the mesencephalon the appearance of the red nucleus in the tegmentum causes the medial lemniscus to take up a more lateral and dorsal position, so that it now comes to lie subjacent to the corpus geniculatum mediale (Fig. 521, p. 587). At this level it exhibits a crescentic outline in transverse section, and the lateral lemniscus has to a large extent disappeared from its lateral side.

A part of the medial lemniscus, which is called the *fasciculus bulbothalamicus*, takes origin in the inferior part of the medulla oblongata from the gracile and cuneate nuclei of the opposite side (p. 560). Seeing that the posterior funiculus of the spinal medulla ends in these nuclei, the medial lemniscus may be considered to continue that funiculus upwards into the brain. Other fibres arise from the terminal nuclei of the various sensory cerebral nerves of the opposite side. The rest of the tract consists of the superior part of the *fasciculus spinothalamicus* from the spinal medulla. In the mesencephalon a considerable contribution of fibres is given by the medial lemniscus to the superior colliculus, and then the remainder of the tract proceeds into the lateral (ventro-lateral) nucleus of the thalamus. Here its fibres end amidst the thalamic cells.

Ganglion Interpedunculare and Fasciculus Retroflexus.—Immediately above the pons a small collection of nerve-cells is found in the median plane, wedged in between the two cerebral peduncles. It is all that is found in the human brain to represent a large nucleus projecting into the interpeduncular fossa in most other animals, especially those with a highly developed sense of smell. In this interpeduncular ganglion ends the *fasciculus retroflexus*, a tract of fibres which comes from the nucleus habenulæ of the epithalamus. We shall return to the consideration of this tract later.

Fountain Decussation.—If the region ventral to the medial longitudinal bundles is examined in the superior part of the mesencephalon a very close decussation of fibres in the median plane will be observed in the interval between the two red nuclei. This is the “fountain decussation.” According to Held, the fibres which take part in the dorsal portion of the fountain decussation (decussation of Meynert) come from the superior colliculi, and, after they have gained the opposite side, they turn downwards in the medial longitudinal fasciculus.

Many of the fibres that cross in this decussation enter a descending tract (*fasciculus tecto-bulbaris et spinalis*) which connects the corpora quadrigemina with the motor nuclei on the other side of the medulla oblongata and spinal medulla.

Basis Pedunculi.—The basis pedunculi presents a somewhat crescentic outline when seen in transverse section, and it stands quite apart from its fellow of the opposite side. It is composed of a compact mass of longitudinally directed fibres, all of which, as Déjerine has shown, arise in the cortex of the cerebrum and pursue an unbroken corticifugal course into and through the pedunculus cerebri. These fibres may be classified into two distinct sets, viz., cerebro-pontine and pyramidal or cerebro-spinal.

The cerebro-pontine fibres possess this leading character: in their course downwards they are all arrested in the ventral part of the pons, and end amidst the cells of the nuclei pontis. These tracts would appear to hold a very definite position within the crus. Thus, it has been satisfactorily established that the fibres coming from the temporal area of the cerebral cortex (*temporo-pontine strand*) form the lateral fifth of the basis pedunculi, whilst those coming from the frontal area (*fronto-pontine strand*) hold a similar position in the medial part of the basis pedunculi.

The pyramidal fibres constitute the great motor tract from the cerebral cortex. They occupy a position corresponding to the middle three-fifths of the basis. The pyramidal tract differs from the cerebro-pontine strands in being carried downwards through the ventral part of the pons and on the ventral aspect of the medulla oblongata into the spinal medulla, which it enters in the form of the fasciculi cerebrospinales lateralis and anterior. On its way through the pons and

medulla oblongata it sends fibres across the median plane to the various motor nuclei on the opposite side of those sections of the brain-stem.

DEVELOPMENT OF THE MESENCEPHALON.

Even in the early embryo the mesencephalon constitutes the smallest section of the brain-tube, although the disproportion in size between it and the other primitive subdivisions of the brain is not nearly so marked as in the adult. Owing to the cephalic flexure, the mid-brain for a time occupies the summit of the head. Later it becomes completely covered over by the expanding cerebral hemispheres.

The corpora quadrigemina are derived from the alar laminae of the lateral walls of the brain-tube, whilst the basal laminae thicken and ultimately form the tegmenta. The original cavity of the mid-brain is retained as the aqueduct.

For a considerable time the cavity of the mesencephalon remains relatively large, and the lower part of its dorsal wall is carried downwards in the form of a diverticulum or recess, which overlaps the cerebellar plate. About this time, also, the dorsal wall shows a median fold or ridge. Both of these conditions are transitory. As the corpora quadrigemina take shape, the median ridge disappears and is replaced by the median longitudinal groove, which separates the quadrigeminal bodies. Only its inferior part is retained, and this is represented by the frenulum veli of the adult brain. The diverticulum of the cavity gradually becomes reduced, and finally disappears as the aqueduct assumes form.

The precise mode of origin of the red nucleus is not known.

Later in this account reasons will be given for the belief that the representatives of the neural crests in the region of the mesencephalon become absorbed and assimilated in the walls of the neural tube as it closes in.

THE DEEP CONNEXIONS OF THE CEREBRAL NERVES ATTACHED TO THE MEDULLA OBLONGATA, PONS, AND MESENCEPHALON.

There are twelve pairs of cerebral nerves, of which the inferior eight are attached to the medulla oblongata and pons. From above downwards these are named the trigeminal (fifth), the abducens (sixth), the facial (seventh), the acoustic (eighth), the glossopharyngeal (ninth), the vagus (tenth), the accessory (eleventh), and the hypoglossal (twelfth). Two others, the trochlear (fourth) and oculomotor (third) spring from the mesencephalon. The hypoglossal, the accessory, the greater part of the facial, the abducens, the motor root of the trigeminal, the trochlear and the oculomotor are efferent nerves; the acoustic, the nervus intermedius (sensory root of the facial) and the sensory root of the trigeminal are purely afferent nerves; whilst the vagus and the glossopharyngeal are composed of both efferent and afferent fibres. In all these cases (with a possible reservation in the case of part of the trigeminal) afferent fibres arise from ganglionic cells placed outside the brain and penetrate the brain-stem, to end in connexion with the cells of certain **nuclei of termination**. Efferent fibres, on the other hand, take origin within the brain as the axons of cells which are grouped together in certain places in the form of **nuclei of origin**.

Nuclei of Origin, or Motor Nuclei.—In the spinal medulla the nuclei of origin are represented by elongated columns of cells which run more or less continuously in the anterior column of gray matter of successive spinal segments, and from these the series of efferent anterior nerve-roots take origin. In the medulla oblongata, pons, and mesencephalon the nuclei of origin, or, in other words, the motor nuclei of the individual nerves, become, for the most part, discontinuous, and are represented by certain isolated clumps of compact gray matter, in which are placed the clusters of cells from which the fibres of the efferent nerves arise. The nucleus ambiguus, however, which consists of a column of cells from which root-fibres of the bulbar part of the accessory, of the vagus, and also of the glossopharyngeal are derived, is an exception to this rule. At the decussation of the pyramids, the anterior column of gray matter of the spinal medulla is broken up by the intercrossing bundles into a detached head and a basal part which remains in relation with the ventro-lateral aspect of the central canal. Certain of the efferent nuclei of the medulla oblongata, pons, and mesencephalon lie in the line of the basal portion of the anterior column of gray matter of the spinal medulla, and, thus, close to the median plane. These are termed **medial somatic nuclei**, and are met with at different levels in the

brain-stem. This group comprises the hypoglossal nucleus, the abducens nucleus and, in the mesencephalon, the trochlear nucleus and part of the oculomotor nucleus. Other motor nuclei of origin are present in the form of isolated clumps or columns of gray matter, which lie at different levels in the medulla oblongata and pons in a more lateral and deeper situation. They are the nucleus ambiguus of the accessory, vagus and glossopharyngeal, the facial nucleus, and the nucleus of the motor root of the trigeminal nerve. From their position in the substantia reticularis of the medulla oblongata and pons they constitute a group to which the name of **lateral somatic nuclei** is applied.

In addition to these two columns of motor nuclei there is a third efferent column of **splanchnic nuclei** represented by the dorsal nucleus of the vagus and glossopharyngeal nerves, and similar nuclei emitting sympathetic fibres into the

FIG. 526.—DIAGRAM REPRESENTING THE DIFFERENT KINDS OF COMPONENTS FOUND IN THE CEREBRAL NERVES AND OF THEIR NUCLEI OF ORIGIN OR TERMINATION.

facial and oculomotor nerves. It is possible some splanchnic efferent fibres may pass into the trigeminal nerve.

The different nuclei of origin of the efferent fibres which belong to the various cerebral nerves, both medial and lateral, are connected with the motor area of the cerebral cortex by fibres of the cerebro-spinal tract of the other side, which enter the nuclei and end in association with their cells.

Nuclei Terminales.—The general scheme of arrangement of the **terminal nuclei** has already been explained (Fig. 526); its details will be further elucidated as the various nerves are considered seriatim.

The axons of many of the cells of the nuclei of termination enter the substantia reticularis as arcuate fibres, and, crossing the median plane, are carried upwards in the substantia reticularis of the opposite side, to establish direct connexions with the thalamus and indirectly through it with the cerebral cortex (Fig. 525).

Others pass to the nuclei of motor nerves, to the cerebellum or other groups of nerve-cells, to form connexions necessary for the performance of reflex actions.

Nervus Hypoglossus.—The nucleus of origin of the hypoglossal nerve, the motor nerve of the tongue, lies in the substance of the medulla oblongata. It is composed of several groups of large multipolar cells, which closely resemble the cells in the anterior column of gray matter in the spinal medulla, and is pervaded by an intricate network of fine fibrils. In form it is elongated and rod-like, and in length it is about 18 mm. It extends from a point immediately above the decussation of the pyramids up to the level of the striæ medullares. The inferior portion of the nucleus is thus placed in the closed part of the medulla oblongata (Fig. 494, p. 561), whilst its superior part is situated in the open part (Fig. 495, p. 561). The former lies in that part of the central gray matter which is continuous with the basal part of the anterior column of gray matter of the

FIG. 527.—THE VENTRAL ASPECT OF THE MEDULLA OBLONGATA, PONS, AND MESENCEPHALON, showing the nerve roots.

spinal medulla. It is thus placed on the anterior and lateral aspect of the central canal, close to the median plane and the corresponding nucleus of the opposite side. The superior part of the nucleus occupies a position in the gray matter on the floor of the fourth ventricle, subjacent to the medial part of the surface area, which has been described under the name of the *trigonum hypoglossi*. Within the nucleus the axons of the cells arrange themselves in converging bundles of fine fibres, which come together and leave the ventral aspect of the nucleus as the *fila radicularia* of the nerve. The nerve bundles thus formed traverse the entire antero-posterior thickness of the medulla oblongata, between the *substantia reticularis grisea* and the *substantia reticularis alba*, and emerge on the surface, in linear order, at the bottom of the furrow between the olive and the pyramid. After they emerge these fibres collect to form three definite bundles like the anterior nerve-roots of three spinal nerves (Fig. 527). In the substance of the medulla oblongata the *fila radicularia* of the

hypoglossal pass between the main inferior olivary nucleus and the medial accessory olivary nucleus, and many of them on their way to the surface pierce the ventral lamina of the main olivary nucleus.

No decussation between the nerves of opposite sides takes place in the medulla oblongata, but commissural fibres pass between the two nuclei (Kölliker). Further, numerous fibres from the opposite pyramidal tract enter the nucleus and end in connexion with its cells. The nucleus is thus brought into connexion with the motor area of the opposite side of the cerebral cortex.

Nervus Accessorius.—The accessory nerve also is a motor nerve, and it is generally described as consisting of a spinal and a cerebral or accessory part.

The **spinal part** of the nerve emerges by a series of roots which issue from the surface of the lateral column of the superior part of the spinal medulla as low down as the fifth cervical nerve. These take origin in a column of cells situated in the anterior column of gray matter of the spinal medulla, close to its lateral margin, and

FIG. 528.—DIAGRAM OF THE SPINAL ORIGIN OF THE ACCESSORY NERVE (after Bruce).

FIG. 529.—SECTION THROUGH THE SUPERIOR PART OF THE CERVICAL REGION OF THE SPINAL MEDULLA (Orang). Showing the origin of the spinal part of the accessory nerve.

immediately behind the nerve-cells which give rise to the fibres of the anterior roots of the upper five cervical nerves. The cells of the accessory nucleus are large, multipolar, and in every respect similar to the motor cells of the spinal nerves. The axons from these cells leave the dorsal aspect of the nucleus in converging groups to form the fila radicularia or root-bundles of the nerve. These, in the first place, proceed straight backwards in the anterior column of gray matter. Reaching the bay between the two columns of gray matter, they turn sharply laterally into the white matter and traverse the lateral funiculus to gain their points of exit from the spinal medulla. At the decussation of the pyramids, fila, which join the accessory nerve, are seen to proceed from the detached head of the anterior column of gray matter.

The **cerebral part** of the accessory nerve has its nucleus of origin in the medulla oblongata; and its fila, as they proceed laterally from this, can be distinguished by the fact that they pursue a course on the ventral side of the tractus spinalis of the trigeminal nerve, whereas the vagus roots, with which they are apt to be confused, pass through or lie on the dorsal aspect of the trigeminal root (Kölliker). The nucleus of origin of the cerebral part of the accessory nerve is formed by the same column of cells which constitutes the **nucleus ambiguus**, and which, at a higher level, gives motor fibres to the vagus and glossopharyngeal nerves.

The part of the accessory nerve which takes origin in the spinal medulla supplies the sterno-mastoid and trapezius muscles. The cerebral portion joins the vagus, and through the external laryngeal and recurrent nerves it supplies the muscles of the larynx. The portion of

the nucleus ambiguus from which it arises has thus been termed the laryngeal nucleus (Edinger) but it is not certain whether it is vagal or accessory.

Collaterals and fibres of the opposite lateral cerebro-spinal tract end in connexion with the cells of origin of the accessory nerve, and thus bring its nucleus into connexion with the motor area of the cerebral cortex. Fibres also from the posterior roots of the spinal nerves (afferent or sensory fibres) end in the nucleus.

Nervus Vagus, Nervus Glossopharyngeus.—The vagus and glossopharyngeal nerves present similar connexions with the brain, and they may therefore be studied together. The greater part of both nerves is composed of afferent fibres, which arise outside the brain-stem from ganglionic cells placed in relation to the nerve-trunks. Both nerves possess efferent fibres also, which spring from two special nuclei of origin situated within the medulla oblongata and termed respectively the **dorsal or splanchnic nucleus** and the **nucleus ambiguus**, which is the **somatic nucleus**. The afferent ganglionic fibres of the vagus and glossopharyngeal enter the brain by a series of roots which penetrate the medulla oblongata along the ventral side of the restiform body. Within the medulla oblongata they separate into two sets, viz., a series of bundles (composed chiefly of vagus fibres, *i.e.* afferent splanchnic), which end in the **dorsal nucleus of termination** of the vagus and glossopharyngeal nerves, and another series of bundles (composed chiefly of glossopharyngeal fibres, *i.e.* taste fibres), which join a conspicuous longitudinal tract of fibres called the **tractus solitarius**.

The **dorsal nucleus** (Figs. 488, p. 557, and 526, p. 593) of the vagus and glossopharyngeal nerves is mixed, and contains both motor cells which give origin to efferent fibres, and cells around which afferent fibres of the vagus, and possibly also of the glossopharyngeal nerve, break up into terminal arborisations. It very nearly equals in length the nucleus of the hypoglossal nerve, with which it is closely related. Above, it reaches as high as the striæ medullares, whilst, below, its inferior end falls slightly short of that of the hypoglossal nucleus. In specimens stained by the Weigert-Pal method the two nuclei offer a marked contrast. The hypoglossal nucleus presents a dark hue, owing to the enormous numbers of fine fibres which twine in and out amidst its cells; the vago-glossopharyngeal dorsal nucleus is pale from the scarcity of such fibres within it. Its cells, like those of all splanchnic efferent nuclei, are much smaller than the somatic cells of the nucleus ambiguus. In the closed part of the medulla oblongata the dorsal vago-glossopharyngeal nucleus lies in the central gray matter immediately behind the hypoglossal nucleus, and upon the lateral aspect of the central canal; in the open part of the medulla oblongata it lies in the gray matter of the floor of the fourth ventricle, immediately to the lateral side of the hypoglossal nucleus and subjacent to the surface area termed the **trigonum vagi** or **ala cinerea**.

All the fibres which arise from this dorsal or splanchnic efferent nucleus are very fine, and in sections of the vagus nerve can readily be distinguished from the much coarser somatic fibres, which come from the nucleus ambiguus, and also from the medium-sized sensory fibres, which spring from the ganglia placed upon the nerves. The fine fibres from the dorsal nucleus are distributed (probably indirectly, *i.e.* after being interrupted in a peripheral ganglion), to the involuntary striped muscle of the œsophagus and heart, and the unstriped muscle of the œsophagus, stomach and respiratory system (van Gehuchten and Molhant, *La Névrose*, June 15, 1912, p. 55).

The **nucleus ambiguus** (Figs. 488, 530, 526) gives origin to the somatic motor fibres of the glossopharyngeal and vagus nerves. All the fibres from this nucleus which pass into the glossopharyngeal nerve end in the stylo-pharyngeus muscle; the vagal branches are distributed to the striated muscles of the pharynx and larynx. The cells of the nucleus ambiguus are large, multipolar, and similar in every respect to the large cells in the anterior column of the spinal medulla. These cells are arranged in a slender column which is best developed in the open part of the medulla oblongata. Here the nucleus can easily be detected, in transverse sections, as a small area of compact gray matter which lies in the substantia reticularis grisea, midway between the dorsal accessory olive and the nucleus tractus spinalis nervi trigemini. It therefore lies more deeply in the substance of the medulla oblongata than the dorsal vago-glossopharyngeal nucleus. Kölliker states that it can be traced downwards as low as the level of the decussation of

the medial lemniscus, and upwards as high as the place of entrance of the cochlear root of the acoustic nerve. From its dorsal aspect the axons of the cells proceed, and in the first instance they pass backwards towards the floor of the fourth ventricle; then, bending suddenly laterally and forwards, they join the afferent roots of the vagus and the glossopharyngeal nerves, and emerge from the brain in company with these.

Sensory or Terminal Nuclei of the Glossopharyngeal and Vagus. Splanchnic and Gustatory Components.—The cells in the portion of the dorsal nucleus which acts as a *nucleus of termination* are spindle-shaped in form and

FIG. 530.—DIAGRAM, showing the brain connexions of the vagus, glossopharyngeal, acoustic, facial, abducens, and trigeminal nerves.

similar to those found in the posterior column of gray matter in the spinal medulla. In connexion with these cells, the greater number of the afferent fibres of the vagus nerve, and a small proportion of the afferent fibres of the glossopharyngeal nerve, end in fine terminal arborisations. A small part of the superior portion of the nucleus may be said to belong to the glossopharyngeal nerve and the remainder of the nucleus to the vagus nerve.

The *tractus solitarius* (Figs. 494, p. 561; 495, p. 561; and 530) is a round bundle of longitudinal fibres which forms a very conspicuous object in transverse sections through the medulla oblongata. It begins at the superior limit of the medulla oblongata, and can be traced downwards through its whole length. Its precise point of termination is not known, but some authorities believe

that it is carried for some distance downwards into the superior part of the spinal medulla, and, according to Kölliker, to the level of the fourth cervical nerve. Most modern writers, however, limit it to the medulla oblongata. The relations of the tractus solitarius are not the same in all parts of its course. It lies immediately to the lateral side of the dorsal vago-glossopharyngeal nucleus; but, whereas in the superior part of the medulla oblongata it is situated somewhat on the ventral side of that nucleus, in the inferior, closed part of the medulla oblongata it is placed on its dorsal aspect. Throughout its entire length it is intimately associated with a column of gelatinous gray substance called the *nucleus tractus solitarii*, which constitutes the nucleus of termination in which its fibres end. When traced from above downwards, the tractus solitarius is observed to become gradually smaller owing to the loss of fibres which it thus sustains. The great bulk of the tractus solitarius is formed of fibres derived from the glossopharyngeal nerve; only a few of the afferent fibres of the vagus enter it, but fibres of the sensory root (*nervus intermedius*) of the facial also enter it. As the fibres of the three nerves join the fasciculus they immediately turn downwards, and at different levels come to an end in the associated nucleus tractus solitarii.

As the afferent root-bundles of the vagus and the glossopharyngeal nerves traverse the substance of the medulla oblongata in a backward and medial direction to reach the tractus solitarius and the dorsal nucleus of termination, they pass through the tractus spinalis of the trigeminal nerve and the nucleus of that tract. As the afferent root of the vagus passes through the trigeminal tractus spinalis and its nucleus, which is somatic sensory in nature, it gives off to this nucleus its own somatic sensory branches, the peripheral ends of which constitute the auricular branch, distributed to the skin on the back of the auricle. The other afferent fibres in the glossopharyngeal and vagus nerves include taste fibres, sensory fibres from the pharynx, larynx, and other parts of the respiratory and alimentary systems, and other splanchnic afferent fibres. Although there is no sharp demarcation between the terminal nuclei of these various components, it is probable that the taste fibres proceed to the nucleus tractus solitarii, the splanchnic afferent fibres to the dorsal nucleus, and the somatic afferent fibres to the nucleus of the spinal trigeminal tract.

Nervus Acusticus.—As this is a nerve of special sense it will be left for consideration after the rest of this series.

Nervus Facialis (Figs. 530 and 531).—The facial nerve is composed of two distinct parts, viz., a large efferent (mainly motor) portion, the *facial nerve proper*, and a small afferent sensory portion termed the *nervus intermedius*.

The facial nerve proper emerges from the brain at the inferior border of the pons, to the medial side of the acoustic nerve, whilst the *nervus intermedius* sinks into the superior part of the medulla oblongata between the facial and acoustic nerves, but alongside the latter, rather than the former, from which it is separated by the fasciculus obliquus pontis (Fig. 527). The three nerves, therefore, lie in intimate relation with each other, where they are attached to the surface of the brain, and they pass in company into the internal acoustic meatus.

The fibres of the *nervus intermedius* arise from the cells of the ganglion geniculi of the facial nerve. These, like the cells of a spinal ganglion, are unipolar, the single process in each case dividing into a peripheral and a central branch. The group of peripheral fibres represent parts of the greater superficial petrosal nerve and chorda tympani branch of the facial nerve, whilst the central fibres form the *nervus intermedius*. The central fibres penetrate the brain, and, passing either through or on the dorsal side of the tractus spinalis of the trigeminal nerve, they finally reach the superior part of the column of gray matter in connexion with the tractus solitarius, and in this they end. The *nervus intermedius* presents, therefore, the same terminal connexions within the brain as the glossopharyngeal nerve.

The motor nucleus of the facial nerve contains elements serially homologous with both the somatic (*nucleus ambiguus*) and splanchnic (*nucleus dorsalis*) efferent nuclei of the glossopharyngeal and vagus. It is composed partly of the larger cells characteristic of the former and the smaller cells distinctive of the latter. The axons of the somatic cells innervate the striated muscles of the face, whereas the splanchnic efferent fibres pass to the sphenopalatine, otic

and submaxillary ganglia (as their white rami communicantes), and are largely concerned with the regulation of the secretory activity of the large salivary glands and other glands around the mouth.

The facial nucleus is situated close to the place where the nerve emerges from the brain, but the nerve does not at once pass to this point of exit. It pursues a long and devious path within the pons before it finally reaches the surface. This intrapontine part of the nerve may be divided into three parts, viz.: (1) a radicular part, (2) an ascending portion, and (3) an emergent part.

The **radicular part of the facial nerve** (Fig. 531) is composed of a large number of fine loosely arranged bundles of fibres, which issue from the lateral and dorsal aspect of the nucleus and proceed backwards and slightly medially through the pons. Reaching the floor of the fourth ventricle they curve medially, and the bundles which lie highest up sweep over the lateral and dorsal aspect of the inferior part of the nucleus of the sixth nerve. Close to the median plane they turn sharply upwards and are collected into a single solid nerve-bundle, which constitutes the **ascending part of the facial nerve** (Figs. 530 and 531). This proceeds upwards immediately beneath the ependyma of the ventricular floor on the dorsal aspect of the medial longitudinal bundle, and along the medial side of the abducent nucleus for a distance of about five millimetres. Then the nerve bends laterally at a right angle, and curves a second time over the dorsal aspect of the abducent nucleus. This gives rise to a prominent hemispherical projection in the floor of the fourth ventricle, the **colliculus facialis** (Fig. 531 and Fig. 482, p. 550). The nerve now passes straight to the place of exit from the brain, and this part of the intrapontine trunk may be termed the **emergent portion** (Figs. 498 and 531). The facial nerve thus forms a curved loop over the dorsal aspect of the abducent nucleus. The **emergent part** of the nerve takes an oblique course through the pons to reach the surface. It inclines laterally and downwards as it proceeds towards the ventral aspect of the pons, and on its way it passes between its own nucleus and the tractus spinalis of the trigeminal nerve.

Entering the facial nucleus, and ending in fine terminal arborisations around its cells, are many fibres from the opposite pyramidal tract; fibres from the spinal tract of the fifth nerve; fibres from the corpus trapezoideum, etc. The nucleus is thus brought into connexion with the motor area of the cerebral cortex, with the trigeminal nerve or sensory nerve of the face, and with the acoustic nerve.

The peculiar course of the efferent fibres of the facial nerve within the pons is to be explained in accordance with the general principle regulating migrations of nerve-cells, to which reference has already been made (p. 554). In the embryo the nucleus facialis develops alongside the nucleus abducens. The latter, controlling one of the eye-muscles, receives most of its afferent impulses from the medial longitudinal bundle (descending from the optic centres in the superior colliculus), and therefore it remains alongside the medial longitudinal bundle

FIG. 531.—DIAGRAM OF THE INTRAPONTINE COURSE OF THE FACIAL NERVE.

Sub. gel. rol. refers to the nucleus of the spinal trigeminal tract.

and perhaps moves slightly upwards, *i.e.* towards the mesencephalon. The facial nucleus, however, receives most of its stimuli from the nucleus tractus spinalis nervi trigemini, and therefore, as the walls of the metencephalon thicken during their growth, this nucleus retains its proximity to the trigeminal nucleus (Fig. 531), and so migrates along a course which remains mapped out by its emerging fibres. Streeter, working with human embryos, and Ariens-Kappers, on comparative and therefore broader lines, have elucidated the meaning of this peculiar intracentral course of the facial nerve.

Nervus Abducens (Figs. 498 and 531).—The **abducens nerve** is a small motor nerve which emerges from the brain at the inferior border of the pons above the lateral side of the pyramid of the medulla oblongata. It is the nerve of supply to the lateral rectus muscle of the eyeball. Its nucleus of origin is a small spherical mass of gray matter, containing large multipolar cells, which lies in the dorsal part of the tegmental portion of the pons, close to the median plane and immediately subjacent to the gray matter of the floor of the fourth ventricle. Its position can be easily indicated on the ventricular floor, seeing that it is placed subjacent to the colliculus facialis and immediately above the level of the striæ medullares. Its peculiar and intimate relation to the intrapontine portion of the facial nerve has already been indicated. It lies on the ventral aspect of, and within the concavity formed by, the two limbs of the loop of that nerve.

The axons of the multipolar cells of this nucleus emerge from the medial aspect of the nucleus in the form of several bundles, which proceed through the whole dorso-ventral thickness of the pons towards the place of exit. As they pass forwards they incline downwards and slightly laterally. In the dorsal part of the pons they proceed forwards on the medial side of the nucleus olivaris superior, whilst in the basilar part of the pons they keep for the most part to the lateral side of the pyramidal bundles, although several of the nerve fila pierce these on their way to the surface.

It would appear probable that certain of the axons of the cells of the abducens nucleus enter the medial longitudinal fasciculus and proceed upwards in it to end in the oculomotor nucleus of the opposite side. Fibres and collaterals from the basis pedunculi of the opposite side enter the nucleus, and, ending around the cells, bring the nucleus into connexion with the motor area of the cerebral cortex. The pedicle of the nucleus olivaris superior ends partly within the nucleus of the abducent nerve (Fig. 530).

Nervus Trigemini.—The **trigeminal nerve** strikes its roots deeply into the brain and establishes a connexion with it which extends from the upper part of the mesencephalon above to the level of the second cervical nerve below. No other cerebral nerve presents so extensive a connexion (Fig. 530, p. 597). It is composed of two roots—a large afferent or sensory root and a small efferent or motor root. Both roots appear close together on the surface of the pons, rather nearer its superior than its inferior border, and in the same line as the facial, and glossopharyngeal and vagus nerves (Fig. 527, p. 594).

The **sensory root of the trigeminal nerve** is composed of fibres which arise outside the brain from the cells of the semilunar ganglion. They end within the brain in a somewhat tadpole-shaped terminal nucleus, the swollen body of which is situated in the pons and is termed the main sensory nucleus of the trigeminal nerve: the tail is a long column of gray matter which is directly continuous below with the substantia gelatinosa of the spinal medulla.

The **main sensory nucleus** (Fig. 532) is an oval mass of gray matter placed half-way up the pons in the lateral part of its dorsal or tegmental portion. It lies close to the lateral surface of the pons and immediately subjacent to the ventral submerged margin of the brachium conjunctivum. It is directly continuous with the substantia gelatinosa, and may be regarded as being merely the enlarged superior end of that column of gray matter.

The fibres of the sensory root of the trigeminal nerve, on reaching the sensory nucleus, divide, in the same way as the fibres of the entering posterior roots of the spinal nerves, into a system of ascending and descending branches (Fig. 530, p. 597). The ascending fibres are short, and almost immediately enter the sensory nucleus and end within it; the descending fibres turn sharply downwards and form the
