tractus spinalis. This tract descends on the lateral side of the column of gray matter formed by the *substantia gelatinosa*, which constitutes its terminal nucleus, **nucleus tractus spinalis nervi trigemini.** Fibres constantly leave it to enter the nucleus, so that the lower it gets the smaller does the spinal tract become until, in the upper part of the spinal medulla, about the level of the first or second spinal nerve, it disappears altogether.

The large spinal tract of the trigeminal nerve is a conspicuous object in sections through the pons and medulla oblongata. In the pons it traverses the dorsal or tegmental part, first, between the emergent part of the facial nerve and the vestibular nerve; and then lower down, between the restiform body and the nucleus of the facial nerve (Fig. 498, p. 565). In cross sections it presents a well-defined semi-lunar or curved piriform outline. In the superior part of the medulla oblongata it lies on the ventral aspect of the restiform body, and therefore nearer the surface than in

FIG. 532.—SECTION THROUGH THE PONS OF THE ORANG, AT THE LEVEL OF THE NUCLEI OF THE TRIGEMINAL NERVE.

the pons (Fig. 495, p. 561). Here it is traversed and broken up into separate bundles by the olivo-cerebellar fibres and the roots of the glossopharyngeal and vagus nerves. Finally, it comes to the surface and its fibres are spread over the area on the side of the medulla oblongata known as the *tuberculum cinereum* of Rolando (Fig. 494, p. 561).

The small **motor part of the trigeminal nerve** is distributed chiefly to the muscles of mastication, and derives its fibres from the motor nucleus.

The **motor nucleus** (Fig. 532) lies in the lateral part of the tegmental portion of the pons, close to the medial side of the main sensory terminal nucleus, but somewhat nearer the floor of the fourth ventricle. It is serially homologous with the motor nuclei of the lateral somatic group, namely, the facial and nucleus ambiguus. It does not become displaced so far forwards as these nuclei, because its chief source of sensory impulses—the terminal nucleus of the trigeminal afferent fibres—is placed alongside it, and there is no need for any definite migration (Fig. 532).

The **mesencephalic root or radix descendens nervi trigemini** takes origin from

a column of loosely arranged pear-shaped unipolar cells which are placed in the extreme lateral part of the gray matter surrounding the aquæductus cerebri. As this root is traced downwards it gradually increases in size by the accession of new fibres, and it assumes a crescentic form in transverse section (Figs. 501, p. 569; 532, p. 601; 533; and 534, p. 603). In the inferior part of the mesencephalon it lies on the medial side of the brachium conjunctivum; and the trochlear nerve, on its way to the surface, runs downwards in its concavity and on its medial aspect. In the superior part of the pons it continues its course downwards on the lateral and deep aspect of the gray matter in the floor of the fourth ventricle. Finally, reaching the level of the nuclei of the trigeminal nerve, the fibres of the mesencephalic root turn forwards and are said to join the *sensory* part (Johnston) of the trigeminal nerve. Otto May and Horsley, however, confirm the usual description, viz., that it passes into the *motor* root; but, according to them, it cannot be traced beyond the semilunar ganglion.

FIG. 533.—SECTION THROUGH THE INFERIOR COLICULUS AND THE TEGMENTUM OF THE MESENCEPHALON AT THE LEVEL OF THE MIDDLE PART OF THE NUCLEUS OF THE TROCHLEAR NERVE (Orange).

It is customary to describe this mesencephalic root as belonging to the motor division of the trigeminal nerve; but Johnston has recently questioned this and claimed: (1) that its fibres become associated at their exit from the central nervous system with the sensory, and not with the motor, root; (2) that its nucleus develops in the alar and not in the basal lamina; and (3) that the pear-shaped unipolar cells, from which its fibres arise, conform to the sensory and not to the motor type.

The reason why its sensory nature has not been suspected hitherto is no doubt the fact that its fibres arise not in some ganglion outside the central nervous system, like other sensory nerves, but from cells in the tectum

mesencephali. If Johnston's view is correct, the neural crest in the mesencephalic region must have been drawn into the neural tube during development and given rise to this sensory nucleus of origin (*not* a terminal nucleus) within the central nervous system.

Otto May and Sir Victor Horsley have shown that the mesencephalic root is a mixture of ascending and descending fibres, but there is no evidence to show that the latter may not be sensory like the former. Nothing is known of their peripheral distribution.

Nervus Trochlearis.—The trochlear nerve supplies the superior oblique muscle of the eyeball. It emerges from the brain, on its dorsal aspect, at the superior part of the anterior medullary velum, immediately below the lower border of the inferior colliculus (Fig. 517, p. 583). The nucleus from which it arises is a small oval mass of gray matter, placed in the ventral part of the central gray matter, at the level of the superior part of the inferior colliculus. The close association of this nucleus with the medial longitudinal bundle has already been referred to. It is sunk deeply in a bay which is hollowed out on the dorsal and medial aspect of that tract. The nerve has a course of some length within the mesencephalon. The axons of the cells leave the lateral aspect of the nuclear mass, and curve backwards and laterally in the central gray matter until they reach the concave medial surface of the mesencephalic root of the trigeminal nerve. Here they are gathered together

into one or two round bundles, which, bending sharply, turn downwards at a right angle and descend on the medial side of the trigeminal root. When the region below the inferior colliculus is reached, the nerve makes another sharp bend. This time it turns medially, enters the superior end of the anterior medullary velum, in which it decussates with its fellow of the opposite side. Having thus crossed the median plane, the trochlear nerve emerges at the medial border of the brachium conjunctivum. The course pursued by the trochlear nerve within the central gray matter may be traced by examining in succession Fig. 533; Fig. 534; Fig. 502, p. 570; and Fig. 512, p. 577.

Nervus Oculomotorius.—The oculomotor nerve supplies the levator palpebræ superioris, all the ocular muscles, with the exception of the superior oblique and the lateral rectus, and also two muscles within the eyeball, viz., the sphincter iridis and the musculus ciliaris. The nucleus of origin is placed in the ventral part of the central gray matter subjacent to the superior colliculus (Fig. 521, p. 587). In length it measures from 5 to 6 mm. Its inferior end is partially continuous with the nucleus of the trochlear nerve, whilst its superior end extends upwards for a short distance beyond the mesencephalon into the gray matter on the lateral wall of the third ventricle. Its relation to the medial longitudinal bundle is even more intimate than that of the trochlear nucleus. It is closely applied to the dorsal and medial aspect of this strand; many of its cells occupy a position in the intervals between the nerve-bundles of the tract, and some even are seen on its ventral or tegmental aspect. The axons of the nuclear cells leave the nucleus in numerous bundles, which describe a series of curves as they proceed forwards through the medial longitudinal bundle, the tegmentum, red nucleus, and medial margin of the substantia nigra, to emerge finally from the brain-stem along the bottom of the sulcus oculo-motorius on the medial aspect of the basis pedunculi.

The cells of the oculomotor nucleus are not uniformly distributed throughout it. They are grouped into several more or less distinct collections or clumps, some of which possess cells which differ in size and appearance from the others. These cell-clusters are very generally believed to possess a definite relation to the several branches of the nerve and the muscles which they supply. Perlia recognises no less than seven such cell-clusters in each nucleus, with a small medial nucleus placed accurately on the median plane, and from which fibres for both nerves spring. Whilst the majority of the fibres in the oculomotor nerve arise from the cell-groups which lie on its own side of the median plane, it has been satisfactorily established that a certain proportion of its fibres are derived from the nucleus of the opposite side, thus forming a crossed connexion and giving rise to a median decussation. These crossed fibres are supposed by some to supply the medial rectus muscle; and we have seen that there is reason to believe that the part of the nucleus from which these fibres are derived stands in connexion through the medial longitudinal fasciculus with the abducens nucleus from which proceeds the nerve of supply for the lateral rectus muscle. The harmonious action of the medial and lateral recti in producing the conjugate movements of the eyeballs is thus explained.

FIG. 534.—SECTION THROUGH THE INFERIOR COLLICULUS AND THE TEGMENTUM OF THE MESENCEPHALON AT THE LEVEL OF THE INFERIOR PART OF THE NUCLEUS OF THE TROCHLEAR NERVE (Orange).

The oculomotor nucleus is connected—(1) with the occipital part of the cerebral cortex by fibres which reach it through the optic radiation; (2) with the vestibular, trochlear and abducent nuclei (and probably with other nuclei) by fibres which come to it through the medial longitudinal bundle; (3) possibly with the facial nerve by fibres which pass out from it into the medial longitudinal bundle (p. 589); (4) with the visual system by fibres which enter it from the cells of the superior colliculus.

It is important to recognise that although the main part of the oculomotor nucleus belongs to the medial somatic group, which also includes the trochlear, abducent and hypoglossal nuclei, it also includes a representative (the Edinger-Westphal group of small cells) of the column of splanchnic efferent nuclei in series with those of the facial, glossopharyngeal, and vagus nerves. Its axons pass out along with the other fibres of the oculomotor nerve and enter the ciliary ganglion, where they end in relationship with the cells that innervate the ciliary muscle and the circular muscle of the iris.

Nervus Acusticus.—This is a large nerve which enters the brain at the inferior border of the pons. Its fibres spring from bipolar ganglionic cells in the immediate neighbourhood of the labyrinth or internal ear (see section dealing with the Organs of Sense). One group of these forms the **spiral ganglion**, the peripheral branches of which are distributed to the organ of Corti in the cochlea; another group constitutes the **vestibular ganglion** (often called **Scarpa's**), which distributes fibres to the ampullæ of the semicircular ducts and the utricle. Although the central processes of the cells in these two ganglia accompany one another and are known collectively as the acoustic nerve they really remain distinct throughout, in their mode of termination in the brain as well as in their peripheral distribution. Reaching the brain the acoustic nerve divides into two parts, viz., the **nervus cochlearis** and the **nervus vestibularis**, which present totally different connexions, corresponding to their distinct functions. In their further course these two divisions deviate from each other so as to embrace the restiform body—the vestibular part entering the pons on the medial aspect of the restiform body, whilst the cochlear part sweeps round its lateral surface. Special nuclei of termination require to be studied in connexion with each part of the nerve.

The **cochlear nerve** is composed of finer fibres than the vestibular nerve, and these acquire their medullary sheaths at a later period. It is the true nerve of hearing, and its fibres end in a nucleus which lies in intimate relation to the restiform body. It may be described as consisting of two parts. Of these one, called the **dorsal cochlear nucleus**, is a piriform mass which is placed on the dorsal aspect of the restiform body—between it and the flocculus of the cerebellum. The second part, termed the **ventral cochlear nucleus**, is placed on the ventral aspect of the restiform body in the interval between the cochlear and vestibular divisions of the acoustic nerve, after they have separated from each other. The fibres of the cochlear nerve enter these two ganglia and end around the cells in arborisations, which are finer, closer, and more intricate than those met with in any other nerve-ending in the brain.

The **vestibular nerve** enters the brain at a slightly higher level than the cochlear nerve and on the medial aspect of the ventral cochlear nucleus. It proceeds backwards through the pons between the restiform body, which lies on its lateral side, and the spinal tract of the trigeminal nerve, which is placed on its medial side. Its fibres end in a series of terminal nuclei (Fig. 530, p. 597), viz.: (1) the **nucleus vestibularis dorsalis**, often known as the principal nucleus, (2) its inferior prolongation, **nucleus tractus descendens**, (3) the **nucleus vestibularis lateralis** (*Deiters'*), (4) the **nucleus vestibularis superior** (*Bechterew's*), and (5) the cerebellar cortex.

The **principal nucleus** (Figs. 498, p. 565, and 535, p. 605) is a large diffuse nuclear mass, which lies in the floor of the fourth ventricle subjacent to the surface district known as the **area acustica** (Fig. 482, p. 550). It is situated, therefore, in both the pons and the medulla oblongata to the lateral side of the fovea superior and the fovea inferior. In transverse section it is prismatic in outline, and crossing the surface of its upper or pontine part immediately under the ependyma of the ventricle are the **striæ medullares**.

When the *nervus vestibularis*, as it traverses the brain, reaches the medial aspect of the dorsal portion of the restiform body, its fibres bifurcate to form ascending and descending tracts. The latter pass vertically downwards in separate bundles and form the descending tract of the vestibular nerve (Figs. 498, p. 565; 495, p. 561; and 530, p. 597). This proceeds through the inferior part of the pons into the medulla oblongata, in which it may be traced as far as the level of the decussation of the medial lemniscus. Associated with the descending tract there is a column of gray matter, with nerve-cells strewn sparsely throughout it. This is the nucleus of the descending tract, and the fibres end in fine arborisations around these nerve-cells.

Some of the ascending fibres of the vestibular nerve end in the **nucleus lateralis**. This nucleus is composed of a number of large and conspicuous multipolar nerve-cells, which are scattered amidst the bundles of the vestibular nerve. As it is traced upwards into the pons the nucleus gradually inclines backwards, and finally it occupies a place in the lateral wall of the fourth ventricle. It attains its greatest development at the level of the emerging part of the facial nerve and this upper part is sometimes termed the **nucleus superior**.

Other ascending fibres pass without interruption into the cerebellum to terminate in the cortex of the vermis and lateral lobe. In their course many of these fibres pass through the nucleus fastigii, and many writers describe them as terminating in this nucleus; but according to Ramon y Cajal they merely traverse it on their way to the cerebellar cortex.

From the large-celled **nucleus lateralis**—best known as **Deiters' nucleus**—a strand of fibres passes medially to reach the medial longitudinal fasciculus, of which it forms one of the most important constituent elements. Some of these fibres pass upwards to the nuclei of the oculomotor, trochlear, and abducens nerves; others downwards, probably to the nucleus of the accessory nerve, which are concerned in regulating the movements of the eyes and the head respectively, because they need to be thus closely linked to the receptive nucleus of the nerve (vestibular), which is concerned with the appreciation of movements of the head and the position of the body in space. Other fibres arise from the lateral nucleus and pass directly to the spinal medulla without passing through the medial longitudinal bundle; they form the **fasciculus vestibulospinalis**, which passes downwards in the funiculus anterior and distributes fibres to the various motor nuclei in the anterior column of the spinal medulla (Fig. 524, p. 590, and Fig. 473, p. 534).

The **nucleus superior** (Bechterew's nucleus) likewise emits a group of fibres

FIG. 535.—CENTRAL CONNEXIONS OF THE COCHLEAR AND VESTIBULAR DIVISIONS OF THE ACOUSTIC NERVE.

Vestibular fibres green. Cochlear fibres yellow.

which pass directly to the mid-brain (*fasciculus vestibulomesencephalicus*), chiefly to the oculomotor and trochlear nuclei (Fig. 524, p. 590).

Central Connexions of the Cochlear Nerve.—The cochlear nuclei are brought into connexion with the inferior colliculus and the medial geniculate body of the opposite side by the fibres of the corpus trapezoideum and the lateral lemniscus.

The fibres of the cochlear nerve end in the ventral cochlear nucleus and in the dorsal cochlear nucleus (*tuberculum acusticum*). From the cells of these nuclei two tracts arise, viz., a **ventral tract**, composed of the fibres of the corpus trapezoideum, and a **dorsal tract**, which is represented by the *striæ medullares*.

The **corpus trapezoideum** (Figs. 531 and 532) is formed of the axons of the cells of the ventral cochlear nucleus, as well as certain of the axons of the cells of the dorsal nucleus. In the midst of the corpus trapezoideum are lodged large cells which are known as the *nucleus trapezoideus*, and these give off axons which join the strand with which they are associated. Many of the fibres of the corpus trapezoideum end in a large mass of gray matter called the **nucleus olivaris superior**, which is placed immediately behind the

trapezoid body. The trapezoid fibres cross the median plane and decussate with the corresponding fibres of the opposite side. Reaching the opposite superior olivary nucleus, more fibres leave the trapezoid body, and almost immediately after this the strand bends upwards and forms the **lemniscus lateralis** (Figs. 535, p. 605 ; 537, p. 607). But still another nucleus is interposed in its path, viz., the **nucleus lemnisci lateralis**. Here some fibres are dropped, whilst from the nuclear cells others are acquired, and the lateral lemniscus then proceeds upwards until it reaches the inferior colliculus and the medial geniculate body, in which its fibres end.

Other fibres arise from the cells of the dorsal cochlear nucleus, and arrange themselves in the conspicuous bundles which sweep round the dorsal aspect of the restiform body and proceed inwards across the floor of the fourth ventricle, often immediately beneath the ependyma (Fig. 482, p. 550). Reaching the median plane they dip forwards into the substance of the pons, and, crossing the median plane, they join the lateral

lemniscus. It is important to remember that the striæ medullares are not always visible in the floor of the fourth ventricle (Fig. 535), but are often buried more or less deeply.

The connexion between the terminal cochlear nuclei and the inferior colliculus is not altogether with that of the opposite side, as the foregoing description and the diagram (Fig. 534) might lead one to infer. A few fibres pass directly to the inferior colliculus of the same side, but none to the corresponding medial geniculate body: the connexion with the latter is entirely *crossed* (Ferrier and Turner).

From the medial geniculate body there proceeds a tract to the cerebral cortex of the transverse temporal gyri (Heschl's). The whole nervous apparatus is thus linked on to the cerebral cortex, and the succession of neurones which build up the entire chain are therefore: (1) in the cochlea of the internal ear, the bipolar cells of the spiral

FIG. 537.—A VERTICAL TRANSVERSE SECTION OF THE BRAIN TO SHOW THE WHOLE OF THE CENTRAL ACOUSTIC PATH. The left hemisphere (right side of the figure) is cut on a plane posterior to that of the right. Motor fibres red. Sensory fibres blue. Acoustic fibres yellow.

ganglion emit axons that terminate in the brain; in (2) the cochlear nuclei, from the nerve-cells of which fibres arise and cross to the lateral lemniscus of the opposite side, proceeding to (3) the medial geniculate body, from which fibres pass to the cerebral cortex.

It must be borne in mind that all the axons of the cells of the superior olive do not join the trapezoid strand. Many leave its dorsal aspect and pass backwards in a group called the **pedicle of the superior olive**, to end in the nucleus of the abducens nerve, and, through the medial longitudinal bundle, in the nuclei of the trochlear and oculo-motor nerves. In this way the organ of hearing is brought into connexion with the nuclei which preside over the movements of the eyeballs (Figs. 531, p. 599, and 536, p. 606).

PROSENCEPHALON OR FORE-BRAIN.

The fore-brain vesicle in the embryo has been subdivided, somewhat arbitrarily,

into two parts—an anterior, termed the **telencephalon**, and a posterior, called the **diencephalon**, which forms the greater part of the walls of the third ventricle. The extreme anterior part of the third ventricle belongs to the telencephalon, and this includes the anterior wall of the neural tube, which is known as the **lamina terminalis**.

DEVELOPMENT OF PARTS DERIVED FROM FORE-BRAIN.

The alar part of each lateral wall of the telencephalon is pushed out to form a diverticulum, which ultimately constitutes the cerebral hemisphere, and thus from a very early period the primitive position of this part of the lateral wall is indicated by the wide **foramen interventriculare**, or aperture of communication between the cavity of the cerebral hemisphere and the third ventricle (Fig. 538).

The alar part of the lateral wall of the diencephalon is utilised for the development of the thalamus, the epithalamus, and the metathalamus. Of these the thalamus is derived from the anterior and by far the greatest part of the alar wall. It arises as a large oval swelling, which gradually approaches its fellow of the opposite side, and thus diminishes the width of the third ventricle. Finally, the two bodies sometimes come into contact in the median plane and cohere over an area corresponding to the *massa intermedia*. This may occur about the end of the second month.

From that section of the lateral wall to which the name of metathalamus is given the two geniculate bodies arise. Each of these shows, in the first place, as a depression on the inside, and a slight elevation on the outside, of the wall of the diencephalon. As the thalamus grows backwards, it encroaches greatly upon the territory occupied by the geniculate bodies. It thus comes about that in the adult brain the medial geniculate body seems to hold a position on the lateral aspect of the mesencephalon, whilst the lateral geniculate body, viewed from the surface, appears to be a part of the thalamus.

From the epithalamic region of the wall of the diencephalon are developed the pineal body, its peduncle, and the habenular region. These parts are relatively much more evident in the embryonic than in the adult brain. The pineal body appears to be developed as a diverticulum of the posterior part of the roof of the diencephalon, but in reality it is a derivative of the alar lamina. Viewed from the dorsal aspect of the brain-tube, this diverticulum shows in the first instance, as a rounded elevation, from either side of which a broad ridge runs forwards. This ridge becomes the *tænia thalami*, whilst in the region of its junction with the pineal elevation the *trigonum habenulæ* takes shape. The pineal diverticulum ultimately becomes solid, but a small portion of the original cavity is retained as the recessus pinealis of the third ventricle.

The part of the diencephalon and telencephalon which represents the basal lamina (*i.e.* lies below the level of the sulcus hypothalamicus) retains its primitive form, and undergoes only slight change. Consequently, when this region in the adult brain is compared with the corresponding region in the embryonic brain, the resemblance between the two is very striking.

In the fore-brain, therefore, it is the alar lamina which plays the predominant part in the formation of the cerebrum. The value, also, of the basal part of the wall of this portion of the neural tube is still further reduced by the fact that it no longer contains the nuclei of origin of efferent nerves. The highest of these nuclei (the oculomotor) is placed in the mesencephalon. [Johnston has recently announced the discovery of a sensory nerve (*nervus terminalis*) attached to the fore-brain in human embryos; and of course the optic and olfactory nerves enter the fore-brain.]

The region of the fore-brain which lies below the sulcus hypothalamicus is termed the hypothalamus. The part of this which corresponds to the diencephalon is called the *pars mamillaris hypothalami*, whilst the part in front, which belongs to the telencephalon, receives the name of *pars optica hypothalami*. From the *pars mamillaris hypothalami* are derived the corpus mamillare and a portion of the tuber cinereum. With the *pars optica hypothalami* are associated the following parts, *viz.*, the tuber cinereum, with the infundibulum and the cerebral part of the hypophysis, the optic chiasma, the optic recess, and the lamina terminalis. The corpora mamillaria form, in the first instance, a relatively large ventral bulging of the floor of the brain-tube. As development goes on this bulging becomes relatively small, and about the fourth month the single projection becomes divided into the two tubercles. The infundibulum and posterior or cerebral lobe of the hypophysis are developed as a hollow downward diverticulum of the floor of the telencephalon (Fig. 538). A portion of the original cavity is retained in the upper part of the infundibulum, and constitutes the infundibular recess in the floor of the third ventricle.

The optic nerve is chiefly formed by the passage of fibres backwards from the retina in the wall of the original optic stalk, whilst the chiasma takes form by the transit of fibres across the median plane in front of the infundibulum and behind the optic recess. To a large extent these fibres are derived from the optic nerve. The optic recess of the third ventricle marks the spot where the hollow optic vesicle was originally attached to the inferior and lateral part of the fore-brain, and in the adult it therefore represents a portion of the primitive cavity of the tubular stalk of the optic vesicle. In the course of development the optic nerve fibres, which appear in the stalk of the optic vesicle to form the optic nerve, seek an attachment much further back, and through the optic tract they are even carried as far as the mesencephalon.

The roof of the fore-brain remains thin, and does not proceed to the development of nervous elements, although its posterior part becomes invaded by nervous tissue to form the pineal body and the posterior commissure. In front of these structures the roof of the fore-brain is epithelial, and remains so during life. It constitutes the epithelial roof of the third ventricle, and it becomes involuted along the median plane into the cavity to form the chorioid plexuses of the ventricle (Fig. 549, p. 622). The posterior commissure appears as a transverse thickening at the bottom of a transverse groove which appears in the roof of the early brain-tube, behind the pineal diverticulum.

PARTS DERIVED FROM THE DIENCEPHALON.

Under this heading we have to consider: (1) the **thalamus**; (2) the **epithalamus**, which comprises the pineal body and the habenular region; (3) the **metathalamus**, or the corpora geniculata; and (4) the **hypothalamus**.

The hypothalamus consists of two portions, viz., the **pars mamillaris hypothalami**, which comprises the corpus mamillare and the portion of the central gray matter which forms the floor of the third ventricle in its immediate vicinity; and the **pars optica hypothalami**, which embraces the tuber cinereum, the infundibulum, the hypophysis (O.T. pituitary body), and the lamina terminalis. Strictly speaking, the optic part of the hypothalamus does not belong to the diencephalon, but it is convenient to study the parts which it represents at this stage.

The original cavity of that part of the brain-tube which forms the diencephalon is represented by the greater part of the third ventricle of the brain.

Thalamus.—The thalamus is the principal object in this section of the brain

(Fig. 538). It is a large ovoid mass of gray matter, which lies obliquely across the path of the cerebral peduncle as it descends from the cerebral hemisphere. The smaller anterior end of the thalamus lies close to the median plane, and is separated from the corresponding part of the opposite side only by a very narrow interval. The enlarged posterior ends of the two thalami are placed more widely apart, and in the interval between them the corpora quadrigemina are situated.

The two thalami, in their anterior two-thirds, lie close together on either side of a deep median cleft, which receives the name of the third ventricle of the brain. The inferior and lateral aspects are in apposition, and, indeed, directly connected with adjacent parts of the brain, and on this account it is customary to study them by means of sections through the brain. The superior and medial surfaces are free.

The *lateral surface* of the thalamus is applied to a thick layer of white matter

FIG. 539.—THE THALAMI AND THE PARTS OF THE BRAIN SURROUNDING THEM.
Superior aspect.

interposed between it and the lentiform nucleus, called the **internal capsule**, and composed of fibres passing both upwards towards and downwards from the cerebral cortex. A large proportion of these fibres descend to form the basis pedunculi. From the entire extent of the lateral surface of the thalamus large numbers of fibres stream out and enter the internal capsule, to reach the cerebral cortex. They constitute what is termed the **thalamic radiation**. As the fibres leave the thalamus, over the whole of the

lateral surface of the ganglionic mass they form a very distinct reticulated zone or stratum, which is termed the **external medullary lamina**.

The *inferior surface* of the thalamus rests on the hypothalamus. From the latter region many fibres enter the thalamus on its inferior aspect, whilst other fibres leave this surface of the thalamus to take part in the thalamic radiation.

The *superior surface* of the thalamus is free. Laterally it is bounded by a groove, which traverses the floor of the lateral ventricle of the brain and intervenes between the thalamus and the caudate nucleus. In this groove are placed a slender band of longitudinal fibres, termed the *stria terminalis*, and in its forepart the *vena terminalis*. Medially, the superior surface of the thalamus is separated from the medial surface in its anterior half by a sharp edge or prominent ledge of the ependyma of the third ventricle. This is termed the *tænia thalami*, and the ridge which it forms is accentuated by the fact

that, subjacent to it, there lies a longitudinal strand of fibres called the *stria medullaris*. When these two structures, viz., the ependymal ridge and the subjacent stria, are traced backwards, they are seen to turn medially and become continuous with the stalk or peduncle of the pineal body. Behind the portion of the *tænia thalami* which turns medially towards the pineal body a small depressed triangular area, the *trigonum habenulæ*, situated in front of the superior colliculus, forms a very definite medial boundary for the posterior part of the superior surface of the thalamus.

The superior surface of the thalamus is slightly bulging or convex, and is of a whitish colour, owing to the presence of a thin superficial covering of nerve-fibres, termed the *stratum zonale*. It is divided into two areas by a faint oblique groove, which begins in front at the medial border, a short distance behind the anterior extremity of the thalamus, and extends laterally and backwards to the lateral part of the posterior extremity. This groove corresponds to the lateral edge of the fornix. The two areas which are thus mapped out are very differently related to the ventricles of the brain, and also to the parts which lie above the thalamus. The *lateral area*, which includes the anterior extremity of the thalamus, forms a part of the floor of the lateral ventricle. It is covered with ependyma, overlapped by the chorioid plexus of this ventricle, and lies immediately subjacent to the corpus callosum. Along the line of the groove the epithelial lining of the lateral ventricle is reflected over the chorioid plexus of this cavity. The *medial area*, which includes the posterior end of the thalamus, intervenes between the lateral and third ventricles of the brain, and takes no part in the formation of the walls of either. It is covered by a fold of pia mater, termed the *tela chorioidea* of the third ventricle, above which is the fornix, and these two structures intervene between the thalamus and the corpus callosum.

The *anterior extremity* of the thalamus, called the *tuberculum anterius thalami*, forms a marked bulging. It projects into the lateral ventricle, behind and to the lateral side of the free portion of the column of the fornix. The foramen interventriculare, a narrow aperture of communication between the lateral and third ventricles of the brain, is bounded in front by the column of the fornix and behind by the anterior tubercle of the thalamus.

The *posterior extremity* of the thalamus is very prominent and forms a cushion-like projection, which overhangs the brachia of the corpora quadrigemina. This prominence is called the *pulvinar*. Another oval bulging on the posterior part of the thalamus receives the name of the *corpus geniculatum laterale*. It is situated below, and to the lateral side of, the pulvinar, and presents a very intimate connexion with the optic tract.

The *medial surfaces* of the two thalami are placed close together, and are covered not only by the lining ependyma of the third ventricle, but also by a tolerably thick layer of gray matter, continuous below with the central gray substance which surrounds the aquæductus cerebri in the mesencephalon. A band of gray matter, termed the *massa intermedia*, crosses the third ventricle and joins the medial surfaces of the two thalami together.

Intimate Structure and Connexions of the Thalamus.—The upper surface of the thalamus is covered by the *stratum zonale*, a thin coating of white fibres derived to some extent from the optic tract, and probably also from the optic radiation. The inner surface has a thick coating of central gray matter, whilst intervening between the internal capsule and the outer surface is the *lamina medullaris externa*. The lower surface merges into the hypothalamus.

The gray matter of the thalamus is marked off into three very apparent parts—termed the anterior, the medial, and the lateral thalamic nuclei—by a thin vertical sheet of white matter, continuous with the *stratum zonale*, termed the *lamina medullaris interna*. The lateral nucleus (*nucleus lateralis thalami*) is by far the largest of the three. It is placed between the medial and the lateral medullary laminae, and it stretches backwards beyond the medial nucleus, and thus includes the whole of the pulvinar (Fig. 541). The *medial nucleus* (*nucleus medialis thalami*) reaches only as far back as the habenular region. It is placed between the central gray matter of the third ventricle and the internal medullary lamina. The lateral nucleus is more extensively pervaded by fibres than the medial nucleus.

From the lateral nucleus by far the greatest number of the fibres which form the *radiatio thalami* pass, and these are seen crossing it in various directions towards the lamina medullaris externa. The **anterior nucleus** (nucleus anterior thalami) is the smallest of the three thalamic nuclei. It forms the prominent anterior tubercle, and is prolonged in a wedge-shaped manner, for a short distance, downwards and backwards between the anterior parts of the medial and lateral nuclei. The internal medullary lamina splits into two parts and partially encloses the anterior nucleus. In connexion with its large cells a very conspicuous bundle of fibres, the *fasciculus thalamomamillaris*, comes to an end. As this bundle arises in the corpus mamillare, it ought to be called "*fasciculus mamillo-thalamicus*."

A diffuse gray mass imperfectly marked off from the inferior surface of the lateral nucleus receives the name of the *ventral nucleus*. Its inferior part is composed of the **central nucleus** of Luys and the **nucleus arcuatus**. In section the former appears as a circular mass of gray matter, which comes into view immediately behind the point where the internal medullary lamina disappears. It would seem to be intimately connected with fibres which reach it from the red nucleus and from the posterior commissure. These fibres pass round it so as to mark it off from the rest of the thalamus, and in front of the nucleus many of them enter the internal medullary lamina. The **nucleus arcuatus** is a small semilunar mass of gray matter placed below and to the lateral side of the central nucleus of Luys.

The **connexions of the thalamus** are of an extremely intricate kind. It would appear to be a ganglionic mass interposed between the tegmental corticopetal tracts and the cerebral cortex. In its posterior part, and through its stratum zonale, it also has important connexions with the optic tract. The corticopetal tegmental tracts, which enter it from below, will be noticed in connexion with the hypothalamic region. Suffice it to say, for the

present, that these fibres end in the midst of the thalamus in connexion with the thalamic cells. In addition to these, enormous numbers of fibres, arising within the thalamus as the axons of its cells, stream out from its lateral and inferior surfaces to form the thalamic radiation. These **thalamo-cortical fibres** pass to every part of the cortex; and although there is no separation of them into distinct groups as they leave the thalamus, it is customary to regard them as constituting a frontal stalk, a parietal stalk, an occipital stalk, and a ventral stalk. But fibres from the cortex, **cortico-thalamic fibres**, likewise stream into the thalamus in large numbers, and end in fine arborisations around its cells. A double connexion with the cerebral cortex is thus established by the thalamus.

FIG. 540.—SCHEMA. Founded on the observations of Flechsig, and Ferrier and Turner.

which they proceed. The **parietal stalk** issues from the lateral surface of the thalamus, and, passing through the internal capsule (and to some extent, also, through the lentiform nucleus and the external capsule), gains the cortex of the posterior part of the frontal lobe and of the parietal lobe. The **occipital stalk** emerges from the lateral aspect of the pulvinar and constitutes the so-called optic radiation. These fibres sweep laterally and backwards round the lateral side of the posterior horn of the lateral ventricle to gain the cortex of the occipital lobe. The

ventral stalk streams out from the under aspect of the anterior part of the thalamus, in front of the hypothalamic tegmental region and the corpus mamillare. Its fibres arise in both the medial and lateral nuclei, and sweep downwards and laterally to reach the region below the lentiform nucleus. One very distinct band which lies dorsal to the other fibres (**ansa lenticularis**) comes from the lentiform nucleus to the thalamus, whilst the remainder (**ansa peduncularis**) proceed in a lateral direction from the thalamus below the lentiform nucleus and gain the cortex of the temporal lobe and of the insula.

Flechsig divides the thalamo-cortical fibres of ordinary sensation into three sensory systems. These he has been able to distinguish by studying the order in which they assume their sheaths of myelin in the fœtus and infant.

Ferrier and Turner, by the degenerative method of investigation, corroborate Flechsig's results. They confirm the observation of Flechsig that, while thalamic fibres are distributed to the several regions of the cerebral cortex to an almost equal extent, there is one district, viz., the frontal pole, to which the supply is scanty. Another very important result has been obtained by these authors. They have established the fact that many of the thalamic fibres cross the median plane in the corpus callosum, and thus gain the cortex of the opposite cerebral hemisphere. Hamilton's crossed callosal tract thus receives confirmation.

Intimate Structure of the Corpus Geniculatum Laterale.—Sections through the lateral geniculate body reveal the fact that it is composed of a series of alternately placed gray and white curved laminæ. This gives it a very characteristic appearance. The white laminæ are composed of fibres which enter the body from the optic tract. The connexions of the geniculate bodies will be studied with the optic tract.

Hypothalamic Region.

The tegmental part of the pedunculus cerebri is prolonged upwards and assumes a position below the posterior part of the thalamus. The **red nucleus** is a conspicuous object in sections through the lower part of this region (Fig. 541). It presents the same appearance as lower down in the mesencephalon, and, gradually diminishing, it disappears before the level of the corpus mamillare is reached. Carried up around it are the same longitudinal tracts of fibres which have been studied in relation to it in the tegmental part of the mesencephalon. Certain of these fibres, placed in immediate relation to the red nucleus, form a coating or capsule for it. This coating is partly derived from those fibres of the brachium conjunctivum which pass directly up into the thalamus and also partly from fibres which issue from the nucleus itself. The **medial lemniscus**, also, which in the superior part of the mesencephalon is observed to take up a position on the lateral and dorsal aspect of the red nucleus, maintains a similar position in the hypothalamic region. When the red nucleus comes to an end these various fibres are continued onwards and form, in the position previously occupied

FIG. 541.—FRONTAL SECTION THROUGH THE CEREBRUM OF AN ORANG PASSING THROUGH THE HYPOTHALAMIC TEGMENTAL REGION.

(Fig. 541). It presents the same appearance as lower down in the mesencephalon, and, gradually diminishing, it disappears before the level of the corpus mamillare is reached. Carried up around it are the same longitudinal tracts of fibres which have been studied in relation to it in the tegmental part of the mesencephalon. Certain of these fibres, placed in immediate relation to the red nucleus, form a coating or capsule for it. This coating is partly derived from those fibres of the brachium conjunctivum which pass directly up into the thalamus and also partly from fibres which issue from the nucleus itself. The **medial lemniscus**, also, which in the superior part of the mesencephalon is observed to take up a position on the lateral and dorsal aspect of the red nucleus, maintains a similar position in the hypothalamic region. When the red nucleus comes to an end these various fibres are continued onwards and form, in the position previously occupied

by the nucleus, a very evident and dense mass of fibres. The fibres of the medial lemniscus, of the brachium conjunctivum, and of the red nucleus are prolonged upwards into the ventral part of the thalamus, where they end in connexion with the thalamic cells (ventro-lateral nucleus).

The *substantia nigra* is likewise carried into the hypothalamic region, where it maintains its original position on the dorsal aspect of the basis pedunculi. As it is traced upwards, it is seen gradually to diminish in amount. It shrinks from the medial to the lateral side, and finally disappears when the posterior part of the corpus mamillare is reached.

In frontal sections through the hypothalamic region, the most conspicuous object which comes into view is the *nucleus hypothalamicus* or the *nucleus of Luys* (Fig. 541). It is a small mass of gray matter, shaped like a biconvex lens, which makes its appearance on the dorsal aspect of the basis pedunculi immediately to the lateral side of the *substantia nigra*. At first it lies in an angle which is formed by the meeting of the cerebral peduncle and the internal capsule; but, rapidly enlarging in a medial direction, it takes the place of the diminishing *substantia nigra* on the dorsal surface of the basis pedunculi at the level of the inferior part of the corpus mamillare. The *nucleus hypothalamicus* is rendered all the more evident by the fact that it is sharply defined by a thin capsule of white fibres. On its medial aspect these fibres proceed medially and form a very evident decussation across the median plane in the floor of the third ventricle, immediately above the posterior ends of the corpora mamillaria.

The *nucleus hypothalamicus*, in the fresh condition, presents a brownish colour, partly from the fact that its cells are pigmented, and partly also on account of the numerous capillary blood-vessels which pervade its substance.

Corpus Pineale.—This is a small, dark, reddish body, about the size of a cherry-stone and shaped after the fashion of a fir-cone. Placed between the posterior ends of the two thalami, it occupies the depression on the dorsal aspect of the mesencephalon, which intervenes between the two superior colliculi. Its base, which is directed upwards, is attached by a hollow stalk or peduncle. This stalk is separated into a dorsal and a ventral part by the prolongation backwards into it of a small pointed recess of the cavity of the third ventricle. The dorsal part of the stalk curves laterally and forwards, and on each thalamus becomes continuous with the *tænia thalami*; the ventral part is folded round a narrow but conspicuous cord-like band of white matter, which crosses the median plane immediately below the base of the pineal body and receives the name of the *posterior commissure* of the cerebrum (Fig. 519, p. 585).

The pineal body is not composed of nervous elements. The only nerves in its midst are the sympathetic filaments which enter it, with its blood-vessels. It is composed of spherical and tubular follicles, filled with epithelial cells, and containing a variable amount of gritty, calcareous matter.

The pineal body is a rudimentary structure, but in certain vertebrates it attains a much higher degree of development than in man. In the lamprey, lizard, etc., it is present in the form of the so-called pineal eye. In structure it resembles, in these animals, an invertebrate eye, and it possesses a long stalk, in which nerve-fibres are developed. Further, it is carried through an aperture in the cranial wall, and consequently lies close to the surface on the dorsum of the head between the parietal bones.

Trigonum Habenulæ.—The small, triangular, depressed area which receives this name is placed immediately in front of the superior colliculus in the interval between the peduncle of the pineal body and the posterior end of the thalamus (Fig. 539, p. 610). It marks the position of an important collection of nerve-cells, which constitute the *ganglion habenulæ*. The axons of these cells are collected on the ventral aspect of the ganglion into a bundle, called the *fasciculus retroflexus*, which takes a curved course downwards and forwards in the tegmentum of the mesencephalon. The *fasciculus retroflexus* lies close to the medial side of the red nucleus, and finally comes to an end in a group of cells termed the *ganglion interpedunculare*, situated in the inferior part of the *substantia perforata posterior* (see p. 591).

The *ganglion habenulæ* is likewise intimately connected with the *stria medullares* (*tænia thalami*) and the dorsal part of the stalk of the pineal body.

As previously stated, the **stria medullaris**—a very evident band of white matter—lies on the thalamus, subjacent to the ependymal ridge termed the *tænia thalami*. When traced backwards, many of the fibres of the stria medullaris are observed to end amongst the cells of the ganglion habenulæ, whilst others are continued past the ganglion to enter the peduncle of the pineal body, and, through it, to reach the ganglion habenulæ of the opposite side, in connexion with the cells of which they terminate. The stria medullaris, therefore, ends partly in the ganglion habenulæ of their own side and partly in the corresponding ganglion of the opposite side. The decussation of fibres across the median plane forms the dorsal part of the pineal stalk or peduncle, and is termed the **commissura habenularum**.

When the stria medullaris is traced in the opposite direction, it is noticed to split into dorsal and ventral parts near the column of the fornix. The *dorsal part* arises from cells in the hippocampus: these fibres pass into the fornix and when they reach its column they turn abruptly backwards to enter the stria medullaris. The *ventral part* springs from a collection of cells in the gray matter on the base of the brain close to the optic chiasma. The striæ medullares are believed to form a part of the olfactory apparatus.

Commissura Posterior.—The posterior commissure is a slender band of white matter, which crosses the median plane under cover of the stalk of the pineal body and overlies the entrance of the aqueduct of the brain into the third ventricle. The fibres which enter into the formation of the posterior commissure are believed to arise in a special nucleus, which is placed in the central gray matter immediately above the oculo-motor nucleus. They decussate with each other across the median plane and thus the commissure is formed. The other connexions of this little band are not satisfactorily established, but Held believes that some of its ventral fibres pass downwards into the medial longitudinal bundle.

Substantia Perforata Posterior.—This has already been described on p. 542. Some delicate bands of white matter, termed the *tænia pontis*, may frequently be seen emerging from the gray matter of this region; they then curve round the pedunculus cerebri in close relation to the superior border of the pons, with which they enter the cerebellum to end in the nucleus dentatus (Horsley).

Corpora Mamillaria.—The corpora mamillaria are two round white bodies, each about the size of a pea, which lie side by side in the interpeduncular fossa on the base of the brain, immediately in front of the substantia perforata posterior.

Each corpus mamillare is coated on the outside by white matter derived from the column of the fornix, and contains, in its interior, a composite gray nucleus with numerous nerve-cells. Several important strands of fibres are connected with the corpus mamillare: (1) The **column of the fornix** curves downwards in the lateral wall of the third ventricle to reach the corpus mamillare, and their fibres end amidst the cells of that body. (2) A bundle of fibres, the **fasciculus mamillo-thalamicus**, takes origin in the midst of each corpus mamillare and extends upwards into the thalamus, to end in fine arborisations around the large cells in the anterior thalamic nucleus. (3) Another bundle of fibres, the **pedunculus corporis mamillaris**, takes form within the corpus mamillare and extends downwards in the gray matter of the floor of the third ventricle, to reach the tegmentum of the mesencephalon. These tracts together with the striæ medullares (thalami) and the fasciculi retroflexi are amongst the most ancient fibre-systems in the brain. They represent the paths by which olfactory impulses may reach the brain-stem, and perhaps the spinal medulla also, and so influence the muscles of the body.

Tuber Cinereum and Infundibulum.—The tuber cinereum is a small, slightly prominent field of gray matter, which occupies the anterior part of the interpeduncular fossa between the corpora mamillaria behind and the optic chiasma in front. From its anterior part the **infundibulum**, or stalk of the hypophysis, projects downwards and connects that body with the base of the brain. In its upper part the infundibulum is hollow, a small, funnel-shaped diverticulum of the cavity of the third ventricle being prolonged downwards into it.

Hypophysis (O.T. Pituitary Body).—This is a small oval structure, flattened from above downwards, and with its long axis directed transversely, which

occupies the fossa hypophyseos in the floor of the cranium. It is composed of two lobes—a large anterior lobe and a smaller posterior lobe, which are closely applied the one to the other. The infundibulum, which extends downwards from the tuber cinereum, is attached to the posterior lobe.

FIG. 542.—MEDIAN SECTION THROUGH THE HYPOPHYSEAL REGION IN A CHILD TWELVE MONTHS OLD.
(From a photograph by Professor Symington.)

as the functional part of the hypophysis. It is derived from a tubular diverticulum, which grows upwards from the primitive buccal cavity or stomodæum. Its connexion with the latter (canalis craniopharyngeus) is in the course of time cut off, and the diverticulum becomes encased within the cranial cavity in intimate association with the cerebral portion of the organ. Structurally, it consists of tubules or alveoli, lined with epithelial cells and surrounded by capillary vessels. Its structure is in some respects not unlike that of the parathyroid bodies. In the disease known as acromegaly, the hypophysis is usually greatly enlarged.

Lamina Terminalis.—This is a thin, delicate lamina which may be seen on the basal aspect of the brain, stretching from the upper aspect of the optic chiasma in an upward direction to become connected with the anterior end of the corpus callosum.

Anterior Commissure of the Cerebrum.—In the anterior part of the cleft between the two thalami, and immediately in front of the columns of the fornix, a round bundle of fibres crosses the median plane. This is the anterior commissure.

Ventriculus Tertius.—The third ventricle is the narrow cleft which separates the two thalami. Its depth rapidly increases from behind forwards, and it may be said to extend from the pineal body behind to the lamina terminalis in front. Its floor is formed by the tuber cinereum and the corpora mamillaria: the gray matter of the substantia perforata posterior, and the tegmenta of the cerebral peduncles may also be looked upon as forming part of the floor (Figs. 542 and 543). It is interesting to note that the central gray

The infundibulum and posterior lobe of the hypophysis are developed in the form of a hollow diverticulum, which grows downwards from the floor of that part of the embryonic brain which afterwards forms the third ventricle. The original cavity of this diverticulum becomes obliterated, except in the superior part of the infundibulum. In structure, the posterior lobe of the hypophysis shows little trace of its origin from the wall of the brain-tube. It is chiefly composed of connective tissue and blood-vessels, with branched cells scattered throughout it.

The anterior lobe has quite a different origin, and may be regarded

FIG. 543.—MEDIAN SECTION THROUGH THE HYPOPHYSEAL REGION IN THE ADULT.

matter which surrounds the aqueduct is directly continuous with the gray matter of the substantia perforata posterior and tuber cinereum, and in this way it comes to the surface in the base of the brain. The optic chiasma crosses the floor in front and marks the place where the latter becomes continuous with the anterior wall of the cavity. The *front wall* of the third ventricle is formed by the lamina terminalis, which extends upwards from the optic chiasma. The anterior commissure, as it crosses from one side to the other, projects into the ventricle, but of course it is excluded from the cavity by the ventricular epithelial lining. It may be taken as indicating the place where the roof joins the anterior wall. The *roof* of the third ventricle is formed by a thin epithelial layer, which is part of the thin epithelial lining of the cavity, which stretches across the median plane from one tænia thalami to the other. Applied to the superior surface of the epithelial roof

FIG. 544.—THE PARTS OF THE BRAIN CUT THROUGH IN A MEDIAN SAGITTAL SECTION.

The lateral walls of the ventricular cavities are also shown.

is the fold of pia mater, termed the tela chorioidea, and the roof is invaginated into the cavity along its whole length by two delicate chorioid plexuses, which hang down from the under surface of this fold. When the pia mater is removed the thin epithelial roof is torn away with it, leaving only the lines of attachment in the shape of the tænia thalami (Fig. 549).

The *lateral wall* of the third ventricle is formed for the greater part of its extent by the medial surface of the thalamus, covered by a thick layer of central gray matter continuous with the central gray matter of the mesencephalon. A little in front of the middle of the ventricle the cavity is often crossed by the *massa intermedia*, which connects the thalami one with the other, and in front of this the columna fornicis is seen curving downwards and backwards in the lateral wall. At first the bulging which it forms is distinctly prominent, but it gradually subsides as the strand, on its way to end in the corpus mamillare, becomes more and more sunk in the gray matter on the side of the ventricle.

The third ventricle communicates with both of the lateral ventricles, and also with the fourth ventricle. The *aquæductus cerebri*, the narrow channel which tunnels the mesencephalon, brings it into communication with the fourth ventricle. The opening of this aqueduct is placed at the posterior part of the floor of the third ventricle, immediately below the posterior commissure. The *foramina inter-ventricularia* bring it into communication with the lateral ventricles. These apertures are placed at the upper and anterior parts of the lateral walls, and lead laterally and slightly upwards between the most prominent parts of the columns of the fornix and the anterior tubercles of the thalami. They are just large enough to admit a crow-quill, and through these passages the epithelial lining of the three ventricles becomes continuous. From the foramen a distinct groove on

the lateral wall of the ventricle leads posteriorly towards the mouth of the aqueduct. It is termed the *sulcus hypothalamicus*, and is of interest, inasmuch as it is considered by His to represent in the adult brain the furrow which divides the lateral wall of the embryonic brain-tube into an alar and a basal lamina.

The outline of the third ventricle, when viewed from the side in a median section through the brain (Fig. 544), or as it is exhibited in a plaster cast of the ventricular system of the brain (Fig. 545), is seen to be very irregular. It presents several diverticula or recesses. Thus, in the anterior part of the floor there is a funnel-shaped pit or recess, leading down through the tuber cinereum into the infundibulum of the hypophysis. Another recess, the *recessus opticus*, leads forwards immediately in front of this, above the optic chiasma. Posteriorly two diverticula are present. One, the *recessus pinealis*, passes backwards above the posterior commissure and the mouth of the aquæductus cerebri for a short distance into the stalk of the pineal body. The second is placed above this and is carried backwards for a greater distance. It is a diverticulum of the epithelial roof, and, therefore, is difficult to demonstrate. It is termed the *recessus suprapinealis*.

CEREBRAL CONNEXIONS OF THE OPTIC TRACT.

The optic nerve is connected with the hypothalamus. At the optic chiasma the optic nerves of the two sides are joined together and a partial decussation of fibres takes place. The fibres which arise in the medial half of each retina cross the median plane and join the optic tract of the opposite side. The optic tract proceeds backwards round the cerebral peduncle, and in the neighbourhood of the geniculate bodies appears to divide into two roots, viz., a lateral and a medial (Fig. 546), but only the former is really part of the tract.

Commissure of Gudden.—The so-called medial root disappears under cover of

FIG. 546.—THE VENTRAL ASPECT OF PART OF THE PROSENCEPHALON, SHOWING THE RIGHT OPTIC TRACT. The mesencephalon has been cut across. Olfactory area, dull yellow; optic fibres, blue; motor fibres, red; acoustic fibres, bright yellow.

the medial geniculate body and a large proportion of its fibres arise or end in this nuclear body. The medial root, although it is composed of fibres which are intermingled with those of the optic tract, has nothing to do with the optic nerve. These fibres, when traced forwards, cross the median plane in the posterior angle of the optic chiasma and are carried backwards alongside the opposite optic tract. The fibres constitute a bond of union, called the **commissure of Gudden**, between the medial geniculate body of one side and the colliculus inferior of the other (Fig. 547).

The Optic Tract.—The optic tract is composed of fibres which come—(1) from the lateral half of the retina of its own side; and (2) from the medial half of the retina of the opposite side, which have crossed the median plane in the optic chiasma. But in addition to the afferent retinal fibres there are a certain number

of efferent fibres in the optic tract, fibres which take their origin in the brain and end in the retina. These are distinguished from the afferent retinal fibres by their exceeding fineness.

The fibres of the optic tract end in the superior colliculus, in the lateral geniculate body, and in the pulvinar of the thalamus (Fig. 546). The fibres to the superior colliculus reach it through the superior brachium (p. 586), and for the most part sink into its substance to end in terminal arborisations around its cells. The *corpus geniculatum laterale* receives the largest contribution of fibres from the optic tract. These partly sink into its interior and partly spread out over its surface. The former enter into the construction of the curved lamellæ of white matter which traverse this nuclear mass, and to a large extent end in the gray matter which intervenes between these lamellæ. The deep fibres which are not exhausted in this way proceed onwards through the lateral geniculate body and enter the pulvinar. Of the superficial fibres which spread over the surface of the lateral geniculate body some dip into its substance and end there, but the majority are carried over it and enter the stratum zonale of the pulvinar. Most of the fibres of the optic tract, which end in the pulvinar, therefore reach their destination by passing either over or through the lateral geniculate body.

FIG. 547.—DIAGRAM OF THE CENTRAL CONNEXIONS OF THE OPTIC NERVE AND OPTIC TRACT.

of the cerebral hemisphere on the lateral side of the posterior horn of the lateral ventricle. Its connexions will be studied more fully at a later stage.

Cortical Connexions of the Optic Path.—The superior colliculus, the lateral geniculate body, and the pulvinar constitute the lower visual centres or terminal nuclei of the optic tract. The higher visual centre is placed in the cortex of the occipital region of the cerebral hemisphere, and the connexions between this and the lower centres are established by a large strand of fibres which runs in the central white matter of the posterior part of the cerebral hemisphere, and which constitutes the *optic radiation*. The optic radiation is composed both of corticopetal and corticofugal fibres. The former arise as the axons of the cells in the lateral geniculate body and the pulvinar, around which the retinal fibres end, and they terminate in the cortex of the occipital lobe. The corticofugal fibres take origin in the cortex of the occipital lobe and end in the pulvinar and superior quadrigeminal body (Ferrier and Turner). Thus constituted, the optic radiation forms a conspicuous strand (Figs. 546, p. 619; 552, p. 624; 567, p. 638), which, reaching the retrolenticular part of the internal capsule, sweeps backwards into the occipital lobe

THE PARTS DERIVED FROM THE TELENCEPHALON.

CEREBRAL HEMISPHERES.

The cerebral hemispheres form the largest part of the fully developed brain. When viewed from above they form an ovoid mass, the broadest end of which is directed backwards, and the longest transverse diameter of which will be found in

the vicinity of the parts which lie subjacent to the parietal tuberosities of the cranium. The massive rounded character of the anterior or frontal end of each cerebral hemisphere constitutes a leading human characteristic; but the posterior or occipital end is narrow and pointed, and is directed somewhat downwards. The two cerebral hemispheres are separated from each other by a deep median cleft, termed the longitudinal fissure.

The cerebral hemisphere is formed from a small area of the extreme anterior end of the alar lamina in the angle between the fore-most part of the roof and the upper end of the lamina terminalis (Fig. 548, L), which becomes continuous with the roof (at the point marked X).

The rapid expansion of this area leads to the development of a lateral bulging containing a diverticulum of the third ventricle, which is known as the *ventriculus lateralis*. This at first communicates with the third ventricle by means of a wide opening (F.M.), the *foramen inter-ventriculare* [Monroi], corresponding in size to the extent of the area of the lateral wall that was bulged outwards to form the hemisphere vesicle. The thin epithelial roof of the telen-cephalon takes no share in the formation of the two cerebral hemispheres, but serves with the lamina terminalis (L) as a bond of union between them. At a somewhat later stage in development two folds become invaginated from this epithelial roof in the whole extent of the prosencephalon, both its telen-cephalic and diencephalic parts. In the greater part of their length these

fold project into the third ventricle, and form its *chorioid plexus* (Fig. 549); but the anterior parts of the two chorioidal folds, namely, those parts formed from the roof of the interventricular foramina (F.M.), become greatly enlarged and project each into the corresponding lateral ventricle. The furrow corresponding to this invagination of the roof is called the *fissura chorioidea*. When the hemisphere vesicle first begins to expand, the thinner part of the hemisphere wall, which is called the *pallium*, is freely continuous around the vertical caudal margin of the foramen inter-ventriculare (Fig. 548, Y) with the thalamus (TH).

But as development proceeds the wall of the prosencephalon becomes attenuated along the line of this pallio-thalamic junction, and eventually the edge of the pallium fringing this attachment to the thalamus becomes reduced to a thin layer of epithelium which is continuous at its superior end with the lamina chorioidea of

the roof. Into this secondarily formed caudal extension of the chorioid lamina the invagination that commenced in the roof of the foramen interventriculare extends until it reaches the inferior extremity of the deep cleft separating the cerebral hemisphere from the thalamus (Fig. 548, A). Below this point the thalamus remains in uninterrupted continuity with the floor of the cerebral hemisphere (Cs), which is becoming thickened to form the **corpus striatum**.

At a very early stage in the development of the embryo, long before there is any sign of the hemisphere vesicles, the ectoderm upon each side of the anterior neuro-

FIG. 549.—DIAGRAM OF A TRANSVERSE SECTION THROUGH A FETAL BRAIN TO SHOW THE INVAGINATION OF THE ROOF THROUGH EACH INTERVENTRICULAR FORAMEN.

but become attached to the adjoining part of the neural tube. These cells form the **olfactory ganglion**, which acts as the receptive organ for the impressions brought into it by the processes of the sensory cells in the olfactory epithelium; and the

pore (see p. 500) becomes thickened to form the **area olfactoria** (see Fig. 440, D, p. 501). Certain of the epithelial cells in this area become converted into bipolar sensory cells, which become specially adapted to be affected by certain kinds of air-borne chemical stimuli that awaken a consciousness of smell. These cells always remain *in situ* in the olfactory epithelium, just as the most primitive sensory cells do in Hydra (Fig. 439, p. 497). But other nerve-cells seem to be derived from the area olfactoria which do not remain in the parent epithelium,

area of the neural tube to which it becomes attached is destined to become part of the cerebral hemisphere. At the end of the first month this portion of the hemisphere becomes drawn out as a hollow protrusion, the distal end of which is coated with a layer of olfactory ganglion and is known as the **bulbus olfactorius**; the rest forms a peduncle. In the course of its subsequent development in the human brain (though not in those of most mammals) the cavity in the bulb and peduncle becomes completely obliterated. The peduncle becomes so greatly elongated and attenuated that, to the unaided eye, it appears to be wholly formed

of white nerve-fibres passing to and fro between the olfactory bulb and the hemisphere; hence it is called the *tractus olfactorius*.

The cerebral hemisphere first appears in the form of a slight bulging upon each side of the fore-brain, but it soon assumes large dimensions. At first it grows forwards and upwards (Fig. 550), and a distinct cleft, the floor of which is the roof-plate and lamina terminalis, appears between the two hemispheres: this is known as the *fissura longitudinalis cerebri*. The separation of the two cerebral vesicles by the longitudinal fissure begins at the end of the first month. This fissure becomes occupied by mesodermic tissue, which later on forms the *falx cerebri*. The cerebral hemisphere, in its further growth, is carried progressively backwards over the posterior parts of the developing brain. At the end of the third month it has covered the thalamus. A month later it reaches the corpora quadrigemina, and by the seventh month it has not only covered these, but also the entire upper surface of the cerebellum.

In the earlier stages of its development the cerebral hemisphere is a thin-walled vesicle with a relatively large cavity, which represents the primitive condition of the lateral ventricle. At first the vesicle is bean-shaped and the cavity is curved. As development proceeds the posterior portion of the hemisphere grows backwards over the cerebellum in the shape of a hollow protrusion, and a distinct occipital lobe enclosing the posterior horn of the lateral ventricle is the result. This developmental stage begins about the fourth month.

THE CONNEXIONS OF THE OLFACTORY NERVES.

The olfactory nerves are the axons of the spindle-shaped bipolar cells situated in the olfactory mucous membrane (Fig. 551). These axons collect in the submucous layer to form small bundles, which enter the cranial cavity through the foramina in the lamina cribrosa of the ethmoid bone. They at once enter the inferior surface of the *bulbus olfactorius*, and each fibre breaks up into a tuft of terminal filaments. Towards these tufts dendrites proceed from large *mitral cells* placed in a deeper plane within the bulb, and each dendrite also breaks up into numerous terminal branches intertwined with those of the olfactory nerves. In this way are formed a large number of globular bodies, each consisting of the arborescent terminations of a mitral dendrite and of certain olfactory nerve-fibres. These are the *olfactory glomeruli* of the bulb. Each mitral cell gives off several dendrites and one axon. Only one dendrite enters into the formation of a glomerulus, but several nerve-fibres may be connected with such a body. It thus happens that, through its dendrite, a mitral cell may stand in connexion with several olfactory nerve-fibres. The axon of the mitral cell passes upwards to the white matter of the bulb, enters this, and, bending backwards, is conducted through the tract towards the cerebral cortex.

The *olfactory bulb* is a small, flattened, elliptical mass of gray substance placed upon the upper surface of the lamina cribrosa of the ethmoid. Its posterior extremity is attached to the rest of the cerebral hemisphere by the long *tractus olfactorius* (Fig. 476), a prismatic band of white substance placed in a furrow (*sulcus olfactorius*) on the under surface of the frontal region of the cerebral hemisphere. A short distance in front of the optic chiasma each olfactory tract becomes inserted into the hemisphere (Fig. 552). The swollen pyramidal-shaped

FIG. 551.—DIAGRAM OF THE MINUTE STRUCTURE OF THE OLFACTORY BULB.

attached end of the peduncle is called the **trigonum olfactorium**. Immediately behind the trigone a small obliquely placed ovoid area of gray matter, the **tuberculum olfactorium**, can sometimes be detected in the human brain; but in the brains of most mammals with a greater development of the organs of smell this swollen area is much more prominent and constant. In most human brains, however, it is difficult to distinguish it from a much more extensive area, which extends behind and to its lateral side, the **substantia perforata anterior** (Fig. 552). Along the anterior margin of this perforated substance there can sometimes be detected a small, rounded, rope-like strand of gray matter, the medial end of which passes into the trigonum olfactorium. This is the anterior part of the **area piriformis**.

FIG. 552.—PART OF THE VENTRAL SURFACE OF THE PROSENCEPHALON, SHOWING THE ATTACHMENT OF THE OLFACTORY TRACT.

Olfactory area, dull yellow; optic, blue; motor fibres, red; acoustic fibres, bright yellow.

formis—the stalk of the pear-shaped lobe—and upon its surface is placed a very well-defined narrow band of nerve-fibres, the **stria olfactoria lateralis**, which is composed of axons of mitral cells (in the olfactory bulb) proceeding to the piriform area. Even when the anterior part of the piriform area is not distinguishable, the stria lateralis is always a prominent feature.

The piriform area extends transversely laterally in the deep valley between the orbital and temporal regions of the hemisphere (*fossa cerebri lateralis*); becoming slightly broader, and reaching what is known as the **insula** (of which it forms the **limen insulæ**), it becomes sharply bent upon itself (Figs. 552, and 553, C). It then passes medially and backwards, and emerges from the fossa as a broad area upon the under surface of the temporal region (Fig. 553, C). This greatly expanded caudal extremity of the pear is the **area piriformis** in the strict sense of the term.

If the brain of almost any other mammal is examined (take the rabbit's as an example), the area piriformis will be found to constitute relatively an enormously larger proportion of the cerebral hemisphere than it does in the human brain; and it is separated from the part of the hemisphere (**neopallium**) that lies above it by a longitudinal furrow called the **fissura rhinalis**. The enormous expansion of the **neopallium** in the human brain accentuates the flexure of the piriform area at the point x (Fig. 553), and at the point y the exuberant growth of **neopallium** relegates the swollen posterior part of the piriform area on to the medial surface (Fig. 554), where the posterior part of the rhinal fissure persists to separate it from the **neopallium**.

The surface of the piriform area often presents numerous small wart-like

FIG. 553.

Olfactory areas, green; **neopallium**, blue.

excrescences; and it is whitened by a thin layer of fibres (**substantia reticularis alba**) prolonged backwards from the **stria olfactoria lateralis**. By these fibres olfactory impulses are poured directly from the mitral cells of the bulb into the piriform area. If we call the olfactory nerves the **primary olfactory neurones**, the fibres which pass from the bulb to the piriform area would then be **secondary olfactory neurones**.

Formatio Hippocampalis.—From all parts of the area piriformis, as well as the trigonum and tuberculum olfactorium, fibres arise (**tertiary olfactory neurones**), and proceed on to the medial aspect of the hemisphere, where they terminate in the edge of the pallium, alongside the **lamina chorioidea**. In the human brain the vast majority of these tertiary neurones proceed from the posterior extremity of the piriform area, but a certain number arise in the neighbourhood of the **substantia perforata anterior** and proceed at once on to the medial surface of the hemisphere. The large number of small nerve-cells that collect in the medial edge of the pallium become specially modified in structure to form a receptive organ for impressions of smell, known as the **fascia dentata**; and the axons of these cells pass into the pallium immediately surrounding the peripheral edge of the **fascia dentata**, which is known as the **hippocampus** (Fig. 556). In the latter area

impressions of smell are brought into relation with those of other senses (probably taste); and from the hippocampal cells fibres are emitted to form a system known as the *fornix*, which establishes connexions with the hippocampus of the other hemisphere and with the hypothalamus, thalamus, and more distant parts of the brain.

The rudiment of the hippocampal formation that develops on the medial surface begins in front, alongside the place where the stalk of the olfactory peduncle (which becomes the *trigonum olfactorium*) is inserted; it passes upwards to the superior end of the *lamina terminalis*, from the rest of which it is separated by a triangular mass of gray matter, the *corpus paraterminale* (Fig. 555); and then it proceeds backwards, fringing the *fissura chorioidea* in the whole of its extent, ending below in the temporal region alongside the posterior part of the *area piriformis*. The anterior part of this great hippocampal fringe of the *pallium* does not attain its full development in the human brain and remains as a more or less vestigial aborted

FIG. 554.—MEDIAL ASPECT OF THE RIGHT CEREBRAL HEMISPHERE, WITH THE OLFACTORY PARTS COLOURED

structure; but the posterior part undergoes a curious transformation. The tertiary olfactory neurones, coming mainly from the posterior part of the *area piriformis*, enter the margin of the hippocampal formation, and the small cells which receive these incoming fibres multiply rapidly during the third month, and arrange themselves in a densely packed row of granules, which represent the distinctive feature of the *fascia dentata* (Fig. 556). At first this cell-column is continuous at its peripheral margin with a much more loosely packed column of larger and less numerous cells, which represent the *hippocampus*; and these in turn give place to the more diffusely arranged and laminated cells of the typical *cortex cerebri*, which we call the *neopallium*. As development proceeds both the dentate and hippocampal columns of cells rapidly increase in length, and both appear to push their way towards the ventricle (Fig. 556, B) into the substance of the wall, which becomes correspondingly thickened. The ventricular swelling thus formed is the *hippocampus*; and it is important to recognise that this swelling is not produced by any invagination of the surface, such as is usually described under the name of the

fissura hippocampi. *There is no fissura hippocampi in the human brain.* What is usually described under this name is an artificial cleft made by pushing the handle of a scalpel into the hippocampal formation at the edge of the exposed part of the fascia dentata (Fig. 556, B and C, at *x*) and separating the morphological surface of the hippocampus from that of the buried part of the fascia dentata. Cleavage readily occurs along this line because there are numerous nerve-fibres, hippocampal and dentate respectively, upon each side of it.

As development proceeds a break occurs in the cell-column at the junction of its hippocampal and dentate parts, and the two columns (Fig. 556, C) become partially interlocked.

The axons of the hippocampal cells collect upon its ventricular surface to form the *alveus*, the fibres of which converge towards the margin of the fascia dentata, where they bend into the longitudinal direction (*i.e.* parallel to the edge of the pallium and the lamina chorioidea) to form a prominent white marginal fringe, the **fimbria**.

The fibres of the fimbria pass upwards and forwards (Fig. 555), and ultimately reach the upper end of the lamina terminalis, which provides a bridge to conduct a certain number of them across the median plane into the fornix or

FIG. 555.—MEDIAL ASPECT OF THE RIGHT CEREBRAL HEMISPHERE OF A HUMAN FÆTUS OF THE FOURTH MONTH.

The broken red lines indicate the paths taken by callosal fibres in the neopallium to reach the upper end of the lamina terminalis.

FIG. 556.—DIAGRAMS REPRESENTING THREE STAGES IN THE DEVELOPMENT OF THE HIPPOCAMPAL FORMATION.

fimbria of the other hemisphere, so as to link together in functional association the two hippocampi. These crossing fibres are known as the **commissura hippocampi**.

Most of the fibres that go up in the fimbria from the hippocampus do not pass into the hippocampal commissure, but bend downwards in the anterior lip of the foramen interventriculare to enter the thalamic region. They are collected into a vertical rounded column, which is called the **columna fornix**; when it reaches the hypothalamus it bends backward to end in the corpus mamillare.

The olfactory bulb and tract, the area piriformis, tuberculum olfactorium, corpus paraterminale, and the formatio hippocampalis together form a part of the hemisphere, which is concerned mainly with the function of smell. Hence they may be grouped together as the **rhinencephalon**; but this term has been used in so many different ways that it is of doubtful utility.

In the lowest vertebrates the whole hemisphere is practically rhinencephalon. Nevertheless, fibres coming from other parts of the nervous system and conveying impressions from other sense organs than those of smell make their way into the cerebral hemisphere and influence the state of its activities. In other words, the hemisphere is primarily an olfactory receptive nucleus, but is also the place where impressions of smell are brought under the modifying influences of other sensory impressions before they make their effects manifest in behaviour.

But it is only in the most highly organised types of brain, more especially those of mammals and birds, that the non-olfactory senses acquire a representation in the hemisphere which is relatively independent of, or at any rate not wholly subservient to, the influence of the sense of smell. In the mammalian brain a definite area of pallium is set apart to receive impressions of the tactile, visual, acoustic, and other senses. This area is the **neopallium**. In the human brain it has grown to such an extent that it forms almost the whole of the hemispheres—a mass far greater than the whole of the rest of the central nervous system.

THE CEREBRAL COMMISSURES AND THE SEPTUM PELLUCIDUM.

We have seen that certain fibres from the hippocampi cross from one hemisphere to the other, using the upper part of the lamina terminalis as a bridge across the median plane. But at an earlier stage of development other fibres can be detected at a slightly lower level in the lamina terminalis forming a bundle, of oval outline in sagittal section, called the **commissura anterior**. Its fibres come from the olfactory bulb, area piriformis, tuberculum olfactorium, and a small temporal area of neopallium. If the composition of the hippocampal commissure is analysed in a foetus of the third month, it will be found that there are intermingled with the truly hippocampal fibres some which come from the neopallium. During the fourth month the bulk of the neopallial element in this dorsal commissure outgrows the hippocampal element. The latter fibres become crowded into the postero-inferior corner of the commissure and the neopallial fibres come to form a flattened transverse bridge—the **corpus callosum**—above them. These fibres are enclosed in a neuroglial matrix derived from the lamina terminalis and the adjoining paraterminal bodies. Some nerve-cells also may make their way into this matrix. As it elongates, the corpus callosum pushes its way forwards in the upper part of the paraterminal body of each hemisphere, and as development proceeds a small area of this body becomes almost completely circumscribed by the corpus callosum and commissura hippocampi. As these commissural bands increase in size this small circumscribed patch of paraterminal body becomes greatly stretched and expanded to form a thin translucent leaf. The two leaves thus formed in the medial walls of the two hemispheres are known as the **septum pellucidum**; and the narrow cleft that separates them the one from the other in the median plane is called the **cavum septi pellucidi**.

There is still an element of uncertainty concerning the precise manner in which these changes are brought about, and especially as to the precise mode of closure of the cavum septi. As the cerebral hemisphere expands, some parts of it grow forwards, others upwards, and others again backwards. Such growth in each part will naturally tend to exert traction upon its commissural fibres that pass through the corpus callosum. Hence the anterior part of this great commissure becomes drawn forward, its posterior part backwards, and the greater intermediate part upwards, so that it comes to assume the form shown in Fig. 557, C. As the posterior part of the corpus callosum pushes its way backwards, it exerts traction upon the fibres of the hippocampal commissure and their matrix, which becomes enormously stretched so as to form a thin lamella (the floor of the cavum septi) stretching from a point just above the anterior commissure to the under surface of the swollen posterior end of the corpus callosum, which is called the **splenium** (Fig. 558). The hippocampal commissural fibres are scattered throughout this lamella. The backward growth of the splenium also thrusts back the

upper end of the hippocampal formation so that it becomes removed far from the lamina terminalis. The fibres of the fimbria which are prolonged forwards under the corpus callosum and septum pellucidum to bridge this great gap form the **crus fornicis** on each side. As a rule in the human adult brain the crura fornicis of the two hemispheres become crowded together at the median plane so as to obscure the connecting lamella which serves as a matrix for the commissura hippocampi (Fig. 557, C); but the true arrangement can be seen in the brains of fœtuses of the sixth, seventh, and eighth months, and is at once revealed in the adult if the corpus callosum is raised up by an accumulation of fluid in the lateral ventricles (hydrocephalus), so as to put a strain upon the septum pellucidum. The mass formed by the crura fornicis and their commissure is called the **corpus fornicis**.

The fascia dentata appears as a curious notched band behind and below the fimbria; its upper end passes on to the under surface of the splenium of the corpus callosum, where it tapers and ends (**fasciola cinerea**); but as it dwindles the upper end of the hippocampus emerges upon the surface below and behind it and passes into a thin film of gray matter—**indusium griseum**—which is prolonged on to the upper surface of the corpus callosum. It proceeds forward, becoming as a rule still

FIG. 557.—THREE STAGES IN THE DEVELOPMENT OF THE CORPUS CALLOSUM.

more attenuated, and after surrounding the anterior end (**genu**) of the corpus callosum it passes downwards towards the trigonum olfactorium along the line that separates the corpus paraterminale from the neopallium. The indusium represents the atrophied remains of the anterior part of the hippocampal arc of the fœtal brain (Fig. 555), from which the fascia dentata has entirely disappeared. It is accompanied by longitudinal fibres homologous to the fornix system, in other words the fornix fibres of the atrophied supracallosal hippocampus; they form the **striae longitudinales** of the corpus callosum (Fig. 558; Fig. 564, p. 635; Fig. 559, p. 631).

The inferior (or anterior) extremity of the fascia dentata dips into a deep furrow, around which the area piriformis is bent in a hook-like manner (**uncus**); in this it becomes considerably reduced in diameter and then emerges (at right angles to its previous direction) to form Giacomini's "**banderella**," which we may call the **cauda fasciæ dentatæ**. Behind this the inferior end of the hippocampus comes to the surface, but is turned inside out, *hippocampus inversus*. Just in front of the upper ending of the **cauda fasciæ** a little knob of solid gray matter appears upon the surface, surrounded by area piriformis. It is the **nucleus amygdalæ** (Fig. 558).

Corpus Callosum.—The corpus callosum is the great transverse commissure which passes between the two cerebral hemispheres. It is placed nearer the anterior than the posterior aspect of the brain, and it unites the medial surfaces of the hemispheres throughout very nearly a half of their antero-posterior

length. The corpus callosum is highly arched from before backwards, and presents a convex superior surface and a concave inferior surface when viewed from the side (Fig. 558).

The *superior surface* of the corpus callosum forms the bottom of the longitudinal fissure, and on each side of this it is covered by the gyrus cinguli. Only in its posterior part is it approached by the falx cerebri; in front, this process of dura mater falls considerably short of it. The superior surface of the corpus callosum is covered by a thin layer of induseum continuous at the bottom of the sulcus corporis callosi with the gray cortex on the surface of the hemisphere. In this there are embedded on either side of the median plane two delicate longitudinal bands of fibres, called respectively the stria longitudinalis medialis and lateralis. The stria longitudinalis medialis is the more strongly marked of the two, and it is separated from its fellow on the opposite side by a faint median furrow. The stria longitudinalis lateralis is placed farther out, under cover of the callosal

FIG. 558.—THE MEDIAL ASPECT OF THE RIGHT CEREBRAL HEMISPHERE.

gyrus. The thin coating of gray matter, with the two striæ, represents the aborted remains of the hippocampus (see p. 627). So thin is this gray coating that the transverse direction pursued by the callosal fibres proper can be easily perceived through it.

The two extremities of the corpus callosum are much thickened, whilst the intermediate part or body is considerably thinner. The massive *posterior end*, which is full and rounded, lies over the mesencephalon and extends backwards as far as the highest point of the cerebellum. It is called the **splenium**, and it consists of a superior and inferior part. The latter is bent forwards under the upper part, to the inferior surface of which it is closely applied. The *anterior end* of the corpus callosum is not quite so massive, and it is folded downwards and backwards on itself. It is termed the **genu**. The recurved inferior part of the genu is separated from the part of the corpus callosum which lies above, by an interval. It rapidly thins as it passes backwards and receives the name of the **rostrum**. The fine terminal edge of the rostrum becomes connected by means of a band of neuroglial

tissue with the lamina terminalis on the antero-superior aspect of the anterior commissure (Fig. 558).

The *inferior surface* of the corpus callosum on each side of the median plane is coated with ependyma (Fig. 564, p. 635), and forms the roof of the anterior horn and body of the lateral ventricle. In the median plane, however, it is attached to subjacent parts, viz., to the septum pellucidum in front and directly or indirectly (Fig. 564) to the body of the fornix behind (Fig. 558, p. 630).

The transverse fibres of the corpus callosum, as they enter the white medullary centre of the cerebral hemisphere, separate from each other so as to reach most parts of the cerebral cortex. These diverging fibres are termed the *radiatio corporis*

FIG. 559.—THE CORPUS CALLOSUM, exposed from above and the right half dissected, to show the course taken by its fibres.

The lateral longitudinal stria (which lies near the cingulum) is not shown.

callosi and they intersect those which form the corona radiata, or, in other words, the fibres which extend between the internal capsule and the cerebral cortex (Figs. 570, p. 640, and 576, p. 649). The more anterior of the fibres which compose the genu of the corpus callosum sweep forwards in a series of curves into the anterior frontal region of the hemisphere. A large part of the splenium, forming a solid bundle termed the **occipital part of the radiation of the corpus callosum** (O.T. *forceps major*), bends suddenly and abruptly backwards into the occipital lobe (Fig. 559). Fibres from the body and superior part of the splenium, curving round the lateral ventricle, form a very definite stratum, called the **tapetum**. This is a thin layer in the medullary centre of the hemisphere, which constitutes the immediate roof and lateral wall of the posterior horn and the lateral wall of the posterior part of the inferior horn of the lateral ventricle.

In frontal sections through the occipital and posterior temporal regions the tapetum stands out very distinctly (Fig. 559, p. 631; see also Figs. 565, p. 636, and 567, p. 638).

Septum Pellucidum.—The septum pellucidum is a thin vertical partition which intervenes between the two lateral ventricles. It is triangular in shape, and posteriorly it is prolonged backwards for a variable distance between the body of the corpus callosum and the fornix, to both of which it is attached. In front it occupies the gap behind the genu of the corpus callosum, whilst below, in the narrow interval between the posterior edge of the rostrum of the corpus callosum and the fornix, it is prolonged downwards in the paraterminal body towards the base of the brain. The septum pellucidum is composed of two thin laminae in apposition with each other in the median plane (Fig. 562; Fig. 564, p. 635).

Cavum Septi Pellucidi.—This name is applied to the median cleft between the

FIG. 560.—THE MEDIAL ASPECT OF THE RIGHT HALF OF THE BRAIN EXPOSED BY A MEDIAN SAGITTAL SECTION.

two laminae of the septum pellucidum. It varies greatly in size in different brains.

VENTRICULUS LATERALIS.

The cavity in the interior of the cerebral hemisphere is called the **lateral ventricle**. It is lined throughout by *ependyma* continuous with the ependymal lining of the third ventricle. In some places the walls of the cavity are in apposition, whilst in other localities spaces of varying capacity, and containing cerebro-spinal fluid, are left between the bounding walls.

The lateral ventricle communicates with the third ventricle of the brain by means of a small foramen, just large enough to admit a crow-quill, which is termed the **foramen interventriculare**. This aperture is placed in front of the anterior end of the thalamus and behind the column of the fornix.

The highly-irregular shape of the lateral ventricle can be best understood by the

study of a cast of its interior (Figs. 561 and 545, p. 618). It is usual to describe it as being composed of a body and three horns, viz. an anterior, a posterior, and an inferior horn. The **cornu anterius** is that part of the cavity which lies in front of the interventricular foramen. The **body** or **pars centralis** is the portion of the ventricle which extends from the interventricular foramen to the splenium of the corpus callosum. At this point the posterior and inferior horns diverge from the posterior part of the body. The **cornu posterius** curves backwards and medially into the occipital lobe. It is very variable in its length and capacity: the chief reason for this variability is that adhesions between the walls of this part of the ventricle are of common occurrence. The **cornu inferius** proceeds with a bold sweep round the posterior end of the thalamus, and then tunnels in a forward and medial direction through the temporal lobe

FIG. 561.—DRAWING TAKEN FROM A CAST OF THE VENTRICULAR SYSTEM OF THE BRAIN, as seen from above. (After Retzius.)

Vent. III. Third ventricle.

Vent. IV. Fourth ventricle.

R.SP. Recessus suprapinealis.

FIG. 562.—FRONTAL SECTION THROUGH THE CEREBRAL HEMISPHERES so as to cut through the anterior horns of the lateral ventricles, through which the central part of the ventricles, the column of the fornix, and the interventricular foramina can be seen.

towards the temporal pole.

The early foetal lateral ventricle is very capacious and presents an arched or semi-lunar form. It is composed of parts which correspond to the anterior horn, the central part and the inferior horn, and there is little or no demarcation between them. The posterior horn is a later production. It comes into existence as a diverticulum or elongated pouch, which grows

backwards from the superior and posterior part (*i.e.* the convexity) of the primitive cavity.

Cornu Anterius.—The anterior horn forms the foremost part of the cavity, and extends in a forward and lateral direction in the frontal lobe. When seen in frontal section (Fig. 562) it presents a triangular outline, the floor sloping upwards and laterally to meet the roof at an acute angle. It is bounded *in front* by the posterior surface of the genu of the corpus callosum; the *roof* also is formed by the

FIG. 563.—DISSECTION, to show the fornix and lateral ventricles; the body of the corpus callosum has been turned over to the left.

corpus callosum. The *medial wall*, which is vertical, is formed by the septum pellucidum; whilst the sloping *floor* presents a marked elevation or bulging, viz. the smooth, rounded, and prominent extremity of the pear-shaped caudate nucleus.

Pars Centralis.—The pars centralis of the cavity is likewise *roofed* by the corpus callosum. On the *medial side* it is bounded by the posterior part of the septum pellucidum which attaches the fornix to the inferior surface of the corpus callosum. On the *lateral side* it is closed, as in the case of the anterior horn, by the meeting of the floor and the roof of the cavity. On the *floor* a number of important

objects may be recognised. From the lateral to the medial side these are met in the following order: (1) the caudate nucleus; (2) a groove which extends obliquely from before backwards and laterally between the caudate nucleus and the thalamus, in which are placed the vena terminalis and a white band called the stria terminalis; (3) a portion of the superior surface of the thalamus; (4) the chorioid plexus; (5) the thin, sharp edge of the fornix (Fig. 564).

The **caudate nucleus** narrows rapidly as it proceeds backwards on the lateral part of the floor of the lateral ventricle. The **vena terminalis** (vein of the corpus striatum) is covered over by ependyma. It joins the **vena cerebri interna** close to the foramen interventriculare. The connexions of the **stria terminalis** will be dealt with later. The portion of the superior surface of the **thalamus** which appears in the floor of the ventricle is in great part hidden by the chorioid plexus, which lies upon it. The **lamina chorioidea** is an epithelial fringe which is attached to the sharp lateral edge of the fornix superiorly and after surrounding a rich vascular fold of pia mater becomes fixed to the superior surface of the thalamus. The vascular fold is the chorioid plexus. In front it is continuous, in the inter-ventricular foramen, with the corresponding chorioid plexus of the third ventricle (Fig. 560), whilst behind, it is carried into the inferior horn of the ventricle. Although the chorioid plexus has all the appearance of lying free within the ventricle, it must be borne in mind that it is invested by the epithelial

FIG. 564.—DIAGRAM OF TRANSVERSE SECTION ACROSS THE CENTRAL PARTS OF THE LATERAL VENTRICLES.

chorioid lamina which represents a portion of the hemisphere wall and excludes it from the cavity.

Cornu Posterius.—The posterior horn is an elongated diverticulum carried backwards into the occipital lobe from the posterior end of the ventricle. It tapers to a point and describes a gentle curve, the convexity of which is directed laterally. The *roof* and *lateral wall* of this portion of the ventricular cavity are formed by the tapetum of the corpus callosum. In frontal sections through the occipital lobe this is seen as a thin but distinct layer of white fibres, which lies immediately lateral to the ependyma and to the medial side of a much larger strand of fibres in the medullary substance of the occipital lobe, viz., the optic radiation.

On the *medial wall* two elongated curved elevations may be observed. The uppermost of these is termed the **bulb of the cornu** (*bulbus cornu posterioris*), and is produced by the fibres of the radiation of the corpus callosum as they curve abruptly backwards from the lower part of the splenium of the corpus callosum into the occipital lobe. Below this is the elevation known as the **calcar**. It varies greatly in size in different brains, and is caused by an infolding of the ventricular wall in correspondence with the anterior part of the calcarine sulcus on the exterior of the hemisphere. It may come into contact with and adhere to the lateral wall of the ventricle in a part or even the whole of its extent.

Cornu Inferius.—The inferior horn is the continuation of the cavity into the temporal region. At first directed posteriorly and laterally, the inferior horn suddenly sinks downwards behind the thalamus into the temporal region, in the

centre of which it takes a curved course forwards and medially to a point about an inch behind the extremity of the temporal pole.

In the angle between the diverging posterior and descending horns the cavity of the ventricle presents an expansion of a somewhat triangular shape. To this the name of *trigonum collaterale* is sometimes given.

The *roof* of the inferior horn is formed for the most part by the tapetum of the corpus callosum. At the extremity of the horn the roof presents a bulging into the cavity. This is produced by a collection of gray matter termed the amygdaloid nucleus. The *stria terminalis* and the attenuated *tail of the caudate nucleus* are both prolonged into the inferior horn and are carried forwards, in its roof, to the amygdaloid nucleus.

On the *floor* of the inferior horn the following structures are seen: (1) hippocampus; (2) the chorioid plexus; (3) the fimbria; and (4) the *eminentia collateralis*.

The *hippocampus* is for the most part covered by the chorioid plexus of the lateral ventricle. If this is detached a fissure appears between the fimbria and the roof of the ventricular horn. This is the *chorioid fissure*. It appears at a very

FIG. 565.—FRONTAL SECTION THROUGH THE POSTERIOR HORNS OF THE LATERAL VENTRICLES, VIEWED FROM THE FRONT.

early date in the development of the cerebral hemisphere, and takes an arcuate course round the posterior end of the thalamus. In the region of the pars centralis of the lateral ventricle it extends as far forwards as the foramen inter-ventriculare and is formed by the involution of an epithelial part of the wall of the ventricle over the chorioid plexus (p. 622). In the region of the inferior horn, when the chorioid plexus with the involuted epithelial layer which covers it is withdrawn, the chorioid fissure is converted into an artificial gap which leads directly into this part of the ventricular cavity.

The *chorioid plexus* is a convoluted system of blood-vessels in connexion with a fold of pia mater, which is prolonged into the inferior horn of the lateral ventricle. It lies on the surface of the hippocampus and is continuous, behind the posterior part of the thalamus, with the chorioid plexus in the pars centralis of the lateral ventricle. But it must not be supposed that the chorioid plexus lies free in the ventricular cavity. It is clothed in the most intimate manner by an epithelial layer, which represents the medial wall of the inferior horn involuted into the cavity over the chorioid plexus. The ventricle, therefore, opens on the surface only through the chorioid fissure when this thin epithelial layer is torn away by the withdrawal of the chorioid plexus. From the above, it will be under-

stood that the arcuate chorioid fissure, throughout its whole length (viz., from the interventricular foramen to the extremity of the inferior horn of the lateral ventricle), is formed by the involution of the roof and a portion of the wall of the hemisphere which remains epithelial. In the central part of the ventricle this layer is attached, on the one hand, to the sharp lateral margin of the fornix, and on the other to the superior surface of the thalamus; in the inferior horn it is attached, in like manner, to the edge of the fimbria hippocampi or crus of the fornix, whilst above it joins the roof of this portion of the ventricle along the line of the stria terminalis (Fig. 564).

The *eminentia collateralis* shows very great differences in its degree of development.

The *trigonum collaterale* is a smooth elevation in the floor of the ventricle, in the interval which is left between the calcar avis and the hippocampus as they diverge one from the other.

BASAL GANGLIA OF THE CEREBRAL HEMISPHERE.

Under this heading are included certain masses of gray matter more or less completely embedded in the white medullary substance of the hemisphere, and which are developed in its wall. They compose the caudate and lentiform nuclei, which together form the corpus striatum, and the amygdaloid nucleus.

The **nucleus caudatus** bulges into the lateral ventricle. It is a piriform, highly arched mass of gray matter, which presents a thick, swollen head, or anterior extremity, and a long, attenuated tail. The head projects into the anterior horn of the lateral ventricle, whilst its narrower part is prolonged laterally and posteriorly in the floor of the ventricle, where it is separated from the thalamus by the stria terminalis. Finally, its tail curves downwards with a bold sweep and enters the inferior horn of the lateral ventricle. In the roof of this horn it is prolonged forwards to the amygdaloid nucleus, the lower part of which it joins. The caudate nucleus thus presents a free ventricular surface, covered with ependyma, and a deep surface embedded in the white substance of the cerebral hemisphere, and for the most part related to the internal capsule.

Owing to its arched form it follows that, in horizontal sections through the cerebral hemisphere below a particular level, it is cut at two points, and both the head and the tail appear on the field of the section (Fig. 567). In frontal sections behind the amygdaloid nucleus, it is also divided at two places (Fig. 580, p. 652).

The anterior extremity of the head of the caudate nucleus coincides very nearly with that of the anterior horn of the lateral ventricle. In the region of the substantia perforata anterior, the head of the caudate nucleus gains the surface and its gray matter becomes continuous with that of the cerebral cortex.

The **nucleus lentiformis** lies on the lateral side of the caudate nucleus and thalamus, and is for the most part embedded within the white medullary substance of the cerebral hemisphere. It does not extend either so far forwards or so far backwards as the caudate nucleus. Indeed, it presents a very close correspondence in point of extent with the insula on the surface. When seen in horizontal section, it presents a shape similar to that of a biconvex lens. Its medial

FIG. 567.—HORIZONTAL SECTION THROUGH THE RIGHT CEREBRAL HEMISPHERE AT THE LEVEL OF THE WIDEST PART OF THE LENTIFORM NUCLEUS.

barred appearance, which is presented by such a section as this, that the term **corpus striatum** is applied to the two nuclei. In the region of the substantia perforata anterior both nuclei reach the surface and become continuous with the cortex.

When a section is made in a plane further back (*e.g.* immediately posterior to the anterior commissure, as in Fig. 569) the divided lentiform nucleus assumes an altogether different shape, and is seen to be completely cut off from the caudate nucleus by the internal capsule. It is now triangular or wedge-shaped. Its *base* is turned towards the insula and is in direct relation to a thin lamina of white matter, termed the external capsule. Its *medial surface* is oblique and is applied to the internal capsule, whilst its *inferior surface* is horizontal and is directed downwards towards the base of the brain. But, further, two white laminae, the

surface bulges more than the lateral surface, and its point of highest convexity is placed opposite the stria terminalis or the interval between the caudate nucleus and the thalamus. In frontal section the appearance presented by the lentiform nucleus differs very much in different planes of section. Fig. 568 represents a section through its anterior portion. Here it is semilunar or crescentic in outline and is directly continuous below with the head of the caudate nucleus; above, also, it is intimately connected with the caudate nucleus by bands of gray matter, which pass between the two nuclei and break up the white matter of the fore part of the intervening internal capsule. It is due to the ribbed or

external and internal medullary laminae, are now evident, which traverse its substance in a vertical direction and divide it into three masses. The lateral, basal, and larger mass is termed the **putamen**; the two medial portions together constitute the **globus pallidus**.

The **putamen** forms much the largest part of the lentiform nucleus. It is darker in colour than the globus pallidus, and in this respect resembles the caudate nucleus. It is traversed by fine radiating bundles of fibres, which enter it from the external medullary lamina. Both in point of structure and in mode of development it is closely associated with the caudate nucleus, and it is the only part of the lentiform nucleus which is connected by intervening bands of gray matter with the caudate nucleus. The anteroposterior length, as well as the vertical depth of the putamen, is much greater than in the case of the globus pallidus; consequently, in both frontal and horizontal sections through the cerebrum it is encountered before the plane of the globus pallidus is reached.

FIG. 568.—FRONTAL SECTION THROUGH THE CEREBRAL HEMISPHERES so as to cut through the anterior part (putamen) of the lentiform nucleus in front of the globus pallidus. Viewed from in front; looking through the anterior horn into the central part of the ventricle.

The external capsule is loosely connected with the lateral surface of the putamen, and it can be readily stripped off. This accounts for the tendency, exhibited in hæmorrhages in this locality, for the effused blood to spread out in the interval between these structures.

The **globus pallidus** is composed of the two smaller and medial masses of the lentiform nucleus. They present a faint yellowish tint, and are paler and more abundantly traversed by fibres than the putamen. The mass next the putamen (*i.e.* the intermediate part) is much larger than the medial subdivision. It extends forwards to a point a little in front of the plane of the anterior commissure. When the lentiform nucleus is cut in a frontal direction, and in its widest part, the medial mass shows an indication of a separation into two parts, so that here the globus pallidus appears to consist of three subdivisions.

Connexions of the Corpus Striatum.—Recent clinical investigation has demonstrated the importance of the functions of the corpus striatum, which seems to exercise a “steady influence” (Kinnier Wilson) upon the muscles which perform voluntary movements that call for delicate co-ordination. Hence it is desirable to study the connexions of these large masses of gray matter. Fibres of the internal capsule coming from the motor cortex (as well as from all other cortical areas) end in the corpus striatum (Fig. 571), so that when a voluntary movement is initiated this structure is called into activity. Fibres coming from the nucleus caudatus break through the anterior limb of the internal capsule (Fig. 572), some of them to reach the putamen, others to pass through the external medullary lamina to the globus pallidus. Other tracts pass from

FIG. 569.—FRONTAL SECTION THROUGH THE CEREBRUM so as to cut through the three divisions of the lentiform nucleus ; posterior surface of the section shown here.

FIG. 570.—FRONTAL SECTION THROUGH THE LEFT SIDE OF THE CEREBRUM OF AN ORANG (Weigert-Pal specimen).

The section passes through the middle of the lentiform nucleus.

the lentiform nucleus into the caudate nucleus (*fibræ lenticulocaudatæ*). From the globus pallidus fibres arise which proceed into the internal capsule in the region of the genu and the neighbouring part of the posterior limb (Fig. 572). Many of these fibres become collected on the inferior aspect of the lentiform nucleus, where they form a transversely directed bundle (Fig. 570), known as the *ansa lenticularis*, which is distributed to the thalamus (Fig. 571, *fasciculus striothalamicus*) and hypothalamus, the red nucleus (*fasciculus striorubricus*) and substantia nigra (*fasciculus strionigricus*). These connexions afford some explanation of the difficulties of articulation and swallowing and in the performance of delicate voluntary movements that result from damage to the corpus striatum or to this system of fibres.

This system of fibres is phylogenetically very old, being the most primitive efferent tract from the cerebral hemisphere.

FIG. 571.—DIAGRAM OF A FRONTAL SECTION TO ILLUSTRATE THE FIBRE CONNEXIONS OF THE CORPUS STRIATUM.

Clastrum.—This is a thin plate of gray substance embedded in the white matter, which intervenes between the lentiform nucleus and the gray cortex of the insula. Followed in an upward direction, it becomes gradually thinner and ultimately disappears. As it is traced downwards, however, it thickens considerably, and at the base of the brain it comes to the surface at the anterior perforated substance and becomes continuous with the gray matter of the cortex. Its extent corresponds very closely with the area occupied by the insula, and its surface towards this portion of the cerebral cortex shows ridges and depressions corresponding to the insular gyri and sulci.

FIG. 572.—DIAGRAMMATIC REPRESENTATION OF THE INTERNAL CAPSULE (AS SEEN IN HORIZONTAL SECTION).

at the lateral extremity of the substantia perforata anterior (Fig. 584, p. 657). It is part of a large rounded mass, called the **amygdaloid nucleus**, which occupies a position in front of, and to some extent above the extremity of the inferior horn of the lateral ventricle. The tail of the caudate nucleus joins its inferior part (Fig. 573, p. 643), whilst above it is carried up into the putamen (Fig. 570).

Inferiorly it is continuous with the gray cortex of the piriform area, to which it is functionally related, probably in the same way that the major part of the corpus striatum is associated with the neopallium.

Stria Terminalis.—This is a band of fibres which, for the most part, arise in the amygdaloid nucleus. From this it runs backwards in the roof of the inferior horn of the lateral ventricle (Fig. 584, p. 657, and Fig. 573, p. 643), and then arches upwards and forwards, so as to gain the floor of the pars centralis of the lateral ventricle. In both situations it lies close to the medial side of the nucleus caudatus, and finally, at the interventricular foramen, it bends downwards towards the anterior commissure. Some of its fibres pass in front and others behind the commissure, and ultimately they end in the neighbourhood of the substantia perforata anterior (Kölliker).

Internal Capsule.—This term is applied to the broad band of white matter which intervenes between the lentiform nucleus, on the lateral, and the thalamus and caudate nucleus on the medial side. It presents many different appearances, according to the plane in which the brain is cut. A frontal section through the brain which passes through the cerebral peduncles shows that, in great part, the internal capsule is directly continuous with the basal part of the cerebral peduncle (Fig. 580, p. 652). Viewed from the lateral aspect after removing all else of the cerebral hemisphere excepting the corpus striatum (Fig. 573), the cut ends of the fasciculi of the internal capsule form three-fourths of an ellipse, the other fourth of which is occupied by the bridge of union between the lentiform and caudate nuclei, the substantia perforata anterior, the amygdaloid nucleus and the anterior commissure. It may be divided into an **anterior (lenticulo-caudate) part**, a **superior (lenticulo-thalamic) part**, a **retrolenticular part** (not labelled in the figure), and a **postero-inferior (sublenticular) part**. The last three parts are usually grouped together as the posterior limb. In horizontal section the internal capsule is observed to be bent upon itself opposite the stria terminalis, or the interval between the caudate nucleus and the thalamus. This bend, which points medially, is called the **genu**. About one-third of the internal capsule lies in front of the genu, and is termed the anterior limb; the remaining two-thirds, which lie behind the genu, constitute the posterior limb (Fig. 572).

The **anterior limb of the internal capsule** intervenes between the lentiform nucleus and the caudate nucleus. In its inferior and anterior part it is much broken up by the connecting bands of gray matter which pass between the anterior part of the putamen and the caudate nucleus.

The anterior limb of the internal capsule is composed largely of corticopetal fibres belonging to the anterior thalamic radiation. It contains corticifugal fibres also. The *corticopetal fibres* arise in the median and anterior part of the lateral nucleus of the thalamus, and go through the anterior limb of the internal capsule to reach the cortex of the frontal lobe.

The *corticifugal fibres* are represented by the fronto-pontine tract.

The **fronto-pontine tract** arises in the cortex of the frontal region, traverses the anterior limb of the internal capsule, forms the medial fifth of the basis of the cerebral peduncle, and finally ends in the nuclei pontis.

The **posterior limb of the internal capsule** is placed between the thalamus and the lentiform nucleus, and it extends posteriorly for a short distance beyond the posterior end of the putamen on the lateral side of the posterior part of the thalamus and of the tail of the caudate nucleus. The posterior limb, therefore, is spoken of as consisting of a lenticular, a retrolenticular, and a sublenticular part.

The **lenticular** or more properly **lenticulo-thalamic part** of the posterior limb is composed of both corticopetal and corticifugal fibres. The *corticopetal fibres* enter the internal capsule from the lateral aspect of the thalamus, and are composed of fibres which arise within the thalamus from the ventral (ventro-lateral) nucleus, and proceed upwards to the cerebral cortex.

The *corticifugal fibres* consist of the cerebro-spinal tract and the cortico-thalamic fibres.

The great **motor** or **cerebro-spinal tract**, descending from the cerebral cortex, occupies the anterior half of the lenticular part of the internal capsule. The fibres, that go

to the nuclei of the oculomotor, trigeminal, and facial nerves, lie close to the genu, and behind these are the fibres which go to the hypoglossal nucleus; still further back are cerebro-spinal fibres which enter the spinal medulla and end around the motor cells of the anterior column of gray matter. This cerebro-spinal tract has been observed occupying the middle part of the pedunculus cerebri, into which it passes directly from the internal capsule.

According to Monakow the posterior limb contains also an important tract of fibres passing from the motor cortex to the red nucleus (*fasciculus cerebrorubricus*).

The **retrolenticular part** of the posterior limb contains: (1) the fibres of the optic radiation as they pass from the lateral geniculate body to establish their connexions with

FIG. 573.—DISSECTION EXPOSING THE LATERAL ASPECT OF THE LENTIFORM NUCLEUS OF THE LEFT HEMISPHERE.

the occipital cerebral cortex; (2) the fibres of the acoustic radiation, or those which connect the medial geniculate body with the acoustic cortical field in the temporal lobe (Fig. 572, p. 641, and Fig. 578, p. 650); (3) the temporo-pontine tract, which is composed of fibres which take origin in the middle and inferior gyri of the temporal lobe and pass through the sublenticular section of the internal capsule to reach the lateral part of the pedunculus cerebri. Through this they reach the basilar part of the pons, in the gray matter of which they end. This tract is accompanied by the **fasciculus temporothalamicus**, which has a widespread origin from the temporal and occipital regions and passes through the sublenticular part of the internal capsule.

If the fibres of the internal capsule are traced upwards they are found to spread out widely from each other in a radiating or fan-shaped manner, as they

are followed to the various gyri of the cerebral hemisphere. This arrangement is termed the **corona radiata**. The callosal system of fibres, as they proceed into the hemisphere, also radiate, and they intersect the fibres of the corona radiata (Fig. 576, p. 649).

External Capsule.—The thin lamina of white matter between the lateral aspect of the putamen and the claustrum is called the external capsule. This joins with the internal capsule in front of and behind the putamen, and in this manner the nucleus lentiformis is encapsuled by white matter.

INTIMATE STRUCTURE OF THE CEREBRAL HEMISPHERE.

The cerebral hemisphere is composed of an external coating of gray matter, termed the **cortex**, spread over an internal mass of white matter, which is called the **medullary centre**. The cortex is of peculiar interest, seeing that there is good reason for believing that in it the higher functions of the brain, or those which may be classed under the general designation of the intellectual functions, take place. It is within the same layer of gray matter that the influence of those external impressions, which gain access to the cerebro-spinal axis through the senses, finally take shape as consciousness; and in it are placed also the centres which carry on the psycho-motor functions. The white medullary centre is composed of nerve-fibres which constitute the paths along which the influence of impressions is carried to and from the cortex, and from one part of the cortex to another.

THE CEREBRAL CORTEX.

The gray cortex is spread over the entire surface of the cerebral hemisphere, but it does not form a layer of equal thickness in all localities. At the summit of a gyrus it is apt to be thicker than at the bottom of a furrow. The maximum thickness of cortex (about 4 mm.) is attained in the superior parts of the motor area, whilst the minimum (about 1.25 mm.) may be observed in the region of the occipital pole. The amount of gray cortex differs considerably in different individuals, and appreciably diminishes in old age. It is also stated, but upon imperfect evidence, that it is relatively more abundant in the male than in the female.

In structure, likewise, marked differences may be noted in the gray cortex of different regions, and much has been recently done in the direction of pointing out the connexion of these structural peculiarities with the functional characteristics of particular areas and applying them to the determination of the significance of the furrows that subdivide the cerebral cortex into a series of ridges or gyri. This structural difference is quite apparent to the naked eye when sections are made through the cortex in a fresh brain, and sharp transitions in structure occur at the place where one area joins another. It is only to those general structural features which more or less characterise the entire cortical layer that we shall be able to refer.

When sections are made through the fresh brain, and the cut surface is closely inspected, it will usually be apparent that the cortex is distinctly stratified. On the outside there is a thin, whitish layer, and beneath this the gray matter presents two strata of very nearly equal thickness, viz., a middle, gray-coloured stratum and an inner, yellowish-red stratum. Between the two latter layers a narrow white band is, in many places, visible. This is termed the **outer band of Baillarger**. When the layers indicated above are present, four strata, superimposed one upon the other, are recognised; but in certain regions a second white streak traverses the deep or inner gray layer and divides it into further stratifications. This is termed the **inner white band of Baillarger**, and, when it is present, the gray cortex becomes divided obscurely into six alternating white and gray layers.

The outer band of Baillarger is strongly marked in the region behind the calcarine sulcus and gives a characteristic appearance to this portion of the cortex. In this locality it receives the name of the **stria of Gennari** (Fig. 567, p. 638).

White Medullary Centre of the Cerebral Hemisphere.—The white matter of the

hemisphere which lies subjacent to the gray cortex is composed of medullated nerve-fibres, arranged in a very intricate manner. But the arrangement of these fibres cannot be properly understood until the configuration of the surface of the hemisphere has been considered.

THE NEOPALLIUM.

Fibre-tracts proceed into different districts of the neopallium from the various nuclei of the thalamus to serve as the channels through which tactile, visual, acoustic, and other kinds of sensory impressions are poured into it. These districts may be regarded as the receptive sensory areas, tactile, visual, acoustic, etc.; but around each sensory area there is differentiated a series of more or less concentric bands of neopallium, which are related to an incoming sensory path only through the intermediation of the sensory area which it fringes. Finally, there are interposed between the sensory area and its fringing bands of one sense and those of another, certain association areas, which cannot be regarded as the territory of

any one sense, but as the place of meeting (and the physical counterpart of the blending in consciousness) of the impressions of different senses. In the human brain the neopallium becomes mapped out into a large series (more than forty) of areas, which differ one from the other in structure and in their connexions, and presumably therefore in their functions; and many of these areas may be further subdivided into a series of less obtrusively differentiated territories (Figs. 553 and 581).

The gray matter of the neopallium is spread over the surface of the white matter as a thin film (*cortex cerebri*), which is nowhere more than 4 millimetres, and may be only 1.25 millimetres thick. In different regions it presents every gradation of thickness between these two extremes. As the cortex increases in volume it does so not by any addition to its depth, but solely by an expansion of its superficial area. Thus it happens that in all larger mammalian brains, as the cerebral hemisphere expands and there is an increasing disproportion between the bulk of the hemisphere and the area of its surface, the cortex must become folded to accommodate itself to the limited area of surface upon which it has to be packed. But this process of folding does not take place in any haphazard or purely mechanical way. The situations of the furrows or *sulci* which make their appearance are determined, for the most part, by the arrangement and the relative rates of expansion of the various areas into which the neopallium becomes differentiated.

The great majority of the furrows belong to a group, which we may call (1) *sulci terminales*, *i.e.* they make their appearance along the boundary lines between areas of different structure. The *fissura rhinalis* and *sulcus centralis* are examples of this group. Another group, which may be called (2) *sulci axiales*, develop by the folding of areas of uniform structure, *i.e.* along the axis of certain territories. The retro-calcarine sulcus and the *sulcus occipitalis lateralis* belong to this group. There is a third group of (3) *sulci operculati*, where the edge of one area becomes pushed over an adjoining territory, so that a trough is formed (Fig. 575, C), which is neither a limiting nor an axial sulcus. The *sulcus lunatus* is an example. And finally there is a fourth group, in which some more definitely mechanical factor comes into play to complicate the operation of these other factors, or even to determine the development of a furrow. The *sulcus parieto-occipitalis* and the *fissura lateralis* are examples of the fourth group.

[It is the custom to call certain furrows *sulci* and others *fissures*, and to call some of them *complete*, because they indent the whole thickness of the wall of the ventricle, and to call the rest *incomplete*. There is no justification whatever for any such distinctions.

It is usual also to subdivide the surface of the hemisphere in a purely arbitrary manner into "*lobes*" and to speak of *interlobar fissures*, but this is an artificial and misleading terminology which we shall avoid as far as possible.]

Fissura Longitudinalis Cerebri.—The longitudinal fissure is not a fissure of the cortex but is the great cleft between the two cerebral hemispheres. In front and behind it separates the cerebral hemispheres completely the one from the other. In its middle part, however, the fissure is interrupted and floored by the corpus callosum, a white commissural band, which passes between the hemispheres and connects them together. The superior surface of the corpus callosum can be displayed by gently drawing asunder the contiguous medial surfaces of the cerebral hemispheres. The longitudinal fissure is occupied by a median fold of dura mater, termed the *falx cerebri*, which partially subdivides the part of the cranial cavity allotted to the cerebrum into a right and left chamber.

External Configuration of each Cerebral Hemisphere.—Each cerebral hemisphere presents a lateral, a medial, and an inferior surface. The *lateral surface* is convex and is adapted accurately to the internal surface of the cranial vault. The *medial surface* is flat and perpendicular, and bounds the longitudinal fissure. In great part it is separated from the corresponding surface of the opposite hemisphere by the *falx cerebri*. The *inferior surface* is irregular and is adapted to the anterior and middle cranial fossæ of the cranial floor and, behind these, to the superior surface of the tentorium cerebelli. Traversing this surface in a transverse

direction, nearer the anterior end of the hemisphere than the posterior end, is the stem of the lateral fissure. This deep cleft divides the inferior surface into an anterior or *orbital area*, which rests on the orbital part of the frontal bone and is consequently concave from side to side, and a more extensive posterior or *tentorial area*, which lies on the floor of the lateral part of the middle cranial fossa and upon the superior surface of the tentorium cerebelli. This surface is arched from before backwards, and looks medially as well as downwards. In its posterior two-thirds it lies above the cerebellum, from which it is separated by the tentorium cerebelli.

The borders which intervene between these surfaces are the supero-medial, the superciliary, the infero-lateral, the medial occipital and medial orbital. The *supero-medial border*, convex from before backwards, intervenes between the convex lateral surface and the flat medial surface of the hemisphere. The *superciliary border* is highly arched and separates the orbital surface from the lateral surface. The *infero-lateral border* marks off the tentorial surface from the lateral surface. The *medial occipital border* can be seen only in cases where the brain has been hardened *in situ* and faithfully retains the natural form. It extends from the posterior end of the hemisphere towards the posterior extremity of the corpus callosum, and intervenes between the medial and tentorial surfaces. It is the border which lies along the straight blood sinus, and it therefore occupies the angle which is formed by the attachment of the posterior part of the falx cerebri to the superior surface of the tentorium cerebelli. The *medial orbital border* separates the medial from the orbital surface.

The most projecting part of the anterior end of the cerebral hemisphere is called

FIG. 575.—DIAGRAMS TO EXPLAIN THREE TYPES OF CEREBRAL FURROWS.

the **frontal pole**, whilst the most projecting part of the posterior end is termed the **occipital pole**. On the inferior surface of the hemisphere the prominent point of cerebral substance which extends forwards below the lateral fissure receives the name of the **temporal pole**. In a well-hardened brain a broad groove is usually present on the medial and inferior aspect of the occipital pole of the right hemisphere. This corresponds to the commencement of the right transverse venous sinus. A less distinct groove on the occipital pole of the left hemisphere frequently indicates the commencement of the left transverse sinus. On the tentorial surface, a short distance behind the temporal pole, a well-marked depression, **impressio petrosa**, is always visible. This corresponds to the elevation on the anterior surface of the petrous portion of the temporal bone over the superior semicircular canal.

THE WHITE MATTER OF THE CEREBRAL HEMISPHERES.

According to the connexions which they establish the fibres forming the white medullary matter of the hemispheres may be classified into three distinct groups, viz., (1) commissural fibres; (2) association fibres; and (3) projection fibres.

Commissural Fibres.—These are fibres which link together portions of the gray cortex of opposite cerebral hemispheres. They are arranged in three groups forming three definite structures, viz., the corpus callosum, the anterior commissure, and the hippocampal commissure.

The **corpus callosum** has in a great measure been already studied (p. 628). As it enters each hemisphere, its fibres spread out in an extensive radiation (the radi-

tion of the corpus callosum). It thus comes about that every part of the cerebral cortex, with the exception of the bulbi olfactorii, the olfactory parts of the hemisphere, and the inferior and anterior part of the temporal lobe, is reached by the callosal fibres. But it should be clearly understood that all the regions of the cortex do not receive an equal proportion of fibres; in other words, some cortical areas would appear to be more plentifully supplied than others. Another point of some importance consists in the fact that the callosal fibres do not, as a rule, connect together symmetrical portions of the gray cortex. As the fibres cross the median plane they become greatly scattered, so that dissimilar parts of the cortex of opposite hemispheres come to be associated with each other.

The **commissura anterior** is a structure supplemental to the corpus callosum, although originally it was the principal cerebral commissure long before the corpus callosum was evolved. It connects together the two olfactory bulbs, and also portions of the opposite temporal lobes. It presents a cord-like appearance and in median section appears as a small oval bundle in the lamina terminalis (Fig. 544, p. 617). The middle free portion is placed immediately in front of the columns of the fornix as they curve downwards, and also in intimate relation to the anterior end of the third ventricle. Posteriorly, the small portion of the anterior commissure which appears in the ventricle between the two columns of the fornix is clothed with the ventricular ependyma; anteriorly, the commissure is connected with the lamina terminalis as it stretches from the optic chiasma upwards towards the inferior (anterior) end of the hippocampal commissure.

The lateral part of the anterior commissure penetrates the cerebral hemisphere, and, gaining the inferior part of the anterior end of the internal capsule, divides into two portions, viz., a small inferior olfactory part and a much larger temporal part.

The **olfactory portion** of the anterior commissure is an exceedingly small fasciculus. It passes downwards and forwards, and finally enters the olfactory tract. It is composed (1) of true commissural fibres, which bind one olfactory bulb to the other; and (2) of other fibres, which connect the olfactory bulb of one side with the piriform area of the other side.

The **temporal portion** is formed of almost the whole of the fibres of the commissure. It is carried laterally under the lentiform nucleus, until it gains the interval between the globus pallidus and the putamen. At this point it changes its direction and sweeps backwards. In frontal sections through the brain, posterior to this bend, the temporal portion of the anterior commissure appears as an oval bundle of fibres cut transversely and placed in close contact with the inferior surface of the lentiform nucleus (Fig. 576). Finally, it turns sharply downwards on the lateral aspect of the amygdaloid nucleus, and its fibres are lost in the white medullary centre of the temporal lobe. When the lateral part of the anterior commissure is displayed by dissection, it is seen to be twisted like a rope.

The **hippocampal commissure** is composed of fibres which connect the hippocampus of one side with the corresponding structure of the opposite side. It is described on p. 629.

Association Fibres.—The association fibres bind together different portions of the cortex of the same hemisphere. They are grouped into long and short association bundles.

The greater number of the **short association fibres** pass between adjacent gyri. They curve round the bottoms of the sulci in U-shaped loops. Some of these occupy the deepest part of the gray cortex itself, and are termed *intracortical association fibres* (Figs. 577 and 578); others lie immediately subjacent to the gray matter—between it and the general mass of the white matter—and receive the name of *subcortical fibres*. Many groups of short association fibres, instead of linking together contiguous gyri, pass between gyri more or less remote. It is only after birth, when intellectual effort and education have stimulated different portions of the cortex to act in harmony and in conjunction with each other, that these association fibres assume their sheaths of myelin and become functional.

The **long association fibres** are arranged in bundles which run for considerable distances within the white medullary centre of the cerebral hemisphere, and unite

districts of gray cortex which may be far removed from each other. The better known of these fasciculi are the following: (1) the uncinate bundle; (2) the cingulum; (3) the superior longitudinal bundle; (4) the inferior longitudinal; and (5) the occipito-frontal.

The **fasciculus uncinatus** is composed of fibres which arch over the stem of the

FIG. 576.—TWO FRONTAL SECTIONS THROUGH THE CEREBRAL HEMISPHERES OF AN ORANG, IN THE PLANE OF THE ANTERIOR COMMISSURE.

A, Section through the left hemisphere in a plane a short distance behind B, which is a section through the right hemisphere. The positions of the great longitudinal association tracts are indicated in red.

lateral cerebral fissure and connect the frontal pole, and the orbital gyri of the frontal lobe, with the anterior portion of the temporal lobe.

The **cingulum** is a very well-marked and distinct band, which is closely associated with the medial edge of the neopallium. Beginning in front, in the region of the anterior perforated substance, it arches round the genu of the corpus callosum and

FIG. 577.—DIAGRAMS OF THE LEADING ASSOCIATION BUNDLES OF THE CEREBRAL HEMISPHERE. (Founded on the drawings of Déjerine).

A, Lateral aspect of hemisphere.

B, Medial aspect of hemisphere.

is carried posteriorly on the superior surface of this structure at the place where its fibres pass into the callosal radiation. The cingulum, therefore, lies under cover of the gyrus cinguli and stands in intimate relation to the white centre of this gyrus (Fig. 559, p. 631). At the posterior end of the corpus callosum the cingulum turns round the splenium and is carried forwards, in relation to

the hippocampal gyrus, to the uncus and the temporal pole. The cingulum is composed of several systems of fibres which run only for short distances within it.

The *fasciculus longitudinalis superior* is an arcuate bundle which is placed on the lateral aspect of the foot or basal part of the corona radiata and connects the frontal, occipital, and temporal regions of the hemisphere. It lies in the base of the superior operculum and sweeps backwards over the insular region to the posterior end of the lateral cerebral fissure. Here it bends downwards round the posterior end of the putamen and proceeds forwards in the temporal lobe, to reach its anterior extremity. As it turns downwards to reach the temporal lobe numerous fibres radiate from it into the occipital lobe.

The *fasciculus longitudinalis inferior* is a very conspicuous bundle which extends along the whole length of the occipital and temporal regions (Fig. 577, B). Curran has recently demonstrated that the *fasciculus uncinatus* and the inferior longi-

FIG. 578.—DISSECTION TO DISPLAY SOME OF THE PRINCIPAL ASSOCIATION BUNDLES OF THE CEREBRAL HEMISPHERE.

The occipito-temporal extremity of the superior longitudinal bundle has been cut away in order to expose the subjacent inferior occipito-frontal bundle, parts of which in turn have been removed to expose the origin and termination of the still deeper optic radiation (coloured blue); (acoustic fibres, yellow).

tudinal bundle are merely the shorter inferior fibres of a much bigger and longer tract (Fig. 578), to which he has applied the name *occipito-frontalis inferior*. The arrangement of these longitudinal tracts may be put concisely by saying that fibre connexions of differing lengths link together the various cortical areas in the longitudinal direction, the deeper fibres (*i.e.* those furthest removed from the cortex, medial, lateral, superior or inferior) being progressively longer than the superficial. The deepest fibres extend the whole length of the hemisphere and are pushed aside by the insula (Fig. 578) and collected into two great bundles, a superior longitudinal and an inferior occipito-frontal bundle. In the occipital lobe the inferior occipito-frontal bundle is placed on the lateral aspect of the optic radiation, which takes a similar direction and from which it is distinguished by the greater coarseness of its fibres (Figs. 576, p. 649; 578; 559, p. 631). It is not present in the macaque monkey (Ferrier and Turner), but is well developed in the orang and the chimpanzee.

The **fasciculus occipito-frontalis superior** is a bundle of fibres which runs, in a sagittal direction in intimate relation to the lateral ventricle (Fig. 576, p. 649). It may be regarded as the medial edge of the superior longitudinal bundle. It has been pointed out (Forel, Onufrowicz, and others) that, in cases where the corpus callosum fails to develop, the tapetum remains apparently unaffected, and Déjerine has endeavoured to prove that the fibres of this layer really belong to the fasciculus occipito-frontalis. The fasciculus occipito-frontalis lies on the medial aspect of the corona radiata in intimate relation to the caudate nucleus, and posteriorly it spreads out over the superior and lateral aspect of the lateral ventricle, immediately outside the ependyma, where, according to Déjerine, it constitutes the tapetum (see p. 632).

Projection Fibres.—We have already seen that every part of the cerebral cortex is linked to other cortical areas, not only in its own neighbourhood (short association fibres) (Fig. 578), but also in the most distant parts of the hemisphere (long association fibres), as well as to the cortex of the other hemisphere (commissural fibres). In addition there are two large series of fibres: (i.) an ascending group which conveys to the cerebral cortex impulses coming from the thalamus and metathalamus, the corpora quadrigemina and the red nucleus, and the various other sensory nuclei scattered throughout the brain stem and spinal medulla; and (ii.) a descending group connecting the cerebral hemisphere with the corpus striatum, various parts of the diencephalon, mesencephalon and cerebellum, as well as with all the motor nuclei scattered throughout the central nervous system. These two groups of tracts, respectively passing to and from the cerebral cortex, are known collectively as its **projection fibres**.

While examining the general arrangement of these projection fibres of the cerebral hemisphere it is convenient to refer incidentally to certain other fibre-tracts which do not fall strictly within this group.

The Sensory Tracts.—A certain proportion of the fibres that enter the spinal medulla by its posterior root, which are supposed to be the sensory nerves of muscles, tendons, and joints, pass upwards without interruption in the posterior funiculi throughout the whole length of the spinal medulla until they reach the medulla oblongata, where they end in the nucleus gracilis and nucleus cuneatus. From these nuclei, arcuate fibres (**fasciculus bulbothalamicus**) arise and, after crossing the median plane, proceed upwards in the medial lemniscus of the other side to end in the ventro-lateral nucleus of the thalamus, from which a third group of neurones arises and proceeds upwards through the internal capsule to the cerebral cortex, where the impulses conveyed by it excite a consciousness of position and movement. But other sensory fibres end in the spinal medulla near their place of entry into it, and from the cells related to the endings of these fibres a new tract (**fasciculus spinothalamicus**) arises, crosses the median plane to reach the antero-lateral funiculus of the opposite side, in which it proceeds upwards throughout the whole length of the spinal medulla (that lies above its origin), the rhombencephalon and mesencephalon to the thalamus, where it ends alongside the bulbo-thalamic tract in

FIG. 579.—DIAGRAM OF THE SENSORY TRACTS FROM THE SPINAL MEDULLA TO THE CEREBRAL CORTX.

relationship with cells of the ventro-lateral nucleus. The fibres arising from this nucleus proceed to the gyrus centralis posterior, and convey impulses to it, which may excite a consciousness of touch, pressure, pain, heat, or cold. Some of these spino-thalamic fibres enter the medial lemniscus in the medulla oblongata, but others remain separate from it (Fig. 580) until they reach the level of the pons, where they become added to the lateral margin of the bulbo-thalamic tract.

[In Fig. 580 the line from the label "lemniscus medialis" points to the place of junction of the spino- and bulbo-thalamic tracts.]

Other groups of fibres, serially homologous to both the spino-thalamic and the bulbo-thalamic tracts, come from the various sensory cerebral nerves—trigeminal,

FIG. 580.—FRONTAL SECTION OF BRAIN, PASSING IN THE LINE OF THE CEREBRO-SPINAL TRACT (marked in red) IN THE RIGHT HEMISPHERE (left side of Fig.), and on a more posterior plane in the left hemisphere, where the sensory paths (tactile in blue, and acoustic in yellow) have been represented.

facial, glossopharyngeal, and vagus—and become added to the great strands that are proceeding upwards to the thalamus (Figs. 579 and 494, p. 561).

Of the other great ascending tracts in the spinal medulla, such as the two pairs of fasciculi spinocerebellares, nothing further need be said; nor is it necessary to do more than remind the reader that from the nucleus dentatus of the cerebellum a great tract (brachium conjunctivum) ascends to the opposite red nucleus and thalamus, and through them establishes an indirect connexion with the cerebral cortex in the precentral and frontal regions.

The other sensory pathways to the cerebrum, auditory, vestibular, visual, gustatory, and olfactory, are described elsewhere.

The Corticifugal Projection Strands.—The fasciculus cerebrospinalis, the great motor or pyramidal tract, is composed of fibres which arise from giant pyramidal

cells of Betz in the posterior part of the precentral cortex (p. 663) in the district immediately in front of the sulcus centralis. The fibres descend through the corona radiata into the posterior limb of the internal capsule. From this point the further course of the pyramidal tract has been traced, viz., through the central part of the basal region of the cerebral peduncle and pons, and the pyramid of the medulla oblongata. At the level of the foramen magnum it decussates in the manner already described, and enters the spinal medulla as the lateral cerebro-spinal and anterior cerebro-spinal tracts. The fibres composing these end in connexion with the ventral or motor column of cells, from which the fibres of the anterior roots of the spinal nerves arise.

Similar fibres arise from the inferior part of the precentral area and proceed through the internal capsule and cerebral peduncle to all the motor nuclei upon the opposite side of the brain stem (**fasciculi cerebronucleares**). Hence the cerebral cortex of one hemisphere can control all the muscles of the opposite side of the body.

The **fronto-pontine strand** is composed of fibres which arise as the axons of the cells in the cortex which covers the frontal region that lies in front of the precentral furrows. It descends in the anterior limb of the internal capsule, enters the medial part of the base of the cerebral peduncle, through which it gains the basilar part of the pons. In this its fibres end amongst the cells of the nuclei pontis, from which axons arise and establish relations with the cortex of the opposite cerebellar hemisphere.

The **temporo-pontine tract** consists of fibres which spring from the cells of that part of the cortex which covers the middle portions of the lower two temporal gyri. The temporo-pontine tract passes medially under the nucleus lentiformis, enters the retrolenticular part of the posterior limb of the internal capsule, and thus gains the lateral part of the cerebral peduncle. From this it descends into the basilar part of the pons, in which it ends in the nuclei pontis.

Cortico-striate and other Descending Fibres.—From the fibres of the internal capsule numerous collateral branches are given off to the nucleus caudatus and nucleus lentiformis and from these basal ganglia fibres arise which enter the cerebral peduncle as constituent elements of the great cerebro-spinal tract.

Some of the fibres from the corpus striatum, especially the nucleus lentiformis, as well as others descending from the frontal cortex, pass into the red nucleus (Fig. 571), which also receives afferent tracts from the tectum mesencephali and from the cerebellum: it emits an important efferent tract (**fasciculus rubrospinalis**), which crosses the median plane and descends in the brain stem and spinal medulla to the various motor nuclei (see Figs. 454 and 475).

THE SULCI AND GYRI OF THE CEREBRAL HEMISPHERES.

Fissura Cerebri Lateralis (O.T. Fissure of Sylvius).—This is the most conspicuous furrow on the surface of the cerebral hemisphere. In reality it is formed, not as a furrow upon the surface of the hemisphere, but as a great fossa, the margins of which develop into large lip-like folds that bulge over the fossa and meet to form the superficial pattern of the lateral fissure. It is composed of a short main stem, from the lateral extremity of which two or three branches or limbs radiate. The **stem** of the lateral fissure is placed on the inferior surface of the hemisphere. It begins at the substantia perforata anterior and passes laterally, forming a deep cleft between the temporal pole and the orbital surface of the frontal region. Appearing on the lateral surface of the hemisphere, the fissure immediately divides into two or three radiating rami. These are: (1) the ramus posterior; (2) the ramus anterior horizontalis; (3) the ramus anterior ascendens, of which the last is inconstant.

The **posterior ramus** is the longest and most constant of the three limbs. It extends backwards, with a slight inclination upwards, on the lateral surface of the hemisphere for a distance which may vary from about two to three inches. It intervenes between the frontal and parietal regions, which lie above it, and the temporal region which lies below it; and it finally ends in the region subjacent to

Opercula Insulæ.—The overlapping portions of the cerebral substance which cover over the insula are termed the insular opercula, and they form, by the apposition of their margins, the three rami of the lateral fissure. The rami of the fissure extend from the exposed surface of the hemisphere to the submerged surface of the insula, and, in this manner, separate the opercula from each other.

The **temporal operculum** (*pars temporalis*) extends upwards over the insula from the temporal region, and its superior margin forms the inferior lip of the posterior ramus of the lateral fissure.

The **superior operculum** is carried downwards from the parietal (*pars parietalis*) and frontal (*pars frontalis*) regions over the insula, and its inferior margin, meeting the temporal operculum, forms the superior lip of the posterior ramus of the lateral fissure.

The small triangular piece of cerebral substance which sometimes intervenes between the ascending and horizontal anterior rami of the lateral fissure is formed by the bending downwards of the front part of the upper operculum. It

FIG. 582.—PART OF A LEFT CEREBRAL HEMISPHERE WITH THE OPERCULA OF THE INSULA WIDELY SEPARATED TO EXPOSE THE INSULA AND THE SUPERIOR SURFACE OF THE TEMPORAL OPERCULUM.

The *area acustica* is coloured a uniform blue, the *area intermedia* with large blue spots and the *area circumambiens* with fine blue dots.

covers over a small part of the anterior portion of the insula, and is sometimes termed the **pars triangularis**.

The **orbital operculum** is, for the most part, on the inferior surface of the hemisphere. It lies below and to the medial side of the horizontal anterior ramus of the lateral fissure, and proceeds backwards from the orbital aspect of the frontal lobe over the fore-part of the insula.

Development of the Lateral Fissure and of the Insular District of the Cerebral Hemisphere.—It is only during the latter half of the intra-uterine period of development that the opercula take shape and grow over the insula, so as to shut it out from the surface. In its early condition the insula presents the form of a depressed area on the side of the cerebral hemisphere, surrounded by a distinct boundary wall formed by the surrounding more elevated surface of the hemisphere (Fig. 583, A). After a time this depressed area, which is called the *fossa lateralis*, assumes a triangular outline, and then the bounding wall is observed to be composed of three distinct parts, viz., a superior or fronto-parietal, an inferior or temporal, and an anterior or orbital part (Fig. 583, B). The angle formed by the meeting of the superior and anterior portions of the boundary may become flattened, and a short oblique part of the limiting wall develop into a small triangular frontal operculum (Fig. 583, F). Each of these portions of the bounding wall of the fossa becomes a line of growth, from which an operculum

takes origin, and by the approximation of these opercula, as they grow over the surface of the fossa, the insula becomes closed in and the rami of the lateral fissure are formed (Fig. 583, C).

The lateral fissure is an example of the fourth category of furrows enumerated above. It is largely the result of the operation of the mechanical factors incidental to the bending downwards of the pallium in front of and behind the place where the hemisphere-wall is supported and held in position by the corpus striatum. The cortical area roughly corresponding to the surface of the corpus striatum is the insula; the temporal region extends downwards behind it, and to a less extent

FIG. 583.—RIGHT HEMISPHERES OF HUMAN FÆTUSES SHOWING THREE STAGES IN THE DEVELOPMENT OF THE INSULA AND THE INSULAR OPERCULA.

F.P., Superior operculum. F, Frontal operculum. O, Orbital operculum.

the frontal region in front of it (Fig. 583, A). Then towards the end of the fifth month of foetal life the exuberant growth of the free frontoparietal pallium above the insula (Fig. 583, B) and the temporal pallium below and behind it leads to the development of lip-like folds of neopallium—the opercula—which gradually approach one another (Fig. 583, C) and eventually cover up the insula. Other factors come into play in determining the form and topographical relations of the fissura lateralis. For example, the posterior part of the fissure is the morphological boundary between the acoustic and tactile territories of the neopallium.

THE ACOUSTIC AREA AND FIBRE-TRACTS.

In the embryo of the fifth month (Fig. 583, B), as well as in every later stage, even up to the adult condition (Fig. 582), an area upon the superior surface of the temporal operculum can be seen to slope medially towards the upper limb of the sulcus circularis, behind the insula. This area constitutes the receptive centre for acoustic impressions—the *gyrus temporalis transversus* or *Heschl's convolution*—although the extent of this acoustico-sensory area does not coincide exactly with that of the transverse temporal gyrus. The area formed by the upper surface of the temporal operculum immediately behind this prominent transverse gyrus is also called by the same name, so that there are anterior and posterior transverse temporal gyri (Fig. 582; the posterior transverse temporal gyrus is not labelled in the figure).

In studying the brain-stem we have seen that a tract of fibres originating in the cochlear terminal nuclei (in the medulla oblongata) crosses the median plane (corpus trapezoideum) and bends upwards in the lateral lemniscus of the other side (Fig. 580) to end in the medial geniculate body of the metathalamus. From the medial geniculate body a new tract arises (composed of tertiary acoustic neurones), which passes laterally (Figs. 580 and 584) to end in the transverse temporal gyri. This tract may be called the *radiatio thalamotemporalis*.

The area into which this acoustic radiation is inserted occupies not only the region of the anterior transverse temporal gyrus (Fig. 582) hidden within the lateral fissure, but also extends over its inferior lip, on to the exposed surface of the superior temporal gyrus (Fig. 581). Surrounding this area there are two concentric bands,

which are also concerned with acoustic functions, but are related to the acoustic radiation only through the intermediation of the *area acustica* of the transverse gyrus (Figs. 581 and 582).

These areas may be distinguished as the *pars intermedia* and *pars circumambiens*, respectively, of the *gyrus temporalis superior*. During the sixth month of foetal life a furrow makes its appearance along the line of the inferior boundary of the superior temporal area (Fig. 590). It is called the *sulcus temporalis superior*.

At a much later stage of development another furrow (*sulcus temporalis anterior*) makes its appearance further forwards in the temporal region, as the posterior boundary of the *area temporalis polaris*; it often becomes confluent with

FIG. 584.—INFERIOR ASPECT OF PART OF THE BRAIN. The mesencephalon has been cut across and a great part of the cerebral hemisphere dissected away to expose the acoustic radiation (right side of figure in yellow) passing laterally from the medial geniculate body to the deep surface of the transverse temporal gyri, of which a small part is shown in section. Motor fibres in red; optic fibres, blue; olfactory, dull yellow.

the real *sulcus temporalis superior*, and is usually described as part of it. But it is genetically quite distinct from it (Fig. 581).

If the *area acustica* is cut across in a perfectly fresh brain it will be found to be composed of a thin layer (1.75 mm.) of cortical gray matter, in which two very dense and fairly broad bands of white matter are visible (Fig. 584). These bands are composed largely of fibres of the acoustic radiation, which have entered the cortex to terminate in it. The superior temporal area is composed of somewhat thicker cortex with two bands which are not so densely white as those of the *area acustica*. The cortex of the temporal polar area is composed of moderately thick, clear, gray matter in which there is a single, narrow, sharply defined white line.

The remainder of the true temporal region is composed of an extensive district below the superior temporal sulcus. It is composed of thicker cortex than the superior temporal area, ranging from 3 mm. just below the superior temporal sulcus to 2.5 mm. at the inferior border of the hemisphere. It is composed of three bands of different texture, the **middle temporal gyrus**, the **inferior temporal gyrus**, and the **parahinal gyrus**, which fringes the area piriformis on the tentorial surface. Upon the lateral aspect of the temporal region a series of irregular furrows are situated along the line of demarcation between the **gyrus temporalis medius** and the **gyrus temporalis inferior**; they are considered to represent a **sulcus**

temporalis medius, but they are subject to much irregularity, especially in highly developed brains. The **sulcus temporalis inferior**, which forms the line of demarcation between the **gyrus temporalis inferior** and the **gyrus fusiformis**, is placed upon the inferior aspect of the temporal region.

The great extent of the middle and inferior temporal gyri constitutes one of the outstanding features distinctive of the human brain. Flechsig has shown that the fibres passing to and from these two gyri are the last to become medullated, later even than the important parietal and frontal areas.

THE VISUAL AREAS AND FIBRE-TRACTS.

We have already seen (Figs. 578 and 584) that each optic tract ends in the lateral geniculate body, the posterior tubercle of the thalamus, and the superior colliculus. From the lateral geniculate body (and ac-

FIG. 585.—CORTICAL AREAS on the tentorial and orbital aspects of the cerebral hemispheres.

ording to most writers the thalamus also, though this is not admitted by all) a tract arises which conveys visual impulses back to the occipital pole of the hemisphere. This **radiatio thalamo-occipitalis** (**Gratiolet's optic radiation**) is seen from various points of view in the figures mentioned, but it is possible (see Fig. 587) to expose it in a section which will display it in its relationship to the rest of the visual path (Fig. 586).

From this it will be seen that the fibres of the optic radiation, after emerging from the lateral geniculate body, bend backwards in the lateral wall of the ventricle and proceed to an extensive district of thin cortex (1.5 mm. or less in thickness), occupying an area of about 3000 sq. mm. of the medial surface and pole of the occipital area. The cortex in this area is distinguished by the presence of

a very distinct white line or stria, which was first noticed by Gennari in the year 1776.

If this visual receptive area *striata* of the occipital cortex is excised and spread out in one plane, it will be found to present an elongated ovoid form and a superficial extent of about 3000 sq. mm. (varying in different brains from about 2700 to 4000). The narrow extremity of the oval is placed a short distance behind and below the splenium of the corpus callosum; and from this point the area extends horizontally backwards to the occipital pole, or even beyond it on to the lateral aspect of the hemisphere. In the course of development this area *striata* becomes folded along its axis during the sixth month, and the furrow thus formed is called the *sulcus calcarinus*. This name was applied to the furrow by Huxley because its deep anterior part indents the whole thickness of the medial

FIG. 586.—DIAGRAM OF THE CENTRAL CONNEXIONS OF THE OPTIC NERVE AND OPTIC TRACT.

FIG. 587.—A SLIGHTLY OBLIQUE (ALMOST HORIZONTAL) SECTION THROUGH A CEREBRAL HEMISPHERE IN THE PLANE OF THE OPTIC TRACT AND RADIATION.

wall of the hemisphere, and the swelling so produced in the posterior cornu of the lateral ventricle was supposed by the older anatomists to resemble a cock's spur, and was hence called *calcar avis* (see Fig. 566, p. 637).

The anterior part of this furrow is much deeper, more constant in form and position, more precocious in development, and phylogenetically much older than the posterior part. As it is the part of the sulcus which gives rise to the calcar avis, it is the true calcarine; while the newer, shallower posterior part is wholly on the caudal side of the calcar avis, and is called *sulcus calcarinus posterior*. If the area *striata* is prolonged on to the lateral surface, it also may become folded in the line of its axis, and so give rise to a *sulcus calcarinus lateralis*.

There is a fundamental distinction between the calcarine sulcus and the posterior calcarine in their relations to the area *striata*. For the stria of Gennari is found only in the inferior wall of the sulcus calcarinus, which is therefore a sulcus

limitans; whereas the stria extends throughout both walls of the posterior calcarine sulcus, and in most cases beyond its lips on to the surface of the **cuneus** and the **gyrus lingualis** (Figs. 588 and 589), the exposed cortical areas placed upon the superior and inferior aspects respectively of the sulcus calcarinus posterior.

Along the superior and inferior boundary lines of this area shallow limiting sulci usually develop (Fig. 589), and these furrows often pass posteriorly into little arched *sulci polares*, which are furrows of the operculated variety (see p. 646), called into existence by the broadening out of the area striata (not an actual broadening, but an unfolding) as it passes round the edge of the hemisphere.

At the point of transition from the deep sulcus calcarinus into the shallower sulcus calcarinus posterior (Fig. 588) a submerged ridge is usually found—the **gyrus cuneolingualis anterior**; and other similar ridges, which may be exposed on the

FIG. 588.—THE PARIETO-OCCIPITAL AND THE CALCARINE SULCI FULLY OPENED UP, so as to show the deep transitional gyri marking off the several elements of the <-shaped system.

Area striata, uniform blue; *area parastriata*, large blue spots; *area peristriata*, fine blue dots.

surface or may be submerged, are often found interrupting the posterior and lateral calcarine sulci themselves (Fig. 588).

The posterior and lateral calcarine sulci are subject to a very wide range of variation in form, but they are always axial foldings of the area striata.

When the area striata crosses on to the lateral surface of the hemisphere a small semilunar furrow develops a short distance in front of its anterior edge. This is the **sulcus lunatus**. The larger the lateral extension the closer does the edge of the area striata approximate to the caudal lip of the sulcus, which under such circumstances assumes a definitely operculated form. Such cases occur most often in the left hemisphere and in the brains of primitive people; and they represent a perfect realisation of a furrow once supposed not to occur in the human brain, but to be distinctive of the ape. Hence it used to be called the "**Affenspalte**" or **sulcus simialis**.

The area striata is surrounded by two peripheral concentric bands—an inner, which may be called *area parastriata*, and an outer, the *area peristriata*. Sulci develop along the boundary lines of each of these areas; and those which indicate the superior and inferior limits of the peripheral band (*i.e.* peristriate area)

make their appearance relatively early in development and become very deep furrows.

The inferior of these is placed upon the tentorial surface, and is known as the *sulcus collateralis*; the superior limiting furrow of the visual territory (its peristriate part) is upon the superior surface of the hemisphere, and is usually regarded as the *ramus occipitalis* of the *sulcus interparietalis*. But it is genetically independent of the latter furrow, and may be distinguished as the *sulcus paroccipitalis*.

Near the supero-medial margin of the hemisphere there is a furrow, which indicates the line of demarcation between the para- and the peristriate areas—the *sulcus occipitalis paramedialis*. It may be situated upon either the medial or the superior surface of the hemisphere. In some cases it belongs to the category of limiting sulci, in others to the group of operculated sulci (see p. 646).

FIG. 589.—THE CORTICAL AREAS ON THE MEDIAL ASPECT OF THE CEREBRAL HEMISPHERE.

Passing horizontally forwards upon the lateral surface of the hemisphere there is a constant furrow formed by the axial folding of part of the peristriate area, approximately in line with the axial folding of the striate area (*sulcus calcarinus lateralis*); it is the *sulcus occipitalis lateralis*. When there is a fully developed *sulcus lunatus* the lateral occipital sulcus joins it near its midpoint (Fig. 581, p. 654).

The *sulcus* (or *fossa*) *parieto-occipitalis* (Fig. 554) is usually a deep furrow upon the medial aspect of the hemisphere which passes vertically downwards from the supero-medial border and appears to join the calcarine sulcus near its union with the posterior calcarine, forming upon the surface a Y-shaped pattern, the stem of which is calcarine, the limbs posterior calcarine and parieto-occipital respectively, and the wedge-shaped area between the limbs the *cuneus* (Fig. 588; compare with the pattern shown in Fig. 589, where the parieto-occipital sulcus is not labelled).

If, however, the lips of these three furrows are divaricated (Fig. 588), the parieto-occipital depression will be found to be separated from the calcarine by a prominent

submerged cortical ridge, the *gyrus cunei*; and the parieto-occipital will be found to be something more than a mere sulcus. It is, in fact, a great fossa in which are submerged the anterior parts of the area parastriata and area peristriata, and the posterior part of the parietal area known as the *præcuneus*, as well as the sulci which separate these territories one from the other. It is a great trough formed by the splenium of the corpus callosum as in the course of its development it thrusts itself backwards and crumples up the cortex. When the corpus callosum fails to develop, no parieto-occipital fossa makes its appearance. The part of the sulcus that notches the supero-medial border (Figs. 589 and 593) forms a distinct element, which Retzius has called the *incisura parieto-occipitalis*.

Sulcus Collateralis.—The collateral sulcus is a strongly marked furrow on the tentorial face of the cerebral hemisphere. It begins near the occipital pole and extends forwards towards the posterior end of the rhinal fissure, with which it sometimes becomes confluent. In its posterior part it is placed below, and parallel to, the calcarine fissure, from which it is separated by the lingual gyrus. From the posterior extremity a sulcus proceeds forwards and then laterally across the inferior surface of the occipital region, forming a V-shaped pattern with the collateral sulcus (Fig. 585). As it is serially homologous with the latter, being like it an inferior boundary of the area peristriata, it may be called the *sulcus collateralis transversus*. The lingual gyrus is sometimes subdivided by a furrow (*sulcus sagittalis gyri lingualis*) midway between the collateral sulcus and the inferior margin of the area striata. It is the line of demarcation between the parastriate and peristriate areas, and when deep is often mistaken for the collateral sulcus.

THE PARIETAL REGION.

We have seen that the acoustic pathway leads into the temporal region and the visual pathway into the occipital region. The facts of clinical medicine show

that large areas in these two regions beyond the limits of the cortex in which the acoustic and optic radiations end are concerned with the functions of hearing and vision. A large part of the parietal area is interposed between these temporal and occipital territories, and its integrity and normal functioning is a necessary condition for the proper performance of many acts, such as reading written or printed documents, in the acquisition of which both hearing and vision have played some part. But the parietal region also includes the cortical area in which a part, at least, of the chief thalamo-cerebral tract ends—the bundle of fibres that represents the third stage of the great sensory pathway, the first stage of which is formed by the spinal and cerebral sensory nerves and their central prolongations, and the second stage by the spino-thalamic, bulbo-

thalamic, and ponto-thalamic fasciculi, which pass upwards in the medial lemniscus and end in the ventral nucleus of the thalamus (Figs. 579 and 580).

The sensory area in question forms part of the *gyrus centralis posterior*, which intervenes between two oblique furrows, the *sulcus centralis* and the *sulcus post-centralis*, which extend across the whole breadth of the hemisphere above the *sulcus lateralis* (Fig. 581).

Sulcus Centralis.—During the sixth and seventh months of foetal life the expand-

ing posterior central area becomes raised up into a prominent ridge, and a similar ridge is formed immediately in front of it (Fig. 590) from the area which emits the great efferent or motor tract to control all the motor nuclei upon the other side of the brain and spinal medulla. As these ridges become raised up a depression is left between them: this is the **sulcus centralis**. At first it consists of two parts, a superior and an inferior (Fig. 590, r^2 and r^1); but as a rule these become confluent later.

The sulcus centralis in the adult takes an oblique course across the lateral convex surface of the cerebral hemisphere, and intervening between the frontal and parietal regions it forms the immediate posterior boundary of the motor area of the cortex. Its upper end cuts the supero-medial border of the hemisphere a short distance behind the mid-point between the frontal and occipital poles, whilst its inferior end terminates above the middle of the posterior ramus of the lateral fissure. Its superior extremity, as a rule, turns round the supero-medial border of the hemisphere, and is then continued backwards for a short distance on the medial surface. Although, in its general direction, the sulcus is oblique, it is very far from being straight. It takes a sinuous course across the hemisphere. This is largely due to the varying breadth of the motor areas representing the leg, trunk, arm, and head respectively, which are placed immediately in front of it.

When the sulcus centralis is widely opened up, so that its bottom and its opposed sides may be fully inspected, it will be seen that the two bounding gyri are dovetailed into each other by a number of interlocking gyri, which do not appear on the surface (Fig. 591). Further, two of these, placed on opposite sides of the fissure, are frequently joined across the bottom of the sulcus in the form of a sunken bridge of connexion, which constitutes what is termed a *deep transitional gyrus*. The continuity of the sulcus is thus, to some extent, interrupted. This condition is rendered interesting when considered in connexion with the development of the sulcus. The deep interlocking gyri indicate a great exuberance of cortical growth in this situation in the early stages of the development of the sulcus; and the presence of the deep transitional gyrus is explained by the fact that the sulcus generally develops in two pieces, which run into each other to form the continuous sulcus of the adult, viz., a part corresponding to the inferior two-thirds, and a superior part, which represents the superior third and which appears at a slightly later date. In certain very rare cases the sulcus centralis is found to remain double throughout life, through a failure of its two pieces to unite. In such cases the deep transitional gyrus, which is frequently seen at the bottom of the furrow, remains on the surface. Heschl, who examined 2174 cerebral hemispheres, found this anomaly only six times; Eberstaller met with it twice in 200 brains.

FIG. 591.—SULCUS CENTRALIS FULLY OPENED UP, so as to exhibit the interlocking gyri and deep transitional gyrus within it.

Motor cortex coloured red, sensory cortex blue.

If a section is made at right angles to this sulcus in a fresh brain (Fig. 592), it will be seen that its anterior (gyrus centralis anterior) and posterior (gyrus centralis posterior) walls present a marked contrast the one to the other, and that the transition from the one type of cortex to the other takes place precisely at, or near to, the bottom of the sulcus. The anterior wall is composed of thick (3.5 to 4 mm.) motor cortex thickly laden with medullary matter arranged in the form of three or four pale bands with blurred edges and multitudes of fine pencils of fibres passing to and fro between it and the white matter of the hemisphere. The posterior wall is composed of thin (1.5 mm.) cortex containing two narrow and sharply defined white lines.

This sensory area forms little more than the posterior wall of the sulcus centralis, and barely emerges upon the surface to form the posterior lip of the sulcus (Fig. 581). Here it becomes continuous with a slightly thicker cortex with

doubled lines which are less dense than those of the sensory cortex; this area forms the crest of the gyrus centralis posterior, and then gives place to another slightly modified type of cortex which forms the anterior wall of the sulcus postcentralis. Thus the sensory cortex has two fringing bands analogous to those already noticed alongside the visual and acoustic areas.

The motor and sensory areas cross on to the medial aspect of the hemisphere, into a region known as the *lobulus paracentralis*.

FIG. 592.—SECTION ACROSS THE SUPERIOR PART OF THE SULCUS CENTRALIS IN A FRESH BRAIN.

In this region a furrow (*sulcus paracentralis*) is sometimes found along the line of demarcation of the medial parts of the motor and sensory areas (Fig. 589).

That portion of the parietal region which intervenes between the gyrus centralis posterior and the occipital region is usually subdivided into two distinct parts (*lobulus parietalis superior* and *lobulus parietalis inferior*) by a horizontal furrow, called the *sulcus interparietalis proprius*. The term *sulcus interparietalis* is usually applied in a purely arbitrary and artificial manner to a complex of four genetically distinct and independent furrows (Fig. 593, p^1 , p^2 , p^3 , and p^4), the *sulcus postcentralis inferior* (p^1), the *sulcus postcentralis superior* (p^2), the *sulcus interparietalis proprius* (*ramus horizontalis*) (p^3), the *sulcus occipitalis* (p^4), which ends in the *sulcus occipitalis transversus*.

These four furrows develop quite independently one of the other, the postcentral sulci as the posterior boundary of the sensory territory, the paroccipital sulcus as the supero-lateral boundary of the visual territory, and the more variable horizontal ramus (the *sulcus interparietalis*, in the strict sense of the term) as a demarcation

between the two parietal lobules. The four furrows may unite to form any possible combination.

The superior parietal lobule is composed of moderately thick cortex (2.5 to 3 mm.) placed between the interparietal sulcus (*ramus horizontalis*) and the superior border of the hemisphere, where it becomes continuous on the medial surface with the precuneus. Each of these parts is subdivided by a transverse sulcus, the

superior lobule by the sulcus parietalis superior and the precuneus by the sulcus præcuneus (Fig. 589).

The latter sulcus usually joins a small inverted U-shaped furrow (sulcus subparietalis), which encloses a cortical territory of distinctive structure—the area parasplénalis [præcuneus].

The inferior parietal lobule, which from its position is the natural meeting-place for impressions coming from the visual, acoustic, and tactile territories, is naturally a region of great functional significance. It is composed of a series of areas differing in thickness and texture. The anterior region forms a convolution (*gyrus supramarginalis*) surrounding the upturned extremity of the lateral fissure; behind it there is a second convolution called the *gyrus angularis*, which surrounds a vertical sulcus angularis, often described as the extremity of the sulcus temporalis superior; but in reality it is quite independent of the latter furrow, but it often becomes confluent with it. Behind the *gyrus angularis* and separated from it by a transverse furrow (sulcus occipitalis anterior) there is a cortical territory (*area parieto-occipitalis*) which may perhaps be looked upon as a specialised and outlying part of the peristriate area of the visual cortex.

THE FRONTAL REGION.

The frontal region is the biggest of the main cortical areas—the so-called “lobes.” On the lateral surface of the hemisphere, it is bounded behind by the sulcus centralis and below in part by the lateral fissure. It presents a lateral surface, a medial surface, and an inferior or orbital surface.

On its lateral aspect the surface is broken up by a large series of furrows, which exhibit considerable variability.

The inferior precentral sulcus consists of a vertical and an oblique part. The *vertical portion* lies in front of the inferior part of the sulcus centralis, whilst the *oblique part* extends forwards and upwards (Fig. 594).

The superior precentral sulcus is a short vertical sulcus which lies at a higher level than the inferior precentral sulcus, in front of the upper part of the sulcus centralis. It is almost invariably connected with the posterior end of the superior frontal sulcus.

The anterior central gyrus is a long continuous gyrus, which is limited in front by the two precentral furrows and behind by the sulcus centralis. Inferiorly it is continuous with the area subcentralis which links it to the posterior central gyrus, which is limited in front and behind by the *anterior and posterior subcentral sulci* (not labelled in Fig. 594).

The superior frontal sulcus extends forwards in a more or less horizontal direction from the sulcus præcentralis superior.

The *gyrus frontalis superior* is the narrow convolution between the supero-medial border of the hemisphere and the superior frontal sulcus and the continuation of this convolution into a broad area upon the medial surface.

The inferior frontal sulcus occupies a lower level than the superior frontal sulcus. Its posterior end is placed in the angle between the vertical and horizontal parts of the inferior precentral sulcus, and is not infrequently confluent with one or other of these. It proceeds forwards towards the superciliary margin of the hemisphere and ends a short distance from this in a terminal bifurcation (Fig. 594).

The *gyrus frontalis medius* is the name given to the broad convolution which lies between the superior and inferior frontal sulci.

The *gyrus frontalis inferior* is that portion of the lateral surface of the frontal region which is placed in front of the inferior precentral sulcus and below the inferior frontal sulcus. The inferior frontal convolution includes three cortical areas (Fig. 594) differing in structure the one from the other. The sulcus diagonalis separates the intermediate of these from the posterior.

The sulcus frontalis medius begins midway between the anterior ends of the superior and inferior frontal sulci and proceeds obliquely forwards towards the frontal pole. When the furrow reaches the superciliary margin of the hemisphere it ends near a transverse furrow, called the fronto-marginal sulcus.

On the *medial aspect of the frontal lobe* there are two convolutions, the larger peripheral area which forms part of the gyrus frontalis superior and a smaller inner part encircling the corpus callosum, which is called the **gyrus cinguli**. These gyri are separated by the **sulcus cinguli** (Fig. 589).

The posterior part of the sulcus cinguli is genetically distinct from the anterior part and it circumscribes a broader area, the **lobulus paracentralis**, which is continuous with the gyri centrales.

FIG. 594.—AREAS ON LATERAL ASPECT OF LEFT CEREBRAL HEMISPHERE.

The superior, middle, and inferior frontal sulci are not labelled. The middle is in the midst of the green area, the superior and inferior respectively at its superior and inferior boundaries.

On the *orbital aspect of the frontal region* there are two sulci, viz., the olfactory and the orbital.

The **olfactory sulcus** is a straight furrow which runs parallel to the medial border of the hemisphere. It is occupied by the olfactory tract and bulb, and it cuts off a narrow strip of the orbital surface close to the medial border, which receives the name of **gyrus rectus**.

The **orbital sulcus** is a composite furrow which assumes many different forms. It consists essentially of a U-shaped furrow, the convexity of which is directed anteriorly (Fig. 585), and one or two variable branches passing forwards from it.

The conventional manner of subdividing the cortical territory anterior to the sulcus centralis into gyri, which has just been sketched, is apt to convey a misleading idea of the distribution of the anatomical areas of differentiated cortex.

The gyrus centralis anterior together with the major portion of the paracentral lobule and the posterior part of the middle and superior frontal gyri form a natural subdivision of the cortex, which Brodmann calls the **regio præcentralis**. It is composed of a series of areas of different structure, which may be grouped as the **area præcentralis posterior** (the true motor area), the **area præcentralis intermedius**, and

the area *præcentralis anterior* (Fig. 594). Most of the motor area is hidden in the sulcus *centralis*, but towards the supero-medial margin of the hemisphere a considerable area emerges upon the surface of both the gyrus *centralis anterior* and the *paracentral lobule*.

Brodmann calls the rest of the frontal territory the *regio frontalis*; but in the colour scheme adopted in Figs. 585, 589, and 594 the inferior frontal gyrus and the orbital area posterior to the orbital sulcus have been associated with the "precentral" rather than the "frontal" regions.

WEIGHT OF THE BRAIN.

The average weight of the adult male brain may be said to be about 1360 grammes. The female brain weighs rather less, but this is to be expected from the smaller bulk of the female body. Probably the relative weight of the brain in the two sexes is very much the same. The variations met with in brain-weight are very great, but it is doubtful if normal intellectual functions could be carried on in a brain which weighs less than 960 grammes. In microcephalic idiots brains of extremely small size are met with.

THE MENINGES OF THE ENCEPHALON AND MEDULLA SPINALIS.

The brain and spinal medulla are enclosed within three membranes, which are termed the meninges or meningeal membranes. From without inwards these are: (1) the *dura mater*, (2) the *arachnoid*, and (3) the *pia mater*. The space between the *dura mater* and the *arachnoid* receives the name of *subdural space*, while the much more roomy interval between the *arachnoid* and the *pia mater* is called the *subarachnoid space*.

DURA MATER.

The *dura mater* is a dense and thick fibrous membrane which possesses a very considerable degree of strength. Its arrangement within the cranial cavity is so different from that within the vertebral canal that it is customary to speak of it as consisting of two parts, viz., a cranial and a vertebral, although in adopting this subdivision it must be clearly understood that both portions are continuous with each other at the *foramen magnum*.

Dura Mater Encephali.—The cranial *dura mater* is adherent to the inner surface of the cranial wall, and performs a double office. It serves as an internal periosteum for the bones which it lines and constitutes an envelope for the brain. Its inner surface, which bounds the *subdural space*, is smooth and glistening, and is covered with a layer of endothelial cells. The outer surface when separated from the cranial wall, is rough, this being due to numerous fine fibrous processes and blood-vessels which pass between it and the bones. Its degree of adhesion to the cranial wall differs considerably in different regions. To the vault of the cranium, except along the lines of the sutures, the connexion is by no means strong, and in the intervals between the fibrous processes which pass into the bone there are small lymph spaces (*epidural spaces*) where the outer surface of the membrane is covered by endothelial cells. So long as the sutures are open the *dura mater* is connected with the periosteum on the exterior of the skull, along the sutural lines, by a thin layer of fibrous tissue which intervenes between the bony margins. Around the *foramen magnum*, and to the floor of the cranium, the *dura mater* is very firmly adherent. This is more particularly marked in the case of the projecting parts of the cranial floor, as, for example, the petrous portions of the temporal bones, the clinoid processes, and so on. This firm adhesion in these regions is still further strengthened by the fact that the nerves, as they leave the cranium through the various foramina, are followed by sheaths of the fibrous *dura*

mater. Outside the cranium these prolongations of the membrane blend with the fibrous sheaths of the nerves, and likewise become connected with the periosteum on the exterior of the skull. In the child, during the growth of the cranial bones, and also in old age, the dura mater is more adherent to the cranial wall than during the intermediate portion of life.

The cranial dura mater is composed of two layers intimately connected with each other, but yet capable of being demonstrated in most regions of the cranium. Along certain lines these two layers separate from each other so as to form channels lined with endothelium. These channels are the **venous blood-sinuses** which receive the blood from veins which come from various parts of the brain. They are described in the section dealing with the Vascular System.

Strong fibrous partitions or *septa* are given off along certain lines from the deep

FIG. 595.—SAGITTAL SECTION THROUGH THE SKULL, A LITTLE TO THE LEFT OF THE MEDIAN PLANE to show the arrangement of the dura mater.

The cerebral nerves are indicated by numerals.

surface of the dura mater. These project into the cranial cavity, and subdivide it partially into compartments which all freely communicate with each other, and each of which contains a definite subdivision of the brain. These *septa* are: (1) the *falx cerebri*; (2) the *tentorium cerebelli*; (3) the *falx cerebelli*; and (4) the *diaphragma sellæ*.

The *falx cerebri* is a sickle-shaped partition which descends in the great longitudinal fissure between the two hemispheres of the cerebrum. In front it is narrow, and attached to the *crista galli* of the ethmoid bone. As it is followed backwards it increases in breadth, and behind it is attached along the median plane to the upper surface of the *tentorium*. The anterior narrow part of the *falx* is frequently cribriform, and is sometimes perforated by apertures to such an extent that it almost resembles lace-work. Along each border it splits into two layers, so as to enclose a blood-sinus. Along its superior convex attached border runs the *superior sagittal sinus*; along its concave free border sometimes courses the much smaller *inferior*

sagittal sinus; whilst along its attachment to the tentorium is enclosed the *straight sinus*.

The **tentorium cerebelli** is a large crescentic partition of dura mater, which forms a membranous tent-like roof for the posterior cranial fossa, and thus intervenes between the posterior portions of the cerebral hemispheres and the cerebellum. It is accurately applied to the superior surface of the cerebellum. Thus its highest point is in front and in the median plane, and from this it slopes downwards towards its attached border. It is kept at a high degree of tension, and this depends on the integrity of the falx cerebri, which is attached to its superior aspect in the median plane.

The *posterior border* of the tentorium is convex, and is attached to the horizontal ridge which marks the deep surface of the occipital bone. Beyond this, on each side, it is fixed to the postero-inferior angle of the parietal bone, and then forwards along the superior border of the petrous portion of the temporal bone. From the internal occipital protuberance to the postero-inferior angle of the parietal bone this border encloses the *sinus transversus*, whilst along the superior border of the petrous bone it encloses the *superior petrosal sinus*. The *anterior border* of the tentorium is sharp, free, and concave, and forms with the dorsum sellæ an oval opening shaped posteriorly like a pointed arch. This opening receives the name of the *incisura tentorii*, and within it is placed the mesencephalon, or the stalk of connexion between the parts which lie in the posterior cranial fossa and the cerebrum. Beyond the apex of the petrous part of the temporal bone the two margins of the tentorium cross each other like the limbs of the letter X; the free margin is continued forwards, to be attached to the anterior clinoid process, whilst the attached border proceeds medially, to be fixed to the posterior clinoid process.

The **falx cerebelli** is a small, sickle-shaped process of dura mater placed below the tentorium, which projects forwards in the median plane from the internal occipital crest. It occupies the notch which separates the two hemispheres of the cerebellum posteriorly. Inferiorly it bifurcates into two small diverging ridges which gradually fade away as they are traced forwards on each side of the foramen magnum.

The **diaphragma sellæ** is a small circular fold of dura mater which forms a roof for the fossa hypophyseos. A small opening is left in its centre for the transmission of the infundibulum.

Dura Mater Spinalis.—In the vertebral canal the dura mater forms a tube which encloses the spinal medulla, and which extends from the foramen magnum above to the level of the second or third piece of the sacrum below. It is very loosely applied to the spinal medulla and the nerve-roots which form the cauda equina; in other words, it is very capacious in comparison with the volume of its contents. Moreover, its calibre is not uniform. In the cervical and lumbar regions it is considerably wider than in the thoracic region, whilst in the sacral canal it rapidly contracts, and finally ends by blending with the filum terminale externum, the chief bulk of which it forms. At the superior end of the vertebral canal the spinal dura mater is firmly fixed to the third cervical vertebra, to the epistropheus vertebra, and around the margin of the foramen magnum. In the sacral canal the filum terminale externum, with which it blends, extends downwards to the back of the coccyx, to the periosteum of which it is fixed. The inferior end of the tube is thus securely anchored and held in its place.

Within the cranial cavity the dura mater is closely adherent to the bones, and forms for them an internal periosteum. As it is followed into the vertebral canal its two constituent layers separate. The inner layer is carried downwards as the long cylindrical tube which encloses the spinal medulla. The outer layer, which is much thinner, becomes continuous behind and on each side of the foramen magnum with the periosteum on the exterior of the cranium, whilst in front it is prolonged downwards into the vertebral canal in connexion with the periosteum and ligaments on the anterior wall of the canal. The spinal dura mater, therefore, corresponds to the inner layer of the cranial dura mater, and to it alone. It is separated from the walls of the vertebral canal by an interval, the **cavum epidurale**, which is occupied by

soft fat and a plexus of thin-walled veins. In connexion with the spinal dura mater there are no blood-sinuses such as are present in the cranial cavity, but it should be noted that the veins in the epidural space, placed as they are between the periosteum of the vertebral canal and tube of dura mater, occupy the same morphological plane as the cranial blood-sinuses. Another feature which serves to distinguish the spinal dura mater from the cranial dura mater consists in the fact that it gives off from its deep surface no partitions or septa.

The cylindrical tube of spinal dura mater does not lie absolutely free within the vertebral canal. Its attachments, however, are of such a character that they in no way interfere with the free movement of the vertebral column. On each side the spinal nerve-roots, as they pierce the dura mater, carry with them into the intervertebral foramina tubular sheaths of the membrane, whilst in front loose fibrous prolongations—more numerous above and below than in the thoracic region—connect the tube of dura mater to the posterior longitudinal ligament of the vertebral column. No connexion of any kind exists between the dura mater and the posterior wall of the vertebral canal.

When the interior of the tube of spinal dura mater is inspected, the series of apertures of exit for the roots of the spinal nerves is seen. These are ranged in pairs opposite each intervertebral foramen.

Viewed from the inside of the tube of dura mater, each of the two roots of a spinal nerve is seen to carry with it a special and distinct sheath. When examined on the outside, however, the appearance is such that one might be led to conclude that both roots are enveloped in one sheath of dura mater. This is due to the fact that the two sheaths are firmly held together by intervening connective tissue. The two tubular sheaths remain distinct as far as the ganglion on the posterior root, and then blend with each other.

Cavum Subdurale.—The dura mater and the arachnoid are closely applied to each other, and the capillary interval between them is termed the **subdural space**. It contains a minute quantity of fluid, which is just sufficient in amount to moisten the opposed surfaces of the two bounding membranes.

The subdural space in no way communicates with the subarachnoid space. The fluid which it contains is led into the venous blood-sinuses around the arachnoideal granulations (O.T. Pacchionian bodies), and thus gains exit. The subdural space is carried outwards for a very short distance on the various nerves which are connected with the brain and the spinal medulla, and it has a free communication with the lymph-paths present in these nerves. In the case of the optic nerve the sheath of dura mater is carried along its whole length, and with it the subdural space is likewise prolonged to the back of the eyeball.

ARACHNOIDEA.

The **arachnoid** is a very thin membrane, remarkable for its delicacy and transparency, which envelopes both the brain and the spinal medulla between the dura mater and the pia mater. The cranial part of the arachnoid or the **arachnoidea encephali**, except in the case of the longitudinal and the lateral fissures, does not dip into the sulci on the surface of the brain. In this respect it differs from the pia mater. It bridges over the inequalities on the surface of the brain. Consequently, on the basal aspect of the encephalon it is spread out in the form of a very distinct sheet over the medulla oblongata, the pons, and the hollow which lies in front of the pons, and in certain of these regions it is separated from the brain-surface by wide intervals.

The spinal part of the arachnoid or **arachnoidea spinalis**, which is directly continuous with the cranial arachnoidea, forms a loose wide investment for the spinal medulla. This arachnoideal sac is most capacious towards its inferior part, where it envelops the inferior end of the spinal medulla and the collection of long nerve-roots which constitute the cauda equina.

As the nerves, both from the brain and the spinal medulla, pass outwards they receive an investment from the arachnoid, which runs for a short distance upon them and then comes to an end.

Cavum Subarachnoideale.—The interval between the arachnoidea and the pia mater receives the name of the subarachnoid space. It contains the cerebro-spinal fluid, and communicates freely through certain well-defined apertures with the ventricular cavities in the interior of the brain (*aperturæ ventriculi quarti*).

Within the cranium the subarachnoid space is broken up by a meshwork of fine filaments and trabeculæ, which connects the two bounding membranes (*viz.*, the arachnoidea and the pia mater) in the most intimate manner, and forms a delicate sponge-like interlacement between them. Where the arachnoidea passes over the summit of a cerebral convolution, and is consequently closely applied to the subjacent pia mater, the meshwork is so dense and the trabeculæ so short that it is hardly possible to discriminate between the two membranes. To all intents and purposes they form in these localities one lamina. In the intervals between the rounded margins of adjoining convolutions, however, distinct angular spaces exist, where the subarachnoid trabecular tissue can be studied to great advantage. These

FIG. 596.—DIAGRAM to show the relations of the membranes of the brain to the cranial wall and the cerebral convolutions, and also of the arachnoideal granulations to the superior sagittal sinus and the lateral lacunæ.

intervals on the surface of the cerebrum constitute numerous communicating channels which serve for the free passage of the subarachnoid fluid from one part of the brain to another. The larger branches of the arteries and veins of the brain traverse the subarachnoid space; their walls are directly connected with the subarachnoid trabeculæ, and are bathed by subarachnoid fluid.

In certain situations within the cranium the arachnoidea is separated from the pia mater by intervals of considerable width and extent. These expanded portions of the subarachnoid space are termed *cisternæ subarachnoideales*. In these the subarachnoid tissue is much reduced. There is no longer a close meshwork; the trabeculæ connecting the two bounding membranes take the form of long filamentous intersecting threads which traverse the spaces. All the subarachnoid cisterns communicate in the freest manner with each other and also with the narrow channels on the surface of the cerebrum.

Certain of these cisterns require special mention. The largest and most conspicuous is the *cisterna cerebellomedullaris*. It is formed by the arachnoid membrane bridging over the wide interval between the posterior part of the inferior surface of the cerebellum and the medulla oblongata. It is continuous

through the foramen magnum with the posterior part of the wide subarachnoid space of the spinal medulla.

The *cisterna pontis* is the continuation upwards on the floor of the cranium of the anterior part of the subarachnoid space of the spinal medulla. In the region of the medulla oblongata it is continuous behind with the *cisterna cerebello-medullaris*, so that this subdivision of the brain, like the spinal medulla, is surrounded by a wide subarachnoid space.

FIG. 597.—MEMBRANES OF THE SPINAL MEDULLA, AND THE MODE OF ORIGIN OF THE SPINAL NERVES.

of the *optic chiasma* (*cisterna chiasmatis*), and from this it is continued into the longitudinal fissure above the corpus callosum. In this subarachnoid passage the anterior cerebral arteries are lodged.

The spinal part of the subarachnoid space is a very wide interval which is partially subdivided into compartments by three incomplete septa. One of these is a medial partition called the *septum posterius*, which connects the pia mater covering the posterior aspect of the spinal medulla with the arachnoid. In the upper part of the cervical region the *septum posterius* is imperfect, and is merely represented by some strands passing between the two membranes; in the inferior part of the cervical region and in the thoracic region it becomes tolerably complete. The other two septa are formed by the *ligamenta denticulata* which spread laterally one from each side of the spinal medulla. These will be described with the pia mater.

Granulationes Arachnoideales.—When the surface of the dura mater is inspected after the removal of the calvaria, a number of small fleshy-looking excrescences, purplish-red in colour, are seen ranged in clusters on each side of the superior sagittal sinus, and when this sinus is opened they are also observed protruding in considerable numbers into its interior. These are the arachnoideal granulations (O.T. Pacchionian bodies), and they are also found in smaller numbers and distinctly smaller size in connexion with other blood-sinuses, such as the transverse sinus, the straight sinus, and the cavernous sinus. At first sight they appear to belong to the dura mater, but in reality they are projections from the arachnoid. In the child they are exceedingly small and rudimentary, and it is only as life advances that they become large and conspicuous.

Each granulation is a bulbous protrusion of the arachnoid. It is attached to the arachnoid by a narrow pedicle, and into its interior is prolonged through this a continuation of the subarachnoid space and its characteristic mesh-work. The granulations do not pierce the dura mater. As they push their way into a blood-sinus they carry before them a thin covering continuous with the

In front of the pons the arachnoidea bridges across between the projecting temporal lobes, and covers in the deep hollow in this region of the brain. This space is called the *cisterna interpeduncularis*, and within it are placed the large arteries which take part in the formation of the arterial circle (of Willis). Leading out from the interpeduncular cistern there are certain wide subarachnoid channels. Two of these are prolonged into the lateral fissures, and in these are accommodated the middle cerebral arteries. Anteriorly the interpeduncular cistern passes into a space in front

sinus wall. On each side of the superior sagittal sinus there is a number of irregular spaces in the dura mater which communicate with the sinus either by a small aperture or a narrow channel. These spaces are called the *lacunæ laterales*, and certain of the meningeal veins and some of the diploic veins open into them. Granulations push themselves into the lateral lacunæ from below in such a manner that they receive a complete covering from the layer of dura mater which forms the sinus floor. Nor does the bone escape. As the granulations enlarge they cause absorption of the cranial wall, and small pits are hollowed out on its internal surface for their reception. It must be clearly understood, however, that in such cases the granulation is separated from the bone by the following:—(1) A continuation round the granulation of the subdural space; (2) the thinned floor of the lateral lacuna; (3) the lumen of the sinus; and (4) the greatly thinned upper wall of the sinus.

The granulations have a special function to perform. Through them fluid can pass from the subarachnoid space into the venous sinuses with which they stand in connexion. Whenever the pressure of blood in the sinuses is lower than that of the fluid in the subarachnoid space and the ventricles of the brain, the cerebro-

FIG. 598.—MEDIAN SECTION THROUGH THE CRANIAL VAULT IN THE FRONTAL REGION. Displays a portion of the superior sagittal sinus and the arachnoid granulations protruding into it (enlarged).

spinal fluid filtrates through the granulations into the blood-sinuses. This is not the only way that subarachnoid fluid may obtain exit. The subarachnoid space is carried outwards for a short distance on the nerves in connexion with their arachnoid sheaths, and communicates with the lymph channels of the nerves. This connexion is more complete in the case of the olfactory, the optic, and the acoustic nerves than in other nerves. A very free communication between the subarachnoid space and the lymph-vessels of the nasal mucous membrane is said to exist.

THE PIA MATER.

The pia mater forms the immediate investment of the brain and spinal medulla. It is a delicate and very vascular membrane.

Pia Mater Encephali.—The pia mater which covers the brain is finer and more delicate than that which clothes the spinal medulla. It follows closely all the inequalities on the surface of the brain, and in the case of the hemisphere it dips into each sulcus in the form of a fold which lines it completely. On the cerebellum the relation is not so intimate; it is only into the larger fissures that it penetrates in the form of folds.

The larger blood-vessels of the brain lie in the subarachnoid space. The finer twigs ramify in the pia mater before they proceed into the substance of the brain. As they enter they carry with them sheaths derived from the pia mater. When a portion of the membrane is raised from the surface of the encephalon, numerous fine processes are withdrawn from the cerebral surface. These are the blood-vessels with their sheaths, and they give the deep surface of the pia mater a rough and flocculent appearance.

As the pia mater is carried over the inferior part of the roof or posterior wall of the fourth ventricle of the brain it receives the name of the *tela chorioidea*

ventriculi quarti, and it is in connexion with this portion of the pia mater that the chorioid plexuses of that cavity are developed. The **tela chorioidea ventriculi tertii** (O.T. **velum interpositum**), is a fold of pia mater which is invaginated into the brain, so that it comes to lie over the third ventricle and to project in the shape of chorioid plexuses into the lateral ventricles. This invagination requires special notice.

The **tela chorioidea ventriculi tertii** (O.T. **velum interpositum**) is a double layer or fold of pia mater which intervenes between the body of the fornix, which lies above it, and the epithelial roof of the third ventricle and the two thalami, which lie below it. Between its two layers are blood-vessels, and some subarachnoid

FIG. 599.—DISSECTION TO SHOW THE CHORIOID TELA OF THE THIRD VENTRICLE, AND THE PARTS IN IMMEDIATE RELATION TO IT.

trabecular tissue. In shape the chorioid tela of the third ventricle is triangular, and the narrow anterior end or apex reaches forwards as far as the interventricular foramina. The base lies under the splenium of the corpus callosum, and here the two layers of the tela separate and become continuous with the investing pia mater on the surface of the brain by passing out through a cleft called the **transverse fissure**.

Along each lateral margin the tela chorioidea of the third ventricle is bordered by the chorioid plexus of the body of the lateral ventricle, which projects into the ventricular cavity from under cover of the free lateral margin of the fornix. It should be borne in mind that the epithelial lining of the ventricle gives a complete covering to the chorioid plexus. Posteriorly the chorioid plexus is continuous with the similar structure in the inferior horn of the ventricle, whilst in front it

narrows greatly, and becomes continuous across the median plane with the corresponding plexus of the opposite side, behind the epithelial layer which lines the interventricular foramen. From this median junction two much smaller chorioid plexuses run backwards on the under surface of the tela chorioidea, and project downwards into the third ventricle. These are the chorioid plexuses of the third ventricle.

The most conspicuous blood-vessels in the tela chorioidea are the two internal cerebral veins, which run backwards, one on each side of the median plane. In front, each is formed at the apex of the fold by the union of the vena terminalis and a large vein issuing from the chorioid plexus; behind, they unite to form the **vena cerebri magna** [Galen], and this pours its blood into the anterior end of the straight sinus (Fig. 599, p. 674).

The continuous cleft in the brain through which the chorioid tela of the third ventricle and the chorioid plexuses of the two inferior horns of the lateral ventricles are introduced into the interior of the brain is sometimes called the **transverse fissure**. It consists of a superior intermediate part and two lateral parts. The former passes forwards between the corpus callosum and the fornix above and the roof of the third ventricle and the thalami below. It is limited on each side by the epithelial covering of the chorioid plexuses, which shuts out these structures from the cavity of the lateral ventricles. The

lateral part is the **chorioid fissure**. This is continuous with the intermediate part, and has already been described in connexion with the inferior horn of the lateral ventricle (p. 636).

Pia Mater Spinalis.—The pia mater of the spinal medulla is thicker and denser than that of the brain. This is largely due to the addition of an outside fibrous layer, in which the fibres run chiefly in the longitudinal direction. The pia mater is very firmly adherent to the surface of the spinal medulla, and in front it sends a fold into the anterior-median fissure of the spinal medulla. The posterior median septum is likewise firmly attached to its deep surface. In front of the anterior-median fissure of the spinal medulla the pia mater is thickened in the form of a longitudinal glistening band, termed the **linea splendens**, which runs along the whole length of the spinal medulla, and blends with the **filum terminale** below. The blood-vessels of the spinal medulla lie between the two layers of the pia mater.

The nerves which leave both the brain and spinal medulla receive closely

FIG. 600.—DIAGRAM OF A FRONTAL SECTION ACROSS THE CHORIOID TELA OF THE THIRD VENTRICLE.

applied sheaths from the pia mater. These blend with the connective-tissue sheaths of the nerves.

The **ligamentum denticulatum** is a strong fibrous band which stretches out like a wing from the pia mater on each side of the spinal medulla, so as to connect the pia mater with the dura mater. The pial or medial attachment of the ligament extends in a continuous line between the anterior and posterior nerve-roots, from the level of the foramen magnum above to the level of the first lumbar vertebra below. Its lateral margin is serrated or denticulated, and for the most part free. From twenty to twenty-two denticulations may be recognised. They occur in the intervals between the spinal nerves, and pushing the arachnoid before them, they are attached by their pointed ends to the inner surface of the dura mater. The ligamenta denticulata partially subdivide the wide subarachnoid space in the vertebral canal into an anterior and a posterior compartment. The anterior nerve-roots traverse the anterior compartment, whilst the posterior nerve-roots traverse the posterior compartment. Further, the posterior compartment is imperfectly subdivided into a right and a left lateral part by the septum posterius.

By means of the ligamenta denticulata the spinal medulla is suspended in the middle of the tube of dura mater.

THE PERIPHERAL NERVES AND THE SYMPATHETIC SYSTEM.

By A. MELVILLE PATERSON, M.D., F.R.C.S.

Professor of Anatomy in the University of Liverpool.

THE nervous mechanism comprised under this title is responsible for the transmission of peripheral impulses to the brain and spinal medulla, through afferent nerves, and for the distribution of central impulses to peripheral structures through efferent nerves. The peripheral nerves are at the outset divisible into two series :—

FIG. 601.—SCHEME OF THE ARRANGEMENT OF THE MEMBRANES OF THE SPINAL MEDULLA AND THE ROOTS OF THE SPINAL NERVES.

cerebral nerves, derived from or associated with the brain, and spinal nerves, arranged in pairs in relation to the spinal medulla. Associated with the spinal nerves is the sympathetic system. The animal body is naturally divided into two different areas or regions, the somatic area, forming the trunk and body wall, and innervated by the larger (somatic) parts of the spinal nerves, and the splanchnic

area, comprising the chief viscera contained within the body-cavity. This area is governed by the sympathetic system, subordinate to and controlled by its connexions with the splanchnic or visceral branches of the spinal nerves.

The **cerebral nerves** are twelve in number, arranged in pairs; they present striking differences in origin, in distribution, and in functions.

Number.	Name.	Function.	Superficial Attachment to Brain.
I.	Olfactory	Smell	Olfactory bulb.
II.	Optic	Sight	Optic chiasma.
III.	Oculomotor	Motor to the muscles of eyeball and orbit	Cerebral peduncle.
IV.	Trochlear	Motor to superior oblique muscle of eyeball	Anterior medullary velum.
V.	Trigeminal	Sensory to face, tongue, and teeth; motor to muscles of mastication	Pons.
VI.	Abducent	Motor to lateral rectus muscle of eyeball	Junction of pons and medulla oblongata.
VII.	Facial	Motor to muscles of scalp and face, sensory to tongue	Posterior border of pons.
VIII.	Acoustic	Hearing and equilibrium	Posterior border of pons.
IX.	Glossopharyngeal	Sensory to tongue and pharynx	Medulla oblongata.
X.	Vagus	Sensory to pharynx, œsophagus and stomach, and respiratory organs	Medulla oblongata.
XI.	Accessory	(a) Accessory to vagus .—Motor to muscles of palate, pharynx, œsophagus, stomach and intestines, and respiratory organs; inhibitory for heart (b) Spinal part : motor to trapezius and sterno-mastoid muscles	Medulla oblongata. Spinal medulla.
XII.	Hypoglossal	Motor to muscles of the tongue	Medulla oblongata.

The **spinal nerves** are usually thirty-one in number, also arranged in pairs. Each nerve arises by two roots from the spinal medulla, one posterior and ganglionic, the other anterior and not gangliated. After each root has pierced separately the dura mater, the two roots become enclosed in a common sheath, and unite to form the spinal nerve in the intervertebral foramen; emerging from this, the nerve is distributed to the trunk and limbs in a manner to be described later.

The nerves are designated **cervical, thoracic, lumbar, sacral, and coccygeal**, in relation to the vertebræ between which they emerge from the vertebral canal. Each nerve appears below the corresponding vertebra, except the first of the cervical series, which passes out of the vertebral canal between the occipital bone and the atlas. There are thus *eight* cervical nerves (the last appearing between the seventh cervical and first thoracic vertebræ); there are *twelve* thoracic, *five* lumbar, *five* sacral, and *one* coccygeal nerve, all appearing below the corresponding vertebræ.

The thirty-first nerve is occasionally absent; and there are sometimes one or two additional pairs of minute filaments below the thirty-first, which, however, do not emerge from the vertebral canal. These are rudimentary caudal nerves.

The size of the spinal nerves varies extremely. The largest are those which take part in the formation of the great nerve-trunks for the supply of the limbs (lower cervical and first thoracic, and lower lumbar and upper sacral nerves); and of these the nerves destined for the lower limbs are the larger. The coccygeal nerve is the smallest of the spinal nerves; the thoracic nerves (except the first) are much more slender than the limb nerves; and the cervical nerves diminish in size from below upwards.

Systema Sympathicum.—The **sympathetic system** consists of a gangliated trunk, connected on the one hand in certain regions to the spinal nervous system by a series of **white rami communicantes**—splanchnic or visceral branches of the spinal nerves; and on the other hand distributing branches (a) to the spinal nerves (**gray rami communicantes**), and (b) to the viscera and vessels occupying the splanchnic area. It

serves to collect and transmit to the spinal medulla impulses from the viscera, and to distribute efferent fibres to vessels in the splanchnic area, and to glands and involuntary muscle-fibres.

DEVELOPMENT OF THE PERIPHERAL NERVES AND SYMPATHETIC SYSTEM.

DEVELOPMENT OF THE SPINAL NERVES.

I. **Origin of the Spinal Nerve Roots.**—The process of development of the spinal nerves commences by means of the outgrowth of **posterior** and **anterior roots** from the medullary tube. The two roots take origin in pairs in quite different ways.

F, Formation of nerve trunks in relation to the limb: dorsal and ventral trunks corresponding to lateral and anterior trunks in D and E.

The **posterior root** is the first to appear,—before, during, or after the union of the medullary plates and the formation of the neural tube.

It takes origin as a **ganglionic crest**, forming a continuous lateral unsegmented band, on the dorsal surface of the medullary tube. It may arise in one of three ways: (1) from the junction of the medullary plate and surface epiblast, before the closure of the medullary groove; (2) from a *neural crest*, a median ridge on the dorsum of the completed tube; or (3) as a direct outgrowth from the dorsal surface of the medullary tube. The ganglionic crest becomes completely separated from the medullary tube, and secondarily its cells (**neuroblasts**) become rapidly spindle-shaped, and by the end of the fourth week give rise to *two sets of processes*: (1) a **central series**, which grow centrally

and are secondarily connected with the dorso-lateral aspect of the medullary tube as the fibres of the posterior root; and (2) a **peripheral series**, which constitute the posterior root-fibres of the spinal nerve and join the anterior root, to form the spinal nerve proper. It is only after the appearance of these nerve-fibres that the ganglionic crest becomes notched along its peripheral border, and it is gradually divided up to form the individual segmental spinal ganglia.

The **anterior root** of a spinal nerve arises in quite a different way, from cells (**neuroblasts**) in the substance of the medullary tube. In the account of the development of the spinal medulla it has been shown how the cellular constituents of the medullary tube are converted into two classes of cells: (1) **spongioblasts**, which produce the matrix (neuroglia) of the spinal medulla; and (2) **neuroblasts**, which produce the nerve-cells of the gray matter of the spinal medulla. The neuroblasts give rise to the axis-cylinder processes or **axons**, which, penetrating the spongy tissue of the medullary tube and the outer limiting membrane, find their way into the mesodermic tissue on the ventro-lateral surface of the tube. Fibrous from their earliest origin and derived from nerve-cells which remain within the medullary tube, the axons of the anterior root become surrounded by mesodermic cells immediately on their emergence, which give rise to the sheaths of the nerve. The anterior root is a little later in its date of appearance than the posterior root. It begins to be evident at the twenty-fourth day and is completely formed by the twenty-eighth day.

II. Formation of the Spinal Nerve.—The fibres of the posterior root ganglion and the anterior root grow by extension from the cells with which they are respectively connected, and meet in the space between the myotome and the side of the medullary tube to form the **spinal nerve**. In the adult there is a fundamental division of the spinal nerve into posterior and anterior rami. In the process of development this separation is even more obvious. As the fibres of the posterior and anterior roots approximate, they separate at the same time each into two unequal portions: the smaller parts of the two roots unite together to form the **posterior**, and the larger parts unite to form the **anterior ramus** of the spinal nerve.

The **posterior ramus**, curving laterally and dorsally, passes through the myotome and is connected with it. In the substance of the myotome it separates into branches as it proceeds towards the dorsal wall of the embryo. At a later stage, the branches are definitely arranged into a lateral and a medial series.

The **anterior ramus** grows gradually in a ventral direction to reach the somato-splanchnopleuric angle, under cover of the growing myotome. It spreads out at its distal end and eventually separates into two portions: a smaller, **splanchnic**, or **visceral**; and a larger, **somatic**, or **parietal** portion. (1) The smaller, **splanchnic**, or **visceral portion** grows inwards, dorsal to the Wolfian ridge, to be connected through the sympathetic trunk with the innervation of organs in the splanchnic area. This branch of the spinal nerve becomes the **white ramus communicans** of the sympathetic. It is not present in the case of all the spinal nerves, but only in relation to the thoracic and upper lumbar and the third and second or fourth sacral nerves. It will be referred to again in connexion with the sympathetic system. (2) The larger, **somatic**, or **parietal portion** becomes the main part of the anterior ramus of the nerve. It continues the original ventral course of the nerve, and, reaching the body wall, subdivides into two terminal branches—a **lateral branch**, which grows laterally and downwards and reaches the lateral aspect of the trunk, after piercing the myotome; and a **ventral or anterior branch**, which grows onwards in the body wall to reach the ventral axis. This arrangement is met with in the trunk between the limbs and in the neck.

III. Formation of Limb-plexuses.—The method of growth of the spinal nerves, just described, is modified in the regions where the limbs are developed. In relation to the limbs, which exist in the form of buds of undifferentiated cellular mesoblast before the spinal nerves have any connexion with them, the development of the anterior ramus of the nerve proceeds exactly in the way described up to the point of formation of somatic and splanchnic branches. The **somatic branches** then stream out into the limb bud, passing into it below the ends of the myotomes and spreading out into a bundle of fibres at the basal attachment of the limb. Later, the nerves separate each into a pair of definite trunks, which are named posterior or **dorsal** and anterior or **ventral**, and which, dividing round a central core of mesoderm, proceed to the dorsal and ventral surfaces respectively of the limb bud. While this process is going on, a **secondary union** takes place between parts of adjacent dorsal and ventral trunks. Dorsal trunks unite with dorsal trunks, ventral trunks unite with ventral trunks, to form the nerves distributed ultimately to the surfaces and periphery of the limb. These **dorsal and ventral**

trunks are homologous with the **lateral and ventral branches** of the somatic nerves in other regions.

DEVELOPMENT OF THE SYMPATHETIC SYSTEM.

There are two diametrically opposite views of the mode of development of the sympathetic system.

In birds and mammals the first rudiment of the sympathetic trunk occurs in the formation of a longitudinal unsegmented column of mesodermic cells (which stain more deeply than the mesoderm in which they lie) on either side of the aorta, and coterminous with it. This column of cells becomes joined at an early stage by the **visceral branches** of the spinal nerves which grow inwards from the main nerve trunks into the splanchnic area, and result from the division of the nerve into somatic and visceral parts. These visceral branches constitute the **white rami communicantes**. They receive contributions usually from both posterior and anterior roots, and gradually approaching the above-mentioned column of mesodermic cells, they become intimately associated with the cells. In some cases fibres of the visceral nerves pass over the cellular column into the splanchnic area without connexion with it (Fig. 603). By the junction of these visceral nerves with the cells of the column, certain cells persist and produce the **ganglia**. The intervening portions of the column, by changes in the cells, and by the addition of fibres belonging to the visceral nerves, give rise to the **commissural cords**. The cellular column, besides producing the gangliated trunk, by the further growth of its cells and their extension centrally and peripherally, produces the **gray rami communicantes**, parts of the **peripheral branches**, and the **peripheral** (collateral and terminal) **ganglia**, as well as the medullary portion of the **suprarenal gland**. The cervical, lower lumbar, and sacral portions of the sympathetic gangliated trunk are secondary extensions from the primitive trunk, gradually growing upwards and downwards along the main vessels. These portions of the system are not provided with white rami communicantes. The ganglia of the sympathetic assume their segmented appearance (1) from the persistence of the primitive cells and their connexion with the spinal nerves by means of the white and gray rami communicantes, and (2) from the way in which the primitive column is moulded by the surrounding structures (bones, segmental arteries, etc.).

In another account of the development of the sympathetic system (Onodi), the gangliated trunk is described as an outgrowth of the thoracic spinal ganglia of the spinal nerves. It is said that each ganglion gives off a bud at its inferior end, which, growing inwards into the splanchnic area, becomes attached to the trunk of the spinal nerve just beyond the union of the posterior and anterior roots. The bud still extending inwards into the splanchnic area, remains associated with the nerve by an attenuated stalk. These buds, it is said, become the ganglia, which, after reaching their permanent place in the splanchnic area, are supposed to grow upwards and downwards so as to coalesce and form a beaded chain of ganglia. The stalks connecting the ganglia with the spinal nerves become the white rami communicantes. This mode of development does not satisfactorily account for several important features of the sympathetic system—the development of those parts of the gangliated trunk which possess no white rami, the absence of a truly segmental character in the trunk, and the constancy of its continuity. No instance is recorded

FIG. 603.—THE DEVELOPMENT OF THE SYMPATHETIC GANGLIATED TRUNK.

Sy, Sympathetic trunk; Spl, Splanchnic branches of spinal nerves (white rami communicantes); V.S, Vertebral segments; D.G, Spinal ganglia.

of a hiatus between two ganglia. It is, on the other hand, an attractive view, as it ascribes to one germinal layer (ectoderm) the formation of all the elements of the nervous system, and it brings the sympathetic ganglia into serial homology with the isolated ganglia—ciliary, sphenopalatine, and otic—associated with the trunks of the trigeminal cerebral nerve.

THE DEVELOPMENT OF THE CEREBRAL NERVES.

The cerebral nerves are divisible morphologically into three series:—(1) those associated with sense organs—the first or olfactory, second or optic, and eighth or acoustic; (2) those connected with the embryonic branchial arches—the fifth or trigeminal, seventh or facial, ninth, tenth, and eleventh, glossopharyngeal, vagus, and accessory; and (3) motor nerves distributed to muscles derived from cephalic myotomes—the third or oculomotor, fourth or trochlear, sixth or abducent, and twelfth or hypoglossal.

Omitting the olfactory and optic nerves, which are special vesicular outgrowths of the brain itself, it is possible to trace a distinct homology in the process of development of the other cerebral and the spinal nerves. In the primitive brain the gray matter is arranged into **Alar** and **Basal Laminæ** (His), comparable to the postero-lateral and anterior areas of gray matter (columns) of the spinal medulla. The basal lamina again may be split up into lateral and medial areas.

The origin of the third, fourth, sixth, and twelfth cerebral nerves—all motor efferent nerves—is from the medial part of the basal lamina of the primitive brain, in serial homology with the anterior efferent roots of the spinal nerves.

The efferent motor roots of the fifth, seventh, ninth, tenth, and eleventh nerves arise from the lateral part of the basal lamina, and so may be differentiated from the previous series.

The afferent sensory roots of the fifth, seventh (intermediate nerve), eighth, ninth, and tenth nerves are homologous with the posterior roots of the spinal nerves. They are all gangliated, and are connected with the alar lamina of the brain.

I. The **olfactory nerves** are associated in their development with the formation of the olfactory pit and the olfactory bulb.

The **olfactory pits** appear on each side of the front of the head at a little later period than the formation of the lens and the auditory vesicle. They become converted into the nasal cavities by the formation of the pre-oral visceral clefts and arches,—fronto-nasal and ethmo-vomerine in the median plane, and lateral ethmoid and maxillary processes at the sides (p. 49).

The **Rhinencephalon** or **olfactory bulb** is a hollow outgrowth from each telencephalon or cerebral hemisphere, and appears in the first month. It grows forwards into relation with the deep surface of the nasal pit. In many animals (as in the horse) the olfactory bulb remains hollow; but in the human subject it loses its lumen and becomes a solid bulb (**olfactory bulb**) connected to the brain by a narrow stalk, the **olfactory tract**.

The **epithelium of the olfactory pit** is responsible for the formation of the olfactory nerves. There are two views as to the mode of their development from the epithelial cells. Both views admit the proliferation of the epithelium of the nasal pit so as to produce *neuroblasts*. According to the one view these neuroblasts detach themselves from the epithelial surface, and constitute an **olfactory ganglion** which becomes applied to and incorporated with the olfactory bulb. The cells of the ganglion become bi-polar, and the peripheral axons constitute the *olfactory nerves*, while the central axons (in the second month) proceed backwards to the brain along the olfactory tract. According to the other view (based on Disse's investigations), the proliferating cells of the nasal epithelium remain in the wall of the nasal pit, and become the *olfactory cells* of the nasal cavity, with peripheral processes projecting to the surface of the epithelium. Their central axons become the olfactory nerve fibres which end in the olfactory bulb, forming dendrites associated with the dendritic processes of the nerve-cells of the bulb. The central axons of these latter cells develop into the fibres of the olfactory tract.

II. The **optic nerve** is developed wholly from the brain. Its formation begins with the outgrowth of the optic vesicle, a paired hollow outgrowth from the ventral surface of the diencephalon. The ectodermic invagination of the lens, growing inwards from the surface of the head, causes the collapse of the vesicle and its conversion into the **optic**

cup, the narrow tube connecting the vesicle to the brain becoming the **optic stalk**. This stalk becomes solid, and forms the basis of the optic tract, optic chiasma, and optic nerve. The optic cup, bilaminar in form, and by its edge clasping the lens, is imbedded in mesodermic tissue, which gives rise to the envelopes of the eyeball, etc. The *outer layer* of the optic cup produces the layer of hexagonal pigment cells of the retina. The cells of the *inner layer* produce the tissues of the retina proper. They form neuroblasts with peripheral and central processes. The peripheral processes are converted into retinal nerve tissues; the central processes extend backwards along the optic stalk, and give rise to the optic nerve, optic chiasma, and optic tract. Spongioblasts in the inner lamina of the optic cup produce the sustentacular tissue of the retina (Müller's fibres). The mesodermic tissue surrounding the optic cup and lens gives rise to the rest of the structure of the eyeball, the formation of which is described in the section which deals with the organs of sense.

III. The **oculomotor nerve** arises, like the ventral root of a spinal nerve, from a group of neuroblasts in the medial part of the basal lamina of the mid-brain. The peripheral fibres extend forwards, to end around the optic cup in the mesodermic tissue, from which the eye muscles are derived. Numerous cells are carried along with the cell processes in their course, and these have been described as being concerned in the formation of the *ciliary ganglion*.

IV. The **trochlear nerve** also arises from a group of neuroblasts occupying the medial part of the basal lamina of the mid-brain, close to its junction with the hind-brain. The peripheral processes do not emerge directly from the brain, but extend dorsally from their origin along the side of the brain to its dorsal aspect, where they appear, after decussating with the fibres of the opposite nerve, just behind the quadrigeminal lamina.

V. The **trigeminal nerve** is developed by means of a large posterior and a small anterior root. Their origin to a large extent resembles the mode of formation of the roots of a spinal nerve.

The large **posterior (afferent) root** is formed by means of a cellular bud from the alar lamina of the hind-brain. This bud separates from the brain, and forms the semi-lunar ganglion. Its cells becoming bipolar, like the cells of a spinal ganglion, are secondarily connected with the brain by means of their central processes; while the peripheral processes, separating into three groups, proceed along the fronto-nasal and maxillary processes, and along the mandibular arch, to form the three main divisions of the nerve. Numerous cells accompany each main division in its course from the ganglion, and form eventually the subordinate ganglia—the *ciliary* on the ophthalmic nerve, the *spheno-palatine* on the maxillary nerve, and the *otic ganglion* on the mandibular nerve.

The small **anterior (efferent) root** of the trigeminal nerve, like the motor anterior root of a spinal nerve, is later in its appearance than the sensory root. It arises as the peripheral fibres of a group of neuroblasts occupying the lateral part of the basal lamina of the hind-brain, which proceed directly to the surface to join the mandibular division of the nerve.

VI. The **abducens nerve** resembles in its mode of development the oculomotor and trochlear nerves with which in its origin it is in series. It is formed by the peripheral processes of a group of neuroblasts in the medial part of the basal lamina in the upper part of the hind-brain. These processes pierce the part of the brain in which, at a later stage, the fibres of the pyramid are developed. They then proceed to the mesodermic tissue round the optic cup, which is destined to form the eye muscles.

VII. The **facial nerve** has developmentally a double origin. (1) In connexion with the formation of the acoustic nerve a group of cells becomes separated from the alar lamina of the hind-brain opposite the auditory vesicle. This group becomes separated into three parts, of which the middle portion is the rudiment of the **genicular ganglion** which becomes incorporated with the efferent part of the facial nerve, and is connected to the brain by a slender root, known as the **intermediate nerve** (O.T. *pars intermedia*). (2) The **efferent root** of the nerve arises from a group of neuroblasts in the lateral part of the basal lamina of the hind-brain, in series with efferent fibres of the vago-glossopharyngeal nerves; after a tortuous course within the brain its fibres emerge beneath the above-mentioned cellular mass, opposite the auditory vesicle. They are joined by the ganglionic root, and in their course round the auditory vesicle become imbedded in the auditory capsule (canalis facialis). The chorda tympani nerve appears early as a branch of the facial nerve. It is probable that the intermediate nerve, the genicular ganglion, and the chorda tympani nerve together represent the **posterior afferent element** in the constitution of this nerve.

VIII. The **acoustic nerve** arises as a cellular bud from the alar lamina of the hind-

brain, dorsal to the efferent portion of the facial nerve, opposite to the auditory vesicle, and in close association with it.

Becoming separated from the brain, the cellular mass separates into three portions, of which the intermediate part is associated with the facial nerve and intermediate nerve (as the genicular ganglion), while the medial and lateral parts are converted into the medial (vestibular) and, lateral (cochlear) ganglia and the roots of the acoustic nerve. The cells becoming bipolar, their central processes are secondarily connected with the brain on the dorsal (lateral) aspect of the facial nerve; the peripheral processes proceed to the auditory vesicle, to which they are distributed as the vestibular and cochlear nerves. Numerous cells are carried along with the nerve trunks into relation with the auditory capsule, and constitute the vestibular and cochlear ganglia.

IX. and X. The **glossopharyngeal** and **vagus nerves** are developed from the side of the hind-brain, both in the same way, and each by two roots. A collection of cells separates itself from the alar lamina of the hind-brain behind the auditory vesicle to form the **ganglionic afferent root**. The ganglion of the vagus is much larger than that of the glossopharyngeal. Each ganglion becomes divided into two parts, a proximal and a distal portion, connected together by a commissural band of fibres. The proximal ganglion (superior ganglion of the glossopharyngeal; jugular ganglion of the vagus) is secondarily connected by centripetal fibres to the hind-brain. From the distal ganglion (petrous

FIG. 604.—COMPARISON OF ORIGINS OF NERVE ROOTS FROM SPINAL MEDULLA AND HIND-BRAIN (after His).
A. Spinal medulla; B. Hind-brain.

ganglion of the glossopharyngeal; ganglion nodosum of the vagus) peripheral fibres grow outwards to form the nerve trunk.

Each nerve is also provided with a small **efferent root**, consisting of nerve fibres, arising from a collection of neuroblasts in the lateral part of the basal lamina of the hind-brain, and emerging beneath the ganglionic root at the junction of the alar and basal laminae (in series with the fibres of the efferent root of the facial nerve above and of the accessory nerve below).

XI. The **accessory nerve** arises in two parts—one medullary, the other spinal. The **medullary** (accessory) portion develops as the processes of a series of neuroblasts in the lateral portion of the basal lamina of the hind-brain, which emerge in series with the efferent roots of the glossopharyngeal and vagus nerves. The **spinal portion** arises as the processes of a group of neuroblasts in the anterior part of the medullary tube (anterior column), which, turning outwards, emerge as a series of roots on the lateral aspect of the spinal medulla.

XII. The **hypoglossal nerve** is developed, not in series with the nerves above mentioned, but like the third, fourth, and sixth nerves, from the medial part of the basal lamina of the hind-brain, in the space between the glossopharyngeal and other nerves above, and the first cervical nerve below. It is formed as a series of peripheral processes from a collection of neuroblasts occupying the hind-brain. **Froriep's ganglion** is a transitory collection of nerve cells developed from the alar lamina of the hind-brain on the dorsal aspect of the nerve, and represents in a rudimentary condition its posterior ganglionic root. The ganglion gives off no branches and soon disappears.

DESCRIPTION OF THE PERIPHERAL NERVES AND SYMPATHETIC SYSTEM.

I. THE SPINAL NERVES.

Origin of the Spinal Nerves.—Each spinal nerve is attached to the spinal medulla by two roots, called respectively **posterior** (dorsal, afferent) and **anterior** (ventral, efferent).

The **posterior root** is larger than the anterior root; it contains a larger number of radicular fibres, and the individual fibres are of larger size than in the anterior root. It has a vertical linear attachment to the postero-lateral sulcus of the spinal medulla. The fibres of contiguous posterior roots are in close relation, and, in some instances, overlap. The posterior root separates as it passes away from the spinal medulla into two bundles, both of which become connected with the proximal end of a **spinal ganglion**. From the distal end of this ganglion the posterior root proceeds to its junction with the anterior root in the intervertebral foramen.

The **spinal ganglia** are found on the posterior roots of all the spinal nerves. (In the case of the first cervical or sub-occipital nerve, the spinal ganglion may be rudimentary or absent; and the posterior root itself may be wanting, or derived from the accessory nerve.) They occupy the intervertebral foramina, except in the case of the sacral and coccygeal nerves, the ganglia of which lie *within* the vertebral canal; and the first and second cervical nerves, the ganglia of which lie upon the vertebral arches of the atlas and epistropheus respectively. With the exception of the coccygeal ganglia they are outside the cavity of the dura mater, but are invested by the membrane. The ganglia are of ovoid form, bifurcated in some cases at their proximal ends. They consist of unipolar nerve-cells, whose axons, after a very short course, divide into central (root) and peripheral (trunk) fibres. The central fibres form the portion of the root entering the spinal medulla; the peripheral fibres are continued in a lateral direction from the ganglion into the spinal nerve.

Ganglia Aberrantia (aberrant spinal ganglia).—Between the spinal ganglion and the spinal medulla small collections of cells are occasionally found on the posterior roots, either as scattered cells or distinct ganglia. They are most frequently met with on the posterior roots of the lumbar and sacral nerves.

The **anterior root** is smaller than the posterior root. It arises from the anterior surface of the spinal medulla (*anterior root zone*) by means of scattered bundles of nerve-fibres, which occupy a greater horizontal area and are more irregular in their arrangement than the radicular fibres of the posterior root. It possesses no ganglion in its course. The rootlets sometimes overlap, and are not infrequently connected with neighbouring radicular fibres above and below.

The dorsal and ventral roots, from their attachment to the spinal medulla, proceed

FIG. 605.—DIAGRAMMATIC REPRESENTATION OF THE ORIGIN OF THE SPINAL NERVES, showing the position of their roots and ganglia respectively in relation to the vertebral column. The nerves are shown as thick black lines on the left side.

laterally in the vertebral canal towards the intervertebral foramina, where they unite to form the spinal nerve. The direction of the roots of the first two nerves is upwards and laterally; the roots of the remaining nerves course obliquely downwards and laterally, the obliquity gradually increasing until, in the case of the lower lumbar, the sacral and coccygeal nerve-roots, their course is vertically downwards in the vertebral canal. The collection of nerve-roots which occupies the lower part of the canal below the first lumbar vertebra, and comprises all the nerve-roots below those of the first lumbar nerve, is designated the *cauda equina*. They arise from the lumbar enlargement and *conus medullaris*, and surround the *filum terminale* of the spinal medulla.

Within the vertebral canal the nerve-roots are in relation with the meninges of the spinal medulla, and are separated from one another by the *ligamentum denticulatum*, and, in the neck, by the spinal part of the accessory nerve. Each receives a covering of *pia mater*, continuous with the *neurilemma*; the *arachnoid* invests

FIG. 606.—THE ORIGIN AND DISTRIBUTION OF A TYPICAL SPINAL NERVE.

each root as far as the point where it meets with the *dura mater*; and each root pierces the *dura mater* separately. The two roots are thereafter enclosed in a single tubular sheath of *dura mater*, in which is included the spinal ganglion of the posterior root. The spinal nerve thus ensheathed occupies the intervertebral foramen (except the first two cervical and the sacral and coccygeal nerves).

Divisions of a Spinal Nerve.—After emerging from the intervertebral foramen the nerve immediately divides into two primary divisions, named respectively the **posterior** and **anterior rami** (O.T. **posterior** and **anterior primary divisions**). Just before its division each nerve gives off a minute meningeal (**recurrent**) branch, which re-enters the vertebral canal after effecting a junction with a branch from the sympathetic trunk, and is distributed to the spinal medulla and its membranes.

The **posterior** and **anterior rami** of the spinal nerves are mainly somatic in their distribution, and are responsible for the innervation of the skeletal muscles and of the skin covering the trunk and limbs.

White Rami Communicantes.—From the anterior rami of certain nerves (second thoracic to second lumbar inclusive) a series of fine nerves arises, which serves to connect the spinal with the sympathetic system. These **visceral** or **splanchnic branches**, or **white rami communicantes**, through the medium of the gangliated trunk of the sympathetic, serve to innervate the vessels and viscera in the splanchnic area. A second stream of **pelvic splanchnic nerves**, associated with the second and third, or third and fourth sacral nerves, connects these spinal nerves with the pelvic sympathetic plexuses (p. 766).

The posterior and anterior rami of the nerves contain fibres from both posterior and anterior roots. Indeed, each root can be seen, on removal of its sheath, to divide into two portions, of which one portion enters into the formation of the posterior, the other into the formation of the anterior ramus. The posterior rami, with the exception of the first two, are smaller than the anterior rami. They are responsible for the innervation of the skin and axial muscles of the back. They do not supply the muscles of the limbs; although in their cutaneous distribution they are prolonged on to the back of the head, the shoulder, and the buttock. They form two small plexuses—the **posterior cervical** and the **posterior sacral plexuses**. The anterior rami are, with the exception of the first two cervical nerves, much larger than the posterior rami. They supply the sides and anterior parts of the body, the limbs, and the perineum. For the most part they have a complicated arrangement. The thoracic or intercostal nerves alone have a simple mode of distribution; the other nerves give rise to the three great **plexuses**—**cervical**, **brachial**, and **lumbo-sacral**.

Distribution of the Spinal Nerves.—Although the distribution, like the origin of the spinal nerves, presents primarily and essentially a segmental arrangement, this is masked, and in some instances obliterated by developmental changes in the parts supplied. In no region can an isolated nerve be traced to a complete segment. The nearest approach to a complete girdle of innervation is found in the thoracic region, in such a nerve as the sixth thoracic nerve. Yet even such a nerve is not distributed to any part entirely alone. In its cutaneous distribution it supplies a complete belt of skin, a distinctly segmental area from the median plane posteriorly to the median plane anteriorly; yet at the same time the adjacent nerves overstep, so to speak, the boundaries of the area and assist in the cutaneous nerve supply. Its muscular distribution, also, is segmental; the anterior ramus supplies the intercostal muscles of the space in which it lies; but in this it forms communications with adjacent nerves. The posterior ramus supplies axial muscles of the back, not, however, in an obviously segmental manner, on account of the fusion of the segmental myotomes in the formation of complex longitudinal muscles, which are together supplied by the series of muscular branches derived from the posterior rami of contiguous nerves. In other regions still greater changes of structure are accompanied by deviations from a segmental type of distribution, causing the foundation of the nerve-plexuses by which the trunk and limbs are innervated.

POSTERIOR RAMI OF THE SPINAL NERVES.

The **posterior rami** (O.T. posterior primary divisions) of the spinal nerves innervate both skin and muscles; the skin of the trunk posteriorly, the back of the head, the shoulder and the buttock, and the longitudinal muscles of the back, but not the muscles of the limbs.

Each posterior ramus divides as a rule into two parts, a **medial** and a **lateral trunk** (Fig. 606, p. 686). In the upper half of the body the medial trunks generally supply the cutaneous branches, while the lateral trunks are purely muscular nerves. In the lower part of the body the opposite is the case: the lateral trunks provide the cutaneous nerves and the medial trunks are distributed entirely to muscles. The cutaneous branches have a different course in the two cases. In the upper half of the back they course backwards beneath and among the muscles to within a short distance of the spinous processes of the vertebræ, close to which they become superficial. They then extend laterally in the superficial fascia. In the lower half of the back the cutaneous nerves are directed downwards

and laterally among the muscles, and become superficial at a greater distance from the median plane. In both regions the nerves pursue a sinuous course to the surface, and the lower series emerge and become superficial a considerable distance below the level of their spinal origin. There are considerable individual differences in the origin, course, and distribution of the several nerves.

CERVICAL NERVES.

First Cervical Nerve (N. sub-occipitalis).—It has already been pointed out that the posterior root of this nerve may be rudimentary, or even absent altogether. Its posterior ramus is larger than the anterior ramus; it does not divide into medial or lateral branches, and it does not directly supply any cutaneous branch.

Passing backwards, in the space between the occipital bone and the posterior arch of the atlas, the nerve occupies the sub-occipital triangle, and is placed below and behind the vertebral artery, and under cover of the semispinalis capitis muscle. It supplies the following branches:—

(a) Muscular branches to the semispinalis

FIG. 607.—THE DISTRIBUTION OF CUTANEOUS NERVES ON THE BACK OF THE TRUNK.

On one side the distribution of the several nerves is represented, the letters indicating their nomenclature.

G.O. (C.2), Greater occipital; C.3, Third occipital; T.1 et seq., Posterior rami of thoracic nerves; L.1 et seq., Posterior rami of first three lumbar nerves; S.1 et seq., Posterior rami of sacral nerves; Acr, Posterior supra-clavicular branches from cervical plexus; T.2-12, Lateral branches of thoracic nerves; Circ, Cutaneous branches of axillary nerve; L.1, Iliac branch of ilio-hypogastric nerve; E.C, Lateral cutaneous nerve; S.Sc, Posterior cutaneous nerve of thigh.

On the other side a schematic representation is given of the areas supplied by the above nerves, the numerals indicating the spinal origin of the branches of distribution to each area.

capitis, rectus capitis posterior major and minor, and obliqui capitis, superior and inferior.

(b) A **communicating branch** descends to join the second cervical nerve.

The communicating branch may arise in common with the nerve to the obliquus inferior, and reach the second cervical nerve by piercing or passing over or beneath that muscle; or it may accompany the nerve to the semispinalis capitis and communicate with the greater occipital nerve, under or over that muscle.

Second Cervical Nerve.—The posterior ramus of this nerve is larger than the corresponding anterior ramus. It passes backwards between the atlas and epistropheus, and in the interval between the obliquus inferior and the semispinalis cervicis muscles, under cover of the semispinalis capitis muscle. In this situa-

FIG. 608.—POSTERIOR CERVICAL PLEXUS.

tion the nerve gives off several small muscular and communicating branches. The main trunk, after piercing the semispinalis capitis and trapezius muscles, accompanies the occipital artery to the scalp as the **greater occipital nerve**. This is the chief cutaneous nerve for the back part of the scalp. It enters the superficial fascia at the level of the superior nuchal line of the occipital bone and about an inch from the external occipital protuberance. Ramifying over the surface, it supplies the skin of the scalp as far as the vertex. It *communicates* on the scalp with the following nerves: great auricular, lesser occipital, posterior auricular, and third occipital.

The **muscular branches** of the second cervical nerve are destined for the semispinalis capitis, obliquus inferior, semispinalis cervicis, and multifidus.

Its **communicating branches** form the **posterior cervical plexus**. Descending over the posterior arch of the atlas is a branch from the sub-occipital nerve which forms a loop or network with a corresponding branch of the second nerve. From this loop twigs are supplied to the surrounding muscles. A similar loop is formed by a communication between branches of the second and third nerves, from which muscles are also supplied. Occasionally an additional loop is formed between branches of the third and fourth nerves.

Third Cervical Nerve.—This is much smaller than the second nerve. Near its origin it forms a loop of communication with the second, and it may give off a similar communicating branch to the fourth nerve. The main trunk divides into medial cutaneous and lateral muscular branches. The lateral muscular branch enters contiguous muscles; the medial cutaneous branch passes backwards and medially, and becomes superficial as the **third occipital nerve** (*n. occipitalis minimus*), close to the median plane of the neck. It supplies fine branches to the neck and scalp, and communicates with the greater occipital nerve.

The fourth, fifth, and sixth cervical nerves are still smaller. Beneath the semispinalis capitis each divides into lateral muscular and medial cutaneous branches. The muscular branches supply neighbouring muscles; the cutaneous branches are small nerves, which, passing backwards, become superficial close to the median plane. They supply the skin of the back of the neck. The sixth is the smallest, and the cutaneous branches of the fifth and sixth nerves may be absent altogether. In certain cases the fourth nerve forms, with the third, a loop of communication from which muscles are supplied.

Seventh and Eighth Cervical Nerves.—These are the smallest of the posterior rami of the cervical nerves. They give off ordinarily no cutaneous branches, and end in the deep muscles of the back. There is occasionally a small cutaneous offset from the eighth nerve.

THORACIC NERVES.

The posterior ramus of each thoracic nerve divides into **medial** and **lateral branches**. In the case of the upper six or seven thoracic nerves the medial branches are chiefly distributed as cutaneous nerves,—only giving off small muscular branches—while the lateral branches are wholly muscular in their distribution; in the case of the lower five or six thoracic nerves the opposite is the case. In all cases the muscular branches serve to innervate the longitudinal muscles of the back. The distribution of the cutaneous branches is different in the upper and lower part of the back. The *upper six* or *seven* thoracic nerves innervate the skin of the scapular region. The **medial cutaneous branches**, after a sinuous backward course from their origin, among the dorsal muscles, reach the surface near the spines of the vertebræ and are directed almost horizontally laterally over the trapezius muscle. The first is small; the second is very large and reaches to the acromion. The rest diminish in size, from above downwards, and become more and more oblique in direction. The **lateral cutaneous branches** of the *lower five* or *six* thoracic nerves are directed from their origin obliquely downwards and laterally among the parts of the sacro-spinalis muscle. Becoming cutaneous by piercing the latissimus dorsi at some distance from the median plane, they supply the skin of the back in the lower part of the chest and loin, the lowest nerves (eleventh and twelfth) reaching over the iliac crest on to the buttock. The lower nerves often subdivide into two branches before or after their emergence from the latissimus dorsi muscle.

LUMBAR NERVES.

First three Lumbar Nerves.—The posterior rami of the first three lumbar nerves subdivide into medial and lateral branches, in the same way as the lower thoracic nerves. The medial branches are muscular and innervate the deep muscles of the back. The lateral branches are chiefly cutaneous. They are directed obliquely downwards and outwards among the fibres of the sacro-spinalis and become superficial by piercing the lumbo-dorsal fascia, just above the iliac crest and a short distance in front of the posterior iliac spine. They are then directed downwards in the superficial fascia of the buttock, and supply a lengthy strip of skin, extending from the median plane above the iliac crest to a point distal to and behind the greater trochanter of the femur. There may be only two cutaneous branches, derived from the first two lumbar nerves; in other cases the three nerves are the branches of the twelfth thoracic and first two lumbar nerves.

The fourth and fifth lumbar nerves (like the last two cervical nerves) usually supply only muscular branches to the longitudinal muscles of the back. The fifth nerve in many cases sends a branch to form a loop of connexion with the posterior ramus of the first sacral nerve (posterior sacral plexus).

SACRAL AND COCCYGEAL NERVES.

The posterior rami of the sacral nerves issue from the posterior sacral foramina. As in the case of the thoracic and lumbar nerves, the upper sacral nerves differ from the lower in their distribution.

The first three sacral nerves supply medial muscular branches for the multifidus, and lateral cutaneous branches which pierce the fibres of the sacro-tuberous ligament and the glutæus maximus muscle, and supply the skin over the back of the sacrum and contiguous part of the buttock, giving rise to the posterior sacral plexus.

The posterior sacral plexus consists, like the posterior cervical plexus, of loops or plexiform communications over the back of the sacrum between the posterior rami of the first three sacral nerves, to which are frequently joined branches of the last lumbar nerve and fourth and even the fifth sacral nerve. From these loops branches proceed to supply the multifidus muscle; others, piercing the sacro-tuberous ligament, form secondary loops beneath the glutæus maximus muscle. From the secondary loops, two or more cutaneous branches arise, which, after traversing the muscle, supply the skin over the sacrum and medial part of the buttock.

Posterior Ano-coccygeal Nerve.—The posterior rami of the fourth and fifth sacral nerves do not divide into medial and lateral branches. They unite together to form a loop which is joined by the minute posterior ramus of the coccygeal nerve. The union of the three nerves constitutes the posterior ano-coccygeal nerve, which, after perforating the sacro-tuberous ligament, is distributed to the skin in the neighbourhood of the coccyx. It supplies no muscles. This nerve is the representative of the superior caudal trunk of tailed animals.

MORPHOLOGY OF THE POSTERIOR RAMI.

There are several points of morphological interest in relation to the posterior rami of the spinal nerves.

1. **Muscular Distribution.**—In their muscular distribution they are strictly limited to the longitudinal muscles of the back: namely, those associated with the axial skeleton alone.

2. **Cutaneous Distribution.**—Their cutaneous distribution represents two points of interest.

A. In the first place, while the skin of the back is supplied in a regularly segmental manner by the several nerves, certain of them fail to reach the surface at all. The absence of a cutaneous branch from the sub-occipital nerve may be due either to the absence of a perfect posterior root, or to its communication with the second nerve. The other nerves which do not usually supply the skin are the last two, three, or four cervical, and the fourth and fifth lumbar nerves. These nerves are placed in the centre of regions in which the upper and lower limbs are developed. They are minute nerves, while the corresponding anterior rami are among the largest of the spinal nerves. Thus, opposite the centre of each limb, posteriorly, there is a hiatus in the segmental distribution of the posterior rami of the spinal nerves to the skin of the shoulder and buttock, attributable to the formation of the limbs, and the extension into them of the greater part of the nerves of the region. This gap, in the case of the upper limb, commences at the level of the vertebra prominens; in the case of the lower limb it commences opposite the level of the posterior superior iliac spine. It can be continued on to each limb as a hypothetical area (the dorsal axial line), which indicates the area of contact (and overlapping) of cutaneous nerves not in strictly numerical sequence. Thus, in the region of the shoulder, the sixth (or fifth) cervical nerve innervates an area of skin adjoining that supplied by the eighth cervical or first thoracic nerve; in the region of the buttock the third lumbar nerve supplies an area contiguous with that supplied by the fifth lumbar or first sacral nerve.

B. The cutaneous branches of the posterior rami of the spinal nerves differ from the muscular branches in respect of their penetration into regions beyond those supplied by their motor roots. The cutaneous branches, in regions where outgrowths or extensions from the trunk have occurred, follow these extensions; and, in consequence, supply skin covering parts which do not belong to segments represented by the nerves in question. Thus the second and third cervical nerves (greater and third occipital) are drawn upwards so as to supply the posterior part of the scalp; the upper thoracic nerves are drawn laterally over the scapular region; the upper lumbar and sacral nerves supply the skin of the buttock; and the ano-coccygeal nerve forms a rudimentary caudal nerve.

3. **Plexuses.**—The plexuses formed by the posterior rami of the upper cervical and upper sacral nerves are the simplest met with in the human body. The posterior cervical plexus is one from which muscular branches are supplied; the posterior sacral plexus is mainly concerned in producing cutaneous offsets. In the case of the **posterior cervical plexus** the loops of communication between the first three or four cervical nerves result in the formation of a series of nerves for the supply of the semispinales and other muscles, which bring into contact with these muscles, simultaneously, a considerable area of the spinal medulla, and provide a combined and simultaneous innervation for the several parts of each muscle. In the case of the **posterior sacral plexus**, the formation of loops between the nerves results in the innervation of any given spot in the cutaneous area supplied from these loops by more than one spinal nerve. As has been said already, the cutaneous nerves, even without the formation of plexuses, overlap in their cutaneous distribution. The formation of a plexus causes a more intimate union of neighbouring spinal nerves, so that stimulation of the surface affects a wider area in the spinal medulla than if the nerves passed separately to it from the surface. While segmentation becomes less obvious, increased co-ordination is effected both of movement and sensation.

ANTERIOR RAMI OF THE SPINAL NERVES.

The **anterior rami** (O.T. **anterior primary divisions**) of the spinal nerves, are, with the exception of the first two cervical nerves, much larger than the corresponding posterior rami. Composed of elements of both posterior and anterior roots, each nerve separates from the posterior ramus on emerging from the intervertebral foramen, and, proceeding laterally, is distributed to structures on the lateral and anterior aspects of the body,—including the limbs.

Each nerve is joined near its origin by a **gray ramus communicans** from the sympathetic gangliated trunk; and in the case of certain thoracic, lumbar, and sacral nerves, the anterior ramus gives off a delicate bundle of fibres, which forms the **white ramus communicans** of the sympathetic trunk. That part of the spinal nerve which is distributed to the body wall and limbs may be termed **somatic**; the small white ramus communicans, innervating structures in the splanchnic area, may be termed the **visceral** or **splanchnic** part of the spinal nerve.

The anterior rami of the spinal nerves are distributed in a regular segmental manner only in certain cases. Except in the case of the thoracic nerves, the anterior rami combine to form the three great **plexuses**—cervical, brachial, and lumbo-sacral—and their arrangement and distribution is rendered exceedingly complex.

A **thoracic nerve**, such as the fifth or sixth, may be regarded as a type to illustrate the mode of distribution of the anterior rami of the spinal nerves (Fig. 606, p. 686). It occupies an intercostal space; near its origin it possesses *gray* and *white rami communicantes*; it courses through the interval between the intercostal muscles; it supplies branches to these muscles and gives off, when it reaches the side of the chest, a *lateral branch*, which, after supplying small muscular branches, pierces the external intercostal muscle, and is distributed to an area of skin over the lateral part of the trunk, contiguous dorsally with a similar area, innervated by the cutaneous branches of the posterior ramus of the same nerve. The lateral branch generally subdivides into a smaller *posterior* and a larger *anterior ramus*, as it pierces the muscles clothing the wall of the chest. The anterior ramus of the nerve then pursues its course obliquely forwards to the side of the sternum, where, after piercing the pectoral muscles, it appears superficially as the *terminal anterior cutaneous branch*. This supplies an area of skin continuous with that supplied by the anterior part of the lateral branch of the same nerve. Such a nerve thus supplies, by means of its lateral and anterior branches, an area of skin which (with the area supplied by the cutaneous branch of its posterior ramus) forms a continuous and uninterrupted belt, extending from the median plane behind to the median plane in front. The lateral and anterior branches of the nerve innervate in their course the intercostal and other muscles, to be afterwards mentioned in detail.

NERVI CERVICALES.

The anterior rami of the cervical nerves, together with parts of the first and second thoracic nerves, are distributed to the head, neck, and upper extremity.

The first four cervical nerves, by means of the cervical plexus, innervate the neck;

FIG. 609.—THE DISTRIBUTION OF CUTANEOUS NERVES ON THE FRONT OF THE TRUNK.

On one side the distribution of the several nerves is represented, the letters indicating their nomenclature.

G.A., Great auricular nerve ; S.C., N. cutaneus colli ; S.C.L., Supra-clavicular nerves ; ACR., Posterior ; CL., Middle ; St., Anterior ; T.2-12, Lateral and anterior branches of thoracic nerves ; I.H., Ilio-hypogastric nerve ; L.I., Ilio-inguinal nerve ; CIRC., Cutaneous branch of axillary nerve ; L.I.C., Medial cutaneous nerve of the arm (lesser internal cutaneous nerve) ; I.H., Intercosto-brachial ; I.C., Medial cutaneous nerve of the forearm (internal cutaneous) ; M.S., Cutaneous branch of radial nerve ; E.C., Lateral cutaneous nerves ; G.C., Lumbo-inguinal nerve ; M.C.¹, Intermediate cutaneous nerves ; I.C.¹, Branch of medial cutaneous nerve ; P., Branches of pudendal nerve ; S.Sc., Branches of posterior cutaneous nerve of the thigh.

On the other side a schematic representation is given of the areas supplied by the above nerves, the numerals indicating the spinal origin of the branches of distribution to each area.

the last four cervical nerves, together with a large part of the first thoracic nerve,

through the brachial plexus, supply the upper limb. The second thoracic nerve may contribute a trunk to this plexus, and always assists in the innervation of the arm.

PLEXUS CERVICALIS.

The anterior rami of the first four cervical nerves are concerned in forming the cervical plexus. Each nerve emerges from the vertebral canal posterior to the

FIG. 610.—THE CERVICAL PLEXUS.

vertebral artery. Each is joined on its emergence from the intervertebral foramen, at the side of the vertebral column, by a **gray ramus communicans** from the superior cervical ganglion of the sympathetic. In the neck the cervical nerves are concealed by the sterno-mastoid muscle; in front lies the longus capitis muscle, and behind are the scalenus medius, and (behind the first or sub-occipital nerve) the rectus capitis lateralis. The cervical plexus is constituted by the combination of these nerves in an irregular series of loops under cover of the sterno-mastoid muscle.

From these loops the branches of distribution arise, as (*a*) **cutaneous branches** to the head, neck, and shoulder; (*b*) **muscular branches** to muscles of the neck and to

the diaphragm; and (c) **communicating branches** to the vagus, accessory, hypoglossal, and sympathetic nerves.

For convenience of description, the nerves derived from the plexus may be classified as follows:—

I. Superficial (cutaneous) Branches—

<p>A. Ascending Branches (C. 2, 3).
 N. occipitalis minor (smaller occipital),
 N. auricularis magnus (great auricular),
 N. cutaneus colli (O.T. superficial cervical).</p> | <p>B. Descending (supra-clavicular) Branches (C. 3, 4).
 Nn. supraclaviculares anteriores (O.T. supra-sternal),
 Nn. supraclaviculares medii (O.T. supra-clavicular),
 Nn. supraclaviculares posteriores (O.T. supra-acromial).</p> |
|---|--|

II. Deep (muscular and communicating) Branches—

<p>A. Lateral Branches.
 1. Muscular branches to
 Sternomastoid (C. 2),
 Trapezius (C. 3, 4),
 Levator scapulæ (C. 3, 4),
 Scaleni (medius and posterior) (C. 3, 4).
 2. Communicating branches to
 Accessory nerve (C. 2, 3, 4).</p> | <p>B. Medial Branches.
 1. Muscular to
 Prevertebral muscles (C. 1, 2, 3, 4),
 Infra-hyoid muscles (C. 1, 2, 3)
 (ansa hypoglossi),
 Diaphragm (C. 3, 4) (phrenic nerve).
 2. Communicating branches to
 Vagus nerve (C. 1, 2),
 Hypoglossal nerve (C. 1, 2),
 Comm. hypoglossi (C. 2, 3),
 Sympathetic (C. 1, 2, 3, 4).</p> |
|--|---|

The second, third, and fourth cervical nerves are the chief nerves engaged in forming the plexus. The first cervical nerve only enters into the formation of a small part—the medial portion of the deep part of the plexus.

Superficial Cutaneous Branches.—These nerves, six in number, are entirely cutaneous. They radiate from the plexus, and appear in the posterior triangle of the neck at the posterior border of the sternomastoid muscle. They are divisible into two series, the one **ascending**: smaller occipital, great auricular, and cutaneous nerve of the neck; the other **descending** (supra-clavicular): posterior, middle, and anterior.

Ascending Branches.—The smaller occipital nerve is variable in size and is sometimes double. Its origin is from the second and third cervical nerves (more rarely from the second only). It extends backwards beneath the sternomastoid, and then upwards along its posterior border. Piercing the deep fascia near the apex of the posterior triangle, it divides into **auricular, mastoid, and occipital branches**, and supplies small **cervical branches** to the upper part of the neck. The auricular branch supplies the skin of the cranial surface of the auricle; the mastoid and occipital branches supply the scalp. The nerve communicates on the scalp with the greater occipital and great auricular nerves, and with the posterior auricular branch of the facial nerve.

The **great auricular nerve** is the largest of the cutaneous branches. It arises from the second and third cervical nerves (or, more rarely, from the third alone). Winding round the posterior border of the sternomastoid muscle, it courses vertically upwards towards the ear. In this course it crosses the sternomastoid muscle obliquely and is covered by the platysma muscle. Before arriving at the ear it subdivides into mastoid, auricular, and facial branches. The **mastoid branches** ascend over the mastoid process and supply the skin of the scalp behind the ear, communicating with the smaller occipital and posterior auricular nerves. The **auricular branches** ascend to the ear and supply the lower part of the auricle on both aspects; they communicate with the same nerves. The **facial branches**, passing over the angle of the jaw and through the substance of the parotid gland,

supply the skin of the cheek over the inferior part of the masseter muscle and the parotid gland. They communicate with branches of the facial nerve in the parotid gland.

The *nervus cutaneus colli* arises from the second and third cervical nerves. It winds round the posterior border of the sterno-mastoid muscle, and crosses the muscle to reach the anterior triangle, under cover of the platysma muscle and the external jugular vein. It divides near the anterior edge of the sterno-mastoid muscle into superior and inferior branches, which are distributed through the platysma to the skin covering the anterior triangle of the neck. The upper branches communicate freely beneath the platysma with the ramus colli of the facial nerve.

Descending (supra-clavicular) Branches.—By the union of two roots derived

FIG. 611.—DISTRIBUTION OF CUTANEOUS NERVES TO THE HEAD AND NECK.

from the third and fourth cervical nerves a considerable trunk is formed, which emerges from under cover of the sterno-mastoid muscle and extends obliquely downwards through the inferior part of the posterior triangle of the neck. It subdivides into radiating branches—**anterior, middle, and posterior**—which pierce the deep fascia of the neck above the clavicle, and are distributed to the skin of the inferior part of the side of the neck, to the front of the chest, and the shoulder. The **anterior (O.T. supra-sternal)** branches are the smallest. Passing over the medial end of the clavicle, they supply the skin of the neck and chest as far down as the *synchondrosis sternalis*. The **middle (O.T. supra-clavicular)** branches pass over the intermediate third of the clavicle, beneath the platysma, and can be traced as low as the nipple. The **posterior (O.T. supra-acromial)** branches pass over or through the insertion of the trapezius muscle, and over the lateral third of the clavicle, to the

shoulder, where they supply the skin as far down as the distal third of the deltoid muscle.

Deep Branches.—The deep branches of the cervical plexus are naturally separated into a **lateral** and a **medial set** by their relation to the sterno-mastoid muscle. Beneath the muscle, the lateral branches are directed laterally towards the posterior triangle, the medial branches medially towards the anterior triangle.

The **lateral branches** consist of muscular and communicating nerves, which for the most part occupy the posterior triangle.

The **muscular branches** are the following: (1) To the *sterno-mastoid*, from the second cervical nerve. This enters the muscle on its deep surface and communicates with the accessory nerve. (2) To the *trapezius*, from the third and fourth cervical nerves. These nerves cross the posterior triangle and end in the trapezius, after having communicated with the accessory nerve, both in the posterior triangle, and beneath the muscle. (3) To the *levator scapulae*, from the third and fourth cervical

nerves. Two independent branches enter the lateral surface of the muscle in the posterior triangle. (4) To the *scaleni* (medius and posterior), from the third and fourth cervical nerves.

The **communicating branches** are three in number. They join the accessory nerve in three situations:—(a) A branch from the second cervical nerve to the sterno-mastoid joins the accessory nerve *beneath that muscle*. (b) Branches to the trapezius from the third and fourth nerves are connected with the accessory nerve *in the posterior triangle*. (c) Branches from the same nerves join the nerve *beneath the trapezius muscle*.

FIG. 612.—THE NERVES OF THE SIDE OF THE NECK.

The medial branches of the plexus also comprise muscular and communicating branches. The first cervical nerve assists in the formation of this series of nerves, forming a slender loop with part of the second nerve in front of the transverse process of the atlas.

Communicating Branches.—(a) *With the sympathetic.*—Gray rami communicantes pass to each of the first four cervical nerves, near their origins, from the superior cervical ganglion or from the trunk below the ganglion. (b) *With the vagus nerve.*—The ganglion nodosum of the vagus nerve may be connected by a slender nerve with the loop between the first two cervical nerves. This communication is not constant. (c) *With the hypoglossal.*—An important communication occurs between the hypoglossal nerve and the loop between the first and second

cervical nerves (Fig. 613). A trunk from the loop joins the hypoglossal just beyond its exit from the skull. One fine branch from this trunk passes upwards along the hypoglossal nerve to the cranium (*meningeal branch*). The main part of the trunk accompanies the hypoglossal and separates from it to form successively three nerves—the *descendens hypoglossi*, and the nerves to the *thyreo-hyoid* and *genio-hyoid* muscles. The portion of the nerve which remains accompanies the hypoglossal to the muscles of the tongue. It is probable that no part of the hypoglossal nerve itself is concerned in the formation of these three branches. The descending branch of the hypoglossal descends in front of the internal and common carotid

FIG. 613.—THE MUSCLES OF THE HYOID BONE AND STYLOID PROCESS, AND THE EXTRINSIC MUSCLES OF THE TONGUE, WITH THEIR NERVES.

arteries, and is joined in the anterior triangle of the neck by the *descending cervical nerve*, to form the *ansa hypoglossi*, from which the *infra-hyoid* muscles are innervated. (The descending branch of the hypoglossal, in some cases, arises from the vagus nerve.)

Muscular Branches.—The muscles supplied by the medial branches of the plexus are the *prevertebral* muscles, the *genio-hyoid* and the *infra-hyoid* muscles, and the *diaphragm*.

(a) **Prevertebral Muscles.**—1. From the loop between the first and second cervical nerves a small branch arises, for the supply of the *rectus capitis lateralis*,

longus capitis, and the rectus capitis anterior. 2. From the second, third, and fourth nerves small branches supply the inter-transverse, longus colli, and longus capitis muscles. 3. From the fourth nerve a branch arises for the upper part of the scalenus anterior.

(b) **Genio-hyoid and Infra-hyoid Muscles.**—The descending cervical nerve is formed in front of the internal jugular vein by the union of two slender trunks from the second and third cervical nerves (communicantes hypoglossi). It forms a loop of communication in front of the carotid sheath with the descending branch of the hypoglossal nerve (derived ultimately from the first two cervical nerves). This loop of communication is called the *ansa hypoglossi*. It is often plexiform; and from it branches are given to the sterno-hyoid, sterno-thyreoid, and each belly of the omo-hyoid muscles. The nerve to the sterno-hyoid muscle is often continued behind the sternum, to join, in the thorax, with the phrenic nerve or the cardiac plexus.

The thyreo-hyoid and genio-hyoid muscles are supplied by branches of the hypoglossal nerve, which are also traceable back to the communication between the hypoglossal and the first two cervical nerves.

The anterior muscles in immediate relation to the median plane of the neck, between the chin and the sternum, are thus continuously supplied by the first three cervical nerves. The hypoglossal is the nerve of the muscles of the tongue, and it is not certain that it contributes any fibres to the above-named muscles.

(c) **Diaphragm.**—The phrenic nerve supplies the diaphragm.

NERVUS PHRENICUS.

The **phrenic nerve** is derived mainly from the fourth cervical nerve, reinforced by roots from the third (either directly or through the nerve to the sterno-hyoid) and fifth (either directly or through the nerve to the subclavius muscle). It passes downwards in the neck upon the scalenus anterior muscle; at the root of the neck it enters the thorax between the subclavian artery and vein, and traverses the mediastinum to reach the diaphragm, lying in the middle mediastinum between the pericardium and pleura, and anterior to the root of the lung. In its course it presents certain differences on the two sides. In the neck, on the left side, it crosses the first part of the subclavian artery; on the right side it crosses the second part. In the superior mediastinum, on the left side, it lies between the left subclavian and carotid arteries, and crosses the vagus nerve and the aortic arch. On the right side it accompanies the innominate vein and superior vena cava, and is entirely separate from the vagus nerve. The left nerve is longer than the right, owing to the position of the heart and the left half of the diaphragm. The right nerve sends fibres along the inferior vena cava through the foramen venæ cavæ. Reaching the diaphragm the nerve separates into numerous branches for the supply of the muscle; some enter its thoracic surface (sub-pleural branches), but most of the fibres supply it after piercing the muscle (sub-peritoneal branches).

The branches of the phrenic nerve are—1. Muscular (to the diaphragm); 2. pleural; 3. pericardiac; 4. inferior vena-caval; 5. suprarenal; and 6. hepatic.

The branches to the pleura and pericardium arise as the phrenic nerve traverses the mediastinum. The branches to the inferior vena cava, suprarenal gland, and liver arise after communication of the phrenic nerve with the diaphragmatic plexus of the sympathetic on the abdominal surface of the diaphragm.

Communications of the Phrenic Nerve.—1. The phrenic nerve may communicate with the nerve to the subclavius muscle. 2. It may communicate with the *ansa hypoglossi*, or a branch from it (the nerve to the sterno-hyoid). 3. It frequently communicates with the cervical part of the sympathetic. 4. It communicates with the celiac plexus by a junction upon the abdominal surface of the diaphragm with the *diaphragmatic plexus* on the inferior phrenic artery, in which a small *diaphragmatic ganglion* is found on the right side. From this junction branches are given off to the inferior vena cava, suprarenal gland, and hepatic plexus.

MORPHOLOGY OF THE CERVICAL PLEXUS.

The characteristic feature of the cervical plexus is the combination of parts of adjacent nerves into compound nerve-trunks by the formation of series of loops. The result of the formation of these loops is that parts (particularly cutaneous areas) are supplied by branches of more than one spinal nerve.

A. Cutaneous Distribution.—By the combinations of the nerves into loops the discrimination of the elements in the upper cervical nerves, corresponding to the lateral and anterior rami of a typical thoracic nerve, is made a matter of some difficulty. The second, third, and fourth nerves, through the cervical plexus, supply an area of skin extending, laterally, from the side of the head to the shoulder; anteriorly, from the face to the level of the nipple. The higher nerves supply the upper region (second and third); the lower nerves supply the lower region (third and fourth). It is not possible to strictly compare the individual nerves with the lateral and anterior rami of a thoracic nerve. A line drawn from the ear to the middle of the clavicle separates, however, a lateral from an anterior cutaneous area; and certain of the cutaneous nerves fall naturally into one of these two categories. The nerves homologous with anterior rami of intercostal nerves are the *n. cutaneus colli* and the anterior branches of the supra-clavicular series; those homologous with lateral branches are the smaller occipital and posterior supra-clavicular branches. The great auricular and middle supra-clavicular branches are mixed nerves, comprising elements belonging to both sets.

B. Muscular Distribution.—The nerves from the cervical plexus, supplying muscles, are simpler in their arrangement. They are not generally in the form of loops, and they are easily separated into lateral and anterior series. The lateral nerves comprise the branches to the *rectus capitis lateralis*, *sterno-mastoid*, *trapezius*, *levator scapulae*. The nerves in the anterior series are those to the *longus capitis*, *rectus capitis anterior*, the *hyoid* muscles, and the *diaphragm*.

It is noteworthy that the last-named muscles—*genio-hyoid*, *thyreo-hyoid*, *sterno-hyoid*, *omo-hyoid*, *sterno-thyreoid*, and *diaphragm*—are continuously supplied by branches from the first five cervical nerves: the higher muscles by the higher nerves; the lower muscles by the lower nerves.

PLEXUS BRACHIALIS.

The **Brachial Plexus** is formed by the anterior rami of the fifth, sixth, seventh, and eighth cervical nerves, along with the greater part of the first thoracic nerve. In some cases a slender branch of the fourth cervical nerve is also engaged; and the second thoracic nerve, in all cases, also contributes to the innervation of the arm, through the *intercosto-brachial* (*O.T. intercosto-humeral*) nerve. In many cases it contributes also directly to the plexus, by an intra-thoracic communication with the first thoracic nerve.

Position of the Plexus.—The nerves forming the brachial plexus appear in the posterior triangle of the neck between the *scalenus anterior* and *scalenus medius* muscles; the plexus is formed in close relation to the subclavian and axillary arteries; the nerves emanating from it accompany the artery to the axilla, where they are distributed to the shoulder and upper limb.

Communications with the Sympathetic.—The lower four cervical nerves communicate with the cervical portion of the sympathetic by means of **gray rami communicantes**. Two branches arise from the middle cervical ganglion, and join the anterior rami of the fifth and sixth nerves. Two arising from the inferior cervical ganglion join the seventh and eighth nerves. They reach the nerves either by piercing the prevertebral muscles or by passing round the border of the *scalenus anterior* muscle.

Composition of the Brachial Plexus.—In an analysis of the brachial plexus four stages may be always seen:—

- (1) The undivided nerves.
- (2) The separation of the nerves into anterior and posterior trunks; and the formation of three primary cords.
- (3) The formation of three secondary cords—lateral, medial, and posterior.
- (4) The origin of the nerves of distribution.
- (1) The undivided nerves have only a very short independent course at the side of the neck, after passing between the *scalene* muscles.

(2) Almost immediately after entering the posterior triangle there are formed three **primary cords**: the first cord is formed by the union of the fifth and sixth nerves together; the second, by the seventh nerve alone; and the third, by the union of the eighth cervical and first thoracic nerves together. While these cords are being formed, a division occurs in each of the nerves, into anterior and posterior *trunks*. The anterior and posterior trunks of the fifth, sixth, and seventh

nerves are nearly equal in size. The posterior trunk of the eighth cervical nerve is much smaller. The posterior trunk of the first thoracic nerve is very minute, and may not be present at all.

(3) The **secondary cords** of the plexus are formed by combinations of these anterior and posterior trunks in relation to the axillary artery. They are three in number. The **lateral cord** is formed by a combination of the anterior trunks of the fifth, sixth, and seventh nerves, and lies on the lateral side of the axillary artery. The **medial cord** is formed by a combination of the anterior trunk of the eighth cervical with the part of the first thoracic nerve engaged in the formation of the plexus; it lies on the medial side of the axillary artery. The **posterior cord** is made up of all the dorsal trunks from the fifth, sixth, seventh, and eighth cervical and first thoracic nerves, and lies behind the axillary artery.

FIG. 614.—THE NERVES OF THE BRACHIAL PLEXUS.

The first thoracic nerve may not contribute to the posterior cord, and the branch when present is a very small nerve.

(4) The **nerves of distribution** for the shoulder and arm are derived from these secondary cords, and receive in this way various contributions from the constituent spinal nerves. *From the lateral cord* arise the lateral anterior thoracic and musculo-cutaneous nerves, and the lateral head of the median nerve. *From the medial cord* arise the medial head of the median nerve, the ulnar nerve, medial cutaneous nerve of the forearm, medial cutaneous nerve of the arm, and the medial anterior thoracic nerve. *From the posterior cord* arise the axillary, the two subscapular, the thoraco-dorsal, and the radial nerves.

It is to be remembered that, although derived from a secondary cord formed by a certain set of spinal nerves, any given nerve does not necessarily contain fibres from all the constituent nerves; *e.g.* both the musculo-cutaneous and axillary nerves, from the lateral and posterior cords respectively, are ultimately derived only from the fifth and sixth cervical nerves. In other words, the secondary cords are merely collections of nerves of distribution bound together in a common sheath in their passage through the axilla.

THE BRANCHES OF THE BRACHIAL PLEXUS.

It is customary to separate artificially the nerves of distribution of the brachial plexus into two sets: (1) supra-clavicular and (2) infra-clavicular. Clinically it is

important to realise the position of origin of certain nerves. The nerves to the prevertebral muscles, the communication with the phrenic, the dorsal scapular, and long thoracic nerves, arise from the *anterior rami* of the nerves involved in the plexus. The supra-scapular and the nerve to the subclavius arise at the level of formation of the secondary cords; and the anterior thoracic, subscapular, and thoraco-dorsal nerves arise from the secondary cords, prior to their ultimate subdivision into the nerves of distribution for the upper limb.

Pars Supraclavicularis.—The nerves derived from the plexus above the level of the clavicle are, like the main trunks, divisible into two series; **anterior branches** arising from the front, and **posterior branches** arising from the back of the plexus (Fig. 614, p. 701).

Anterior Branches.

1. Nerves to scalenus anterior and longus colli.
2. Communicating nerve to join the phrenic nerve.
3. Nerve to the subclavius muscle.

Posterior Branches.

1. Nerves to scaleni, medius and posterior.
2. Dorsal (posterior) scapular nerve.
3. Long thoracic nerve.
4. Supra-scapular nerve.

The **muscular twigs** to the anterior scalene and longus colli muscles arise from the lower four cervical nerves, as they emerge from the intervertebral foramina.

The **communicating branch to the phrenic nerve** arises usually from the fifth cervical nerve at the lateral border of the anterior scalene muscle. It is sometimes absent, and occasionally an additional root is present from the sixth cervical nerve. In some instances the nerve is replaced by a branch from the nerve to the subclavius, which passes medially behind the sterno-mastoid muscle to join the phrenic at the inlet of the thorax.

N. Subclavius.—The nerve to the subclavius is a slender nerve, which arises from the front of the cord formed by the fifth and sixth cervical nerves. It descends in the posterior triangle of the neck over the third part of the subclavian artery. It often communicates with the phrenic nerve.

The branches to the scaleni, medius and posterior, are small trunks which arise from the lower four cervical nerves as they emerge from the intervertebral foramina.

N. Dorsalis Scapulæ.—The dorsal scapular nerve (O.T. posterior scapular or nerve to the rhomboids) arises from the back of the fifth cervical nerve, as it emerges from the intervertebral foramen. It appears in the posterior triangle of the neck, after piercing the scalenus medius muscle. It is directed downwards, under cover of the levator scapulæ and rhomboid muscles, and along the vertebral margin of the scapula, to be distributed to the levator scapulæ, rhomboideus minor, and rhomboideus major muscles. It occasionally pierces the levator scapulæ.

N. Thoracalis Longus.—The long thoracic nerve (O.T. posterior thoracic or external respiratory nerve of Bell) arises by three roots, of which the middle one is usually the largest, from the back of the fifth, sixth, and seventh nerves, as they emerge from the intervertebral foramina. The nerve pierces the scalenus medius as two trunks, of which the lower represents the contribution from the seventh cervical nerve, and, descending along the side of the neck behind the cords of the brachial plexus, it enters the axilla between the superior edge of the serratus

FIG. 615.—DIAGRAM OF THE ORIGIN AND DISTRIBUTION OF THE NERVES TO THE PECTORAL MUSCLES.

anterior muscle and the axillary artery. It continues its downward course over the outer surface of the serratus, to the slips of which it is distributed.

There is a more or less definite relation between the roots of this nerve and the parts of the serratus muscle. The first part of the muscle is innervated by the fifth nerve alone; the second part by the fifth and sixth, or the sixth alone; the third part by the sixth and seventh, or the seventh nerve alone.

N. Suprascapularis.—The supra-scapular nerve arises from the back of the cord formed by the fifth and sixth cervical nerves in the posterior triangle of the neck. It occupies a position above the main cords of the brachial plexus, and courses downwards and laterally parallel to them towards the superior margin of the scapula. It passes through the scapular notch to reach the dorsum of the scapula. After supplying the supra-spinatus muscle it winds round the great scapular notch in company with the transverse scapular artery and terminates in the infra-spinatus muscle. It also supplies articular branches to the back of the shoulder-joint.

Pars Infraclavicularis.—The so-called infra-clavicular branches of the brachial plexus are distributed to the chest, shoulder, and arm. According to their origin they are divisible into two sets—an **anterior set**, derived from the lateral and medial cords, and a **posterior set**, derived from the posterior cord. In their distribution the same arrangement is maintained. The anterior nerves of distribution, springing from the lateral and medial cords, supply the chest and the front of the limb; the posterior nerves, springing from the posterior cord, supply the shoulder and the back of the limb.

Anterior Branches.

From the Lateral Cord.

Lateral anterior thoracic.
Median (lateral head).
Musculo-cutaneous.

From the Medial Cord.

Medial cutaneous nerve of forearm (O.T. internal cutaneous).
Medial cutaneous nerve of arm (O.T. lesser internal cutaneous).

Posterior Branches.

Axillary nerve.
Radial nerve.
Two subscapular nerves.
Thoraco-dorsal nerve.

NERVI THORACALES ANTERIORES.

The **anterior thoracic nerves** are two in number, lateral and medial. The **lateral anterior thoracic nerve** arises from the lateral cord of the brachial plexus by three roots—from the fifth, sixth, and seventh cervical nerves. The **medial anterior thoracic nerve** arises from the medial cord of the plexus, from the eighth cervical and first thoracic nerves. Each courses downwards and forwards on either side of the axillary artery. A loop of communication is formed between them in front of the artery. They are finally distributed to the pectoralis major and minor muscles (Fig. 615).

The nerves are distributed to the pectoral muscles in the following way. Two sets of branches from the lateral anterior thoracic nerve pierce the costo-coracoid membrane. The superior branches supply the *clavicular part* of the pectoralis major; the inferior branches are distributed to the superior fibres of the *sternal portion* of the muscle. The superior branches come from the fifth and sixth cervical nerves; the inferior branches, from the fifth, sixth, and seventh nerves. The *pectoralis minor* is pierced by two sets of nerves—the superior set is derived from the loop of communication between the two anterior thoracic nerves over the axillary artery; the inferior set is derived from the medial anterior

thoracic nerve alone. These nerves supply the *pectoralis minor* muscle, and, after piercing it, supply the *sternal part* of the *pectoralis major*. The inferior nerve, in many cases, sends its branches to the *pectoralis major* round the inferior border of the

pectoralis minor, and it may supply on its way the *axillary arches*, if present. These two branches are derived—the superior from the seventh and eighth cervical, and first thoracic nerves; the inferior from the eighth cervical and first thoracic nerves. The pectoral muscles are thus both supplied by the two anterior thoracic nerves. The clavicular fibres of the *pectoralis major* are innervated by the fifth and sixth nerves; the sternal fibres, from above downwards, by the fifth, sixth, seventh, and eighth cervical, and first thoracic nerves; and the *pectoralis minor* is supplied by the seventh and eighth cervical, and first thoracic nerves.

FIG. 616.—THE DEEPER NERVES OF THE ARM.

NERVUS MUSCULOCUTANEUS.

The **musculo-cutaneous nerve** takes origin from the lateral cord of the plexus, from the fifth and sixth cervical nerves (Fig. 614). The nerve to the *coracobrachialis* muscle, arising from the seventh or sixth and seventh nerves, is usually associated with it. Separating from the lateral head of the median nerve, the musculo-cutaneous nerve lies at first between the *coracobrachialis* muscle and the *axillary* artery. It is then directed distally between the two parts of the *coracobrachialis*, and passes between the *biceps* and *brachialis* muscles, to the bend of the elbow. It pierces the deep fascia over the front of the elbow, between the *biceps* and *brachioradialis*, and terminates as the lateral cutaneous nerve for the supply of the lateral aspect of the forearm. In its course it

may send a branch under the *biceps* to join the median nerve.

The branches of the nerve are muscular and cutaneous. The **muscular branches** are supplied to the two heads of the *biceps* and the *brachialis*, as the nerve lies between the muscles. The nerve to the *coracobrachialis* (usually incorporated with the trunk of the musculo-cutaneous nerve) has an independent origin from

the seventh or sixth and seventh nerves. It is usually double, one branch entering each portion of the muscle. The **lateral cutaneous nerve of the forearm** divides into volar and dorsal branches (Fig. 616, p. 704). The **volar branch** runs distally along the front of the lateral aspect of the forearm to the wrist, and supplies an area extending medially to the middle line of the forearm anteriorly, and distally so as to include the ball of the thumb. It communicates, proximal to the wrist with the superficial ramus of the radial nerve, and supplies branches to the radial artery. The **dorsal branch** passes posteriorly and distally over the extensor muscles and supplies the skin on the lateral aspect of the forearm posteriorly in its proximal three-fourths, communicating with the cutaneous branches of the radial nerve.

In addition to the above branches, the musculo-cutaneous nerve supplies in many cases the following small twigs in the arm: (1) a medullary branch to the humerus; (2) a periosteal branch to the distal end of the humerus on its anterior surface; and (3) a branch to the brachial artery.

NERVUS MEDIANUS.

The **median nerve** arises by two heads—one from the lateral cord, the other from the medial cord of the brachial plexus. The lateral head, from the (fifth), sixth, and seventh nerves, descends along the lateral side of the axillary artery; the medial head, from the eighth cervical and first thoracic nerves, crosses the end of the axillary artery or the beginning of the brachial artery, to join the other head in the proximal part of the arm. Descending along the lateral aspect of the brachial artery, the nerve crosses over it obliquely in the distal half of the arm. In the hollow of the elbow, it lies on the medial side of the brachial artery, beneath the *lacertus fibrosus* and the median basilic vein. It passes into the forearm between the two heads of the pronator teres muscle, separated from the ulnar artery by the deep origin of that muscle. Extending distally along the middle of the forearm, between the superficial and deep muscles, to the wrist, it enters the palm of the hand on the lateral side of the flexor tendons of the fingers, and beneath the transverse carpal ligament. In the hand it spreads out at the distal border of the transverse carpal ligament beneath the palmar aponeurosis and superficial palmar arch, and separates into its six terminal branches. In the forearm a small artery accompanies it,—the median branch of the volar interosseous artery. Proximal to the wrist it is comparatively superficial, lying on the lateral side of the superficial flexor tendons and directly beneath the tendon of the *palmaris longus*.

Branches.—The median nerve usually gives off no branches in the (upper) arm.

Branches in the Forearm.—(1) **Articular Branches.**—Minute articular filaments are distributed to the front of the elbow-joint.

(2) **Muscular Branches.**—Just below the elbow a bundle of nerves arises to be distributed to the following muscles: pronator teres, flexor carpi radialis, palmaris longus, flexor digitorum sublimis. Nerves are also generally traceable from this bundle to the upper fibres of the flexor pollicis longus and flexor digitorum profundus. The nerve to the pronator teres often arises independently in the hollow of the elbow.

(3) The **volar interosseous nerve of the forearm** (O.T. **anterior interosseous**) arises from the posterior surface of the median nerve in the forearm, passes distally on the volar aspect of the interosseous membrane along with the volar interosseous artery, passes dorsal to the pronator quadratus muscle, and terminates by supplying articular filaments to the radio-carpal articulation. In its course the nerve supplies muscular branches to the flexor pollicis longus, the lateral half of the flexor digitorum profundus, and the pronator quadratus, minute medullary branches to the radius and ulna, and twigs to the periosteum and interosseous membrane.

(4) **Palmar Ramus.**—In the distal third of the forearm a small cutaneous branch arises, which pierces the deep fascia and crosses the transverse carpal ligament to reach the palm of the hand. It supplies the skin of the palm and com-

municates with a similar branch of the ulnar nerve. This branch is not always present.

Branches in the Hand.—In the hand the median nerve gives off its terminal branches. These are muscular and cutaneous.

The main muscular branch arises just distal to the transverse carpal ligament and passes to the base of the thenar eminence; entering the ball of the thumb superficially on the medial side, it supplies branches to the abductor pollicis brevis, opponens pollicis, and the flexor pollicis brevis.

FIG. 617.—THE DISTRIBUTION OF CUTANEOUS NERVES ON THE FRONT OF THE ARM AND HAND.

(B) is a schematic representation of the areas supplied by the above nerves, the lettering indicating the spinal origin of the branches of distribution to each area. V.A.L., Ventral axial line.

The cutaneous branches are five in number. Three separate branches supply each side of the thumb and the lateral side of the index finger. The two remaining branches (*nn. digitales volares communes*) subdivide at the cleft between the second and third, and the third and fourth fingers respectively, into branches (*nn. digitales volares proprii*) which supply the adjacent sides of the second and third, and the third and fourth fingers. From the nerves which supply respectively the lateral side of the index finger, and the contiguous sides of the index and third fingers, fine muscular branches arise for the first two lumbrical muscles. The cutaneous branches of the median nerve are placed in the palm between the superficial palmar arch and the flexor tendons. They become super-

ficial at the roots of the fingers between the slips of the palmar aponeurosis, or, in the case of the nerves to the thumb and lateral side of the index finger, at the lateral edge of the central portion of the palmar aponeurosis. In the fingers they are placed superficial to the digital arteries, and are distributed to the sides and volar aspects of the fingers. Each nerve supplies one or more *dorsal branches*, distributed to the skin on the dorsal aspect of the terminal phalanx of the thumb and the distal two

FIG. 618.—THE DISTRIBUTION OF CUTANEOUS NERVES ON THE BACK OF THE ARM AND HAND.

(B) is a schematic representation of the areas supplied by the above nerves, the lettering indicating the spinal origin of the branches of distribution to each area. D.A.L., Dorsal axial line.

phalanges of the first two and a half fingers, thus making up for the deficiency of the superficial branch of the radial nerve in these situations.

Communications.—(1) The median nerve, in some cases, receives a communicating branch from the musculo-cutaneous nerve in the arm. (2) It communicates in some cases, in the proximal part of the forearm, with the ulnar nerve beneath the flexor muscles. (3) It communicates by means of its cutaneous branches with the ulnar nerve in the palm of the hand (*ramus anastomoticus cum nervo ulnari*).

NERVUS ULNARIS.

The **ulnar nerve** arises from the medial cord of the brachial plexus, from the eighth cervical and first thoracic nerves. It also occasionally has a root from the lateral cord of the plexus (seventh cervical nerve). In the axilla it lies between the axillary artery and vein, and behind the medial cutaneous nerve of the forearm (O.T. internal cutaneous); in the proximal half of the arm it lies on the medial side of the brachial artery anterior to the triceps muscle. In the distal half of the arm it is separated from the brachial artery; and passing behind the intermuscular septum, and in front of the medial head of the triceps in company with the superior ulnar collateral (O.T. inferior profunda) artery, it reaches the interval between the medial epicondyle of the humerus and the olecranon. It is here protected by an arch of deep fascia stretching between the epicondyle and the olecranon. It enters the forearm between the humeral and ulnar origins of the flexor carpi ulnaris, and courses distally between the flexor carpi ulnaris and flexor digitorum profundus. In the distal half of the forearm it becomes comparatively superficial, lying on the medial side of the ulnar artery beneath the tendon of the flexor carpi ulnaris. Just proximal to the transverse carpal ligament, and lateral to the pisiform bone, it pierces the deep fascia in company with the artery and passes into the hand over the transverse carpal

FIG. 619.—THE AXILLARY AND RADIAL NERVES.

ligament. Reaching the palm it divides beneath the palmaris brevis muscle into its two terminal branches, superficial and deep.

Branches.—The ulnar nerve gives off no branches till it reaches the forearm. In the forearm it gives off articular, muscular, and cutaneous branches.

The **articular branch** is distributed to the elbow-joint and arises as the nerve passes behind the medial epicondyle of the humerus.

The **muscular branches** arise as soon as the nerve enters the forearm. They are distributed to the muscles between which the ulnar nerve lies—the flexor carpi ulnaris and the medial half of the flexor digitorum profundus.

The **cutaneous branches** are two in number, palmar and dorsal.

The **palmar cutaneous ramus** is variable in size and position. It pierces the deep fascia in the distal third of the forearm and passes to the hypothenar eminence and palm of the hand, to the skin over which it is distributed. It gives branches to the ulnar artery, and communicates often with the medial cutaneous nerve of the forearm and the palmar branch of the median nerve.

The **dorsal ramus of the hand** is much larger (Fig. 618). It arises from the ulnar nerve in the middle third of the forearm; and, directed obliquely distally and posteriorly beneath the tendon of the flexor carpi ulnaris, it becomes cutaneous on the medial side of the forearm in its distal fourth. It passes on to the back of the hand, and after giving off branches to the skin of the wrist and hand, which communicate with the superficial ramus of the radial nerve, it terminates in two *dorsal digital nerves*, to supply the little finger and half the ring-finger in the following way:—the medial branch courses along the medial side of the dorsum of the hand and little finger: the lateral branch subdivides at the cleft between the ring and little fingers to supply the adjacent sides of these fingers; this branch communicates with the superficial ramus of the radial nerve. The nerve may supply two and a half fingers on the dorsum of the hand.

Ramus Volaris Manus.—*In the palm* the ulnar nerve supplies a small muscular branch to the palmaris brevis, and then subdivides into its terminal branches, which are named superficial and deep.

Ramus Superficialis.—The **superficial branch** is purely cutaneous; it passes distally beneath the palmar aponeurosis, and subdivides into a medial and a lateral branch. The medial branch courses along the medial border of the little finger, which it supplies on its palmar aspect. The lateral branch (*common volar digital nerve*) becomes superficial at the cleft between the fourth and fifth fingers, between the slips of the palmar aponeurosis, and subdivides into two branches (*proper volar digital nerves*) which supply the adjacent sides of these fingers on their palmar aspect. It communicates with the adjacent digital branch of the median nerve.

Ramus Profundus.—The **deep branch** is purely muscular. It separates from the superficial branch, and passes deeply between the flexor brevis and abductor digiti quinti muscles; it supplies these muscles and the opponens digiti quinti, and, turning laterally along the line of the deep palmar arch and under cover of the deep flexor tendons, it supplies branches to the following muscles: interossei, third and fourth lumbricales (on their deep surfaces), the adductor pollicis (oblique and transverse parts), and the *interosseus primus volaris* (deep part of the flexor pollicis brevis).

Communications.—(1) The ulnar nerve communicates in some cases with the median nerve in the forearm; (2) with the medial cutaneous nerve of the forearm and sometimes the median nerve by its palmar branch; (3) with the cutaneous part of the median nerve in the palm by means of its terminal cutaneous branches; (4) with the superficial ramus of the radial nerve on the dorsum of the hand by means of its dorsal branch.

NERVUS CUTANEUS ANTIBRACHII MEDIALIS.

The **medial cutaneous nerve of the forearm** (O.T. **internal cutaneous nerve**) arises from the medial cord of the brachial plexus, from the eighth cervical and first thoracic nerves (Figs. 614 and 617). In the axilla and proximal half of the arm it lies superficial to the main artery. It becomes cutaneous by piercing the deep fascia about the middle of the arm on its medial side, and accompanying the basilic vein through the distal half of the arm, it divides at the front of the elbow into its two terminal branches.

Branches.—In the arm, as soon as it becomes superficial, the nerve gives off a branch which supplies the skin of the distal half of the anterior surface of the

arm on its medial side. At the elbow it divides into two terminal branches—*volar* and *ulnar*, which, crossing over or under the median basilic vein, are distributed to the medial side of the forearm.

The **volar branch** can be followed to the wrist and supplies the whole of the volar surface of the forearm in the medial half; the **ulnar branch** is not so large, and, passing obliquely backwards and distally over the origins of the pronator and flexor muscles, it is distributed to the proximal two-thirds or three-fourths of the dorsal aspect of the forearm on the medial side.

Communication.—The medial nerve of the forearm communicates with the volar branch of the ulnar nerve in the distal part of the forearm.

NERVUS CUTANEUS BRACHII MEDIALIS.

The **medial cutaneous nerve of the arm** (O.T. **lesser internal cutaneous nerve**) arises from the medial cord of the brachial plexus, and ultimately from the first thoracic nerve (Fig. 614, p. 701). It lies at first between the axillary artery and vein; and after descending over, under, or even, in some cases, through the axillary vein, it perforates the deep fascia and is distributed to the skin of the arm for the proximal half or more on its medial side.

The nerve varies considerably in size. It may be absent, its place being taken by branches of the intercosto-brachial or by branches from the posterior cutaneous branch of the radial nerve. It generally bears a distinct relation in size to the intercosto-brachial, due to the fact that the size of the latter depends upon the size of the part of the second thoracic nerve connected with the first in the thorax. If an intra-thoracic connexion occurs between the first and second thoracic nerves, the intercosto-brachial may be deprived of a certain number of its fibres, which in that case reach the upper limb through the medial cutaneous nerve of the arm. When traced up to the plexus the medial cutaneous nerve of the arm is found to have an origin from the posterior part of the cord formed by the eighth cervical and first thoracic nerves, and usually receives fibres from the first thoracic nerve only. In cases where "*axillary arches*" are present they may be supplied by this nerve.

NERVUS AXILLARIS.

The **axillary nerve** (O.T. **circumflex**) at its origin is just below the supra-scapular and comes from the same spinal nerves—the fifth and sixth cervical nerves (Fig. 614, p. 701). Extending distally and laterally behind the axillary artery, it leaves the axilla by passing round the lateral border of the subscapularis muscle, in company with the posterior circumflex artery of the humerus, in a quadrilateral space bounded by the humerus, subscapularis, triceps (long head), and teres major. Winding round the surgical neck of the humerus from medial to lateral side, it terminates by supplying the deltoid muscle (Fig. 619, p. 708).

Branches.—**Muscular branches** are supplied to the teres minor and deltoid muscles. The nerve to the teres minor enters the lateral aspect of the muscle. It possesses a pseudo-ganglion, a thickening of fibrous tissue, on its trunk.

Articular branches enter the posterior part of the capsule of the shoulder-joint.

A **cutaneous branch** of considerable size—the *lateral cutaneous nerve of the arm*—passes obliquely distally and forwards from beneath the deltoid muscle, becoming superficial at its posterior border. Sometimes branches pierce the muscle. It supplies the skin over the insertion of the deltoid and the proximal half of the arm on its lateral aspect (Figs. 617, p. 706, and 618, p. 707).

NERVUS RADIALIS.

The **radial nerve** (O.T. **musculo-spiral**) appears to be the continuation into the upper limb of the posterior cord of the brachial plexus. It usually takes origin from all the nerves which form the posterior cord—the fifth, sixth, seventh, and eighth cervical and first thoracic nerves (Fig. 614, p. 701). In some cases the first thoracic contributes no fibres, and often the fifth cervical nerve is excluded from it. It extends from the axilla round the back of the humerus to the bend of the elbow, where it ends by dividing into its *superficial* and *deep* terminal branches.

In the axilla it lies behind the axillary artery, and in front of the subscapularis, teres major, and latissimus dorsi muscles.

In the arm, in the proximal third, it lies to the medial side of the humerus, behind the brachial artery, and upon the long head of the triceps. In the middle third of the arm it courses obliquely laterally and distally in the radial groove of the humerus, along with the profunda brachii artery, separating the long, lateral, and medial heads of the triceps muscle (Fig. 619, p. 708). In the distal third of the arm, piercing the proximal part of the intermuscular septum at the lateral border of the triceps muscle, it passes to the bend of the elbow in front of the lateral epicondyle of the humerus, in the interval between the brachio-radialis and brachialis muscles. Under cover of the former muscle, in the hollow of the elbow, it divides into its two terminal branches, the superficial and deep rami.

The **collateral branches** are in three sets, arising (a) on the medial side, (b) on the back, and (c) on the lateral side of the humerus (Fig. 620).

I. Branches arising medial to the Humerus.—

1. **N. cutaneus brachii posterior** (O.T. upper internal cutaneous branch of musculo-spiral).—This branch, arising in common with one of the following, or independently, pierces the fascia on the medial side of the arm near the axilla. It supplies the skin of the medial side of the arm in the proximal third, proximal and posterior to the area supplied by the medial nerve of the arm (O.T. lesser internal cutaneous) (Fig. 618, p. 707). This nerve varies in size, according to the bulk of the last-named and the intercosto-brachial nerves.

2. **Rami Musculares (Muscular Branches).**—These are in two sets. One series supplies the long head of the triceps muscle near its origin; the other series enters the medial head of the muscle. One of the latter, separating itself from the rest, accompanies the ulnar nerve in the middle third of the arm, and supplies the distal part of the muscle. This is sometimes called the **collateral ulnar nerve**.

II. **Branches arising on the Posterior Surface of the Humerus.**—Muscular branches arise from the nerve in the radial groove for the supply of all three heads of the triceps muscle. The branch which enters the medial head of the muscle, besides supplying it, passes through the muscle and behind the lateral epicondyle of the humerus, to terminate in the anconeus.

III. **Branches arising at the Lateral Side of the Humerus.**—1. The **dorsal cutaneous nerve of the forearm** consists of two branches, proximal and distal. Arising from the radial nerve before it pierces the lateral intermuscular septum, these branches pierce the deep fascia close together on the lateral side of the arm in its distal half. Passing distally over the back of the lateral epicondyle, the *proximal branch* supplies the skin of the lateral side and posterior surface of the arm in its distal third, and the dorsal surface of the forearm in its proximal half. The *distal branch* supplies an area of skin on the dorsal surface of the forearm in the proximal two-thirds, medial to the area innervated by the musculo-cutaneous nerve (Fig. 618, p. 707).

2. **Muscular Branches.**—The radial nerve, as it lies in the interval between the brachialis and brachio-radialis muscles, supplies a small branch to the brachialis (which in some cases is not present) and nerves to the brachio-radialis and extensor carpi radialis longus. It may also provide the nerve to the extensor carpi radialis brevis.

FIG. 620.—DIAGRAMMATIC REPRESENTATION OF THE BRANCHES OF THE RADIAL NERVE.

RAMUS SUPERFICIALIS NERVI RADIALIS.

The **superficial ramus** (O.T. **radial nerve**) is entirely cutaneous in its distribution. Arising in the hollow of the elbow beneath the brachio-radialis, it

FIG. 621.—DISTRIBUTION OF THE DEEP BRANCH OF THE RADIAL NERVE.

courses distally under cover of that muscle through the proximal two-thirds of the forearm, and accompanies the radial artery in the middle third of the forearm. It then passes posteriorly beneath the tendon of the brachio-radialis and pierces the deep fascia on the lateral aspect of the forearm in the distal third. It is distributed to the skin of the dorsum of the wrist, the lateral side and the dorsum of the hand, and the dorsum of the thumb and lateral two and a half fingers (Fig. 618, p. 707). Its branches communicate on the ball of the thumb with the musculo-cutaneous nerve, and on the dorsum of the hand with the dorsal branch of the ulnar nerve (*ramus anastomoticus ulnaris*). The **digital nerves** are small, and are five in number. Two pass to the back of the thumb and reach the level of the inter-phalangeal articulation. One supplies the lateral side of the index finger as far as the second phalanx. The remaining two branches divide at the clefts between the second and third, and third and fourth fingers respectively, and innervate the adjacent sides of these fingers as far as the second phalanx. The rest of the skin of these digits to the tips is supplied by digital branches of the median nerve. The nerve may only supply the thumb and one and a half fingers, being replaced by branches from the ulnar nerve.

RAMUS PROFUNDUS NERVI RADIALIS.

The **deep ramus** (O.T. **posterior interosseous nerve**) is entirely muscular and articular in its distribution. It arises like the superficial ramus beneath the brachio-radialis muscle. Directed obliquely distally and posteriorly, it reaches the back of the forearm, after passing round the lateral aspect of the radius, by piercing the fibres of the supinator muscle (Fig. 621). On the dorsal surface of the

forearm it is called the **dorsal interosseous nerve**, and is placed in the proximal part of its course beneath the superficial extensor muscles, and upon the supinator and abductor pollicis longus, along with the dorsal interosseous artery. In the distal half of the forearm it passes beneath the extensor pollicis longus, and lies upon the interosseous membrane. At the wrist it passes beneath the extensor tendons on to the back of the carpus, where it terminates in a gangliform enlargement of small size, from which branches pass to the inter-carpal articulations. The nerve supplies the following branches:—

(1) **Terminal articular branches** to the carpal joints.

(2) **Muscular branches**, in its course through the forearm. Thus on the lateral side of the radius it supplies the extensor carpi radialis brevis and the supinator muscles before it enters the fibres of the last-named muscle. After emerging from the supinator it supplies a large bundle of nerves which enter the extensor digitorum communis, extensor digiti quinti proprius, and extensor carpi ulnaris near their origins. At a more distal level the nerve gives off branches to the abductor pollicis longus, extensor pollicis longus and extensor pollicis brevis, and extensor indicis proprius.

NERVI SUBSCAPULARES.

There are two subscapular nerves (Figs. 614 and 616).

The **first or short subscapular nerve** is generally double, and there may be three trunks present. It arises from the posterior cord of the plexus behind the axillary nerve, and comes from the fifth and sixth cervical nerves. It passes distally behind the axillary artery and enters the subscapularis muscle.

The **second or lower subscapular nerve** also arises behind the axillary nerve from the posterior cord of the plexus (from the fifth and sixth cervical nerves). Its origin is distal and lateral to that of the first nerve. It courses distally behind the axillary artery and the axillary and radial nerves, to the teres major muscle. It supplies branches to the lateral part of the subscapularis muscle and ends in the teres major.

NERVUS THORACODORSALIS.

The **thoraco-dorsal nerve** (O.T. long subscapular) arises from the back of the posterior cord of the plexus, behind the radial nerve, and from the sixth, seventh, and eighth cervical nerves, or from the seventh and eighth nerves only. It is directed distally and laterally between the two previous nerves, behind the axillary artery and over the posterior wall of the axilla, in company with the subscapular artery, to the latissimus dorsi muscle, which it supplies on its anterior (deep) surface.

NERVI THORACALES.

The anterior rami of the **thoracic nerves** are twelve in number, each nerve emerging below the corresponding vertebra and rib. Eleven of the series are intercostal, the twelfth lying below the last rib. The first, second, third, and twelfth nerves present peculiarities in their course and distribution. The other thoracic nerves, as already stated, are simple, and may be regarded as types both in course and distribution.

The anterior ramus of the **first thoracic nerve** is the largest of the series. It emerges from the vertebral canal below the neck of the first rib, and divides in the first intercostal space into two very unequal, superior and inferior, parts. The *superior* and larger part ascends obliquely over the neck of the first rib, lying lateral to the arteria intercostalis suprema, and enters the neck behind the subclavian artery and the pleura. It proceeds laterally upon the scalenus medius muscle and enters into the formation of the brachial plexus, as already described.

The *inferior, intercostal part* of the nerve is much smaller in size. It courses

forwards in the first intercostal space and supplies the intercostal muscles. It usually gives off no anterior branch to the skin of the chest and no lateral cutaneous branch.

In some cases a lateral cutaneous branch emerges from the side of the first intercostal space. This may be derived from the first nerve, or it may be the *intercosto-brachial nerve*, the lateral branch of the second thoracic nerve. In many cases an anterior cutaneous branch perforates the first intercostal space and supplies the skin on the front of the chest. This branch, similarly, is sometimes traceable to the second thoracic nerve.

Communications.—Besides its junction with the eighth cervical to form the brachial plexus, the first thoracic nerve effects the following communications:—(a) The last cervical or first thoracic ganglion of the sympathetic sends a *gray ramus communicans* to join the nerve on its appearance in the thorax. (b) The second thoracic nerve in a majority of cases communicates with the first. This communication varies considerably in size and distribution. It may reinforce the intercostal branch of the nerve, it may send one branch to the intercostal portion and another to the part of the nerve joining the

FIG. 622.—SCHEME OF THE DISTRIBUTION OF A TYPICAL SPINAL NERVE.

brachial plexus, or it may consist of a nerve proceeding solely to join the brachial plexus by a junction in the first intercostal space with the part of the first thoracic nerve, which is engaged in forming the plexus. (c) It is possible that the first *white ramus communicans* in the thoracic region connects the first thoracic nerve with the sympathetic trunk, but this is not known with certainty.

The anterior ramus of the **second thoracic nerve** is of large size, though much smaller than the first. It passes forwards in the second intercostal space, lying at first in the costal groove, between the external and internal intercostal muscles. At the level of the mid-axillary line it gives off a large lateral branch; continuing its course it pierces the internal intercostal muscle and lies upon the pleura; finally, at the lateral border of the sternum, it passes forwards in front of the internal mammary artery and through the internal intercostal muscle, and

the aponeurosis of the external intercostal muscle and pectoralis major, and ends

FIG. 623.—THE DISTRIBUTION OF CUTANEOUS NERVES ON THE FRONT OF THE TRUNK.

On one side the distribution of the several nerves is represented, the letters indicating their nomenclature.

G.A, Great auricular nerve ; S.C, N. cutaneus colli ; S.CL, Supra-clavicular nerves ; ACR, Posterior ; CL, Middle ; St, Anterior ; T.2-12, Lateral and anterior branches of thoracic nerves ; I.H, Ilio-hypogastric nerve ; I.I, Ilio-inguinal nerve ; CIRC, Cutaneous branch of axillary nerve ; L.I.C, Medial cutaneous nerve of the arm (O.T. lesser internal cutaneous) ; I.H, Intercosto-brachial ; I.C, Medial cutaneous nerve of the forearm (O.T. internal cutaneous) ; M.S, Cutaneous branch of radial nerve ; E.C, Lateral cutaneous nerves ; G.C, Lumbo-inguinal nerve ; M.C¹, Intermediate cutaneous nerves ; I.C¹, Branch of medial cutaneous nerve ; P, Branches of pudendal nerve ; S.Sc, Branches of posterior cutaneous nerve of the thigh.

On the other side a schematic representation is given of the areas supplied by the above nerves, the numerals indicating the spinal origin of the branches of distribution to each area.

by supplying the skin of the front of the chest over the second intercostal space.

The nerve supplies the following branches:—

1. **Muscular branches** to the muscles of the second intercostal space.

2. **Cutaneous branches.** (a) **Anterior terminal branches** to the skin over the second intercostal space (Fig. 623). (b) A large lateral cutaneous branch, the **intercosto-brachial** (O.T. **intercosto-humeral**) **nerve** (Fig. 614, p. 701). This nerve pierces the intercostal and serratus anterior muscles, and, crossing the axilla, extends to the arm. It pierces the deep fascia just beyond the posterior fold of the axilla, and can be traced as far as the interval between the medial epicondyle of the humerus and the olecranon. It supplies an area of skin stretching across the axilla and along the posterior surface of the arm on the medial side as far as the elbow (Fig. 617, p. 706). It may supply the axillary arches, when present.

The intercosto-brachial nerve varies in size. It may pierce the first intercostal space, and it is often divisible into anterior and posterior branches, like the lateral branch of an ordinary intercostal nerve.

Communications.—(1) The intercosto-brachial nerve communicates with two adjacent nerves. Either before or after piercing the fascia of the axilla it is joined by the medial cutaneous nerve of the arm. It also communicates with the posterior part of the lateral branch of the third intercostal nerve by means of the branches distributed to the floor and boundaries of the axilla. (2) Besides the branches referred to, the second thoracic nerve in many cases transmits a nerve to the brachial plexus, which becomes incorporated with the first thoracic nerve after passing over the neck of the second rib. This branch is inconstant. As already mentioned, it may join only the intercostal part of the first thoracic nerve, it may join the brachial plexus only, or it may send branches to both parts of the first thoracic nerve. (3) Besides the communications effected by branches of the second thoracic nerve in its course, it also receives a *gray ramus communicans* from the second thoracic ganglion of the sympathetic trunk in the thorax. It also sends to the sympathetic a *white ramus communicans*, probably the first, though this is not known with certainty.

The anterior ramus of the **third thoracic nerve** differs from a typical thoracic nerve only in one respect. Its **lateral branch** divides in the usual way into anterior and posterior parts, of which the latter is carried to the arm and supplies an area of skin on the medial side near the root of the limb. It effects a junction with the intercosto-brachial nerve (Fig. 614, p. 701).

The anterior rami of the **fourth, fifth, and sixth thoracic nerves** have a course and distribution which is simple and typical. Except for the peculiarities above mentioned, the second and third thoracic nerves have a similar distribution.

The nerves lie on the posterior wall of the thorax, in the costal groove of the corresponding rib. They extend forwards between the intercostal muscles as far as the middle of the chest wall, lying at a lower level than the intercostal vessels. At the side of the chest each nerve passes obliquely through the internal intercostal muscle, and comes to lie upon the pleura, transversus thoracis muscle, and internal mammary artery. Thereafter, piercing the fibres of the internal intercostal muscle, the aponeurosis of the external muscle, and the pectoralis major, each nerve ends by supplying the skin of the front of the chest, over an area corresponding to the medial or anterior part of the intercostal space to which it belongs.

Branches.—Each intercostal nerve supplies, in addition to the anterior terminal cutaneous branches, *muscular branches* to the intercostal muscles and a **lateral cutaneous ramus**, which, piercing the intercostal and serratus anterior muscles, divides into anterior and posterior branches for the innervation of the skin over the side of the chest. Each area of skin thus innervated is continuous anteriorly with the area innervated by the anterior rami of the same nerves, and posteriorly with the areas supplied by their posterior rami.

The upper six intercostal nerves supply the muscles of the first six intercostal spaces and the transversus thoracis (3, 4, 5, 6). The second, third, fourth, fifth, and sixth nerves supply the skin of the front of the chest: the second, opposite the sternal synchondrosis; the sixth, opposite the base of the xiphoid process. Their lateral branches supply branches to the intercostal muscles and the skin of

the side of the chest, the second (intercosto-brachial) and the third, in part, being drawn out to the arm. The fourth supplies the nipple (Fig. 623).

Communications.—Each of these intercostal nerves communicates with the sympathetic trunk and ganglia by two branches—a *white ramus communicans* to the corresponding sympathetic ganglion or the adjacent part of the sympathetic trunk; and a *gray ramus communicans*, which passes to each nerve from the corresponding ganglion.

The anterior rami of the **seventh, eighth, ninth, tenth, and eleventh thoracic nerves** differ from the preceding nerves only in regard to a part of their course and distribution. Each has the same course and communications as the preceding nerves in the thoracic wall. In addition, these nerves have a further course and distribution in the abdominal wall. Each nerve traverses an intercostal space in the way described. At the anterior end of the space, the nerve pierces the attachment of the diaphragm and the transversus abdominis muscle to the costal cartilages, and courses forwards in the abdominal wall between the transversus and obliquus internus muscles. The nerve then passes between the rectus abdominis muscle and the posterior layer of its sheath, and eventually reaches the anterior abdominal wall and becomes cutaneous by piercing the rectus abdominis itself and the anterior layer of its sheath.

Muscular Branches.—The lower intercostal nerves supply the intercostal muscles of the spaces in which they lie; and in the abdominal wall they innervate the transversus, obliquus externus and internus, and rectus abdominis. The branches arise from the main trunk as well as from its lateral and anterior branches. (The ninth, tenth, and eleventh nerves are described as assisting in the innervation of the diaphragm by communications with the phrenic nerve.)

Cutaneous Branches.—These are lateral and anterior. The lateral branches divide into anterior and posterior parts, and, becoming superficial along the line of inter-digitation of the obliquus externus muscle with the serratus anterior and latissimus dorsi, they are directed more obliquely downwards than the lateral branches of the higher intercostal nerves, and are distributed to the skin of the loin as low down as the buttock. The lateral branch of the eleventh nerve can be traced over the iliac crest (Fig. 625).

The **anterior branches** are small. That of the seventh nerve innervates the skin at the level of the xiphoid process. The eighth and ninth appear between the xiphoid process and the umbilicus; the tenth nerve supplies the region of the umbilicus; and the eleventh, the area immediately below the umbilicus.

The cutaneous branches of these nerves, including those of the posterior rami, thus supply continuous belts of skin, which can be mapped out on the body from the vertebral column behind to the median plane in front. These areas are not placed horizontally, but tend to be drawn downwards as the series is followed from the upper to the lower nerves.

The anterior ramus of the **twelfth thoracic nerve** is peculiar in its course and distribution. It emerges below the last rib (Fig. 625), and passes laterally and downwards in the posterior abdominal wall under cover of the psoas muscle, and between the lateral lumbo-costal arch and the quadratus lumborum muscle; it pierces the transversus abdominis muscle, and courses forwards in the interval between it and the obliquus internus as far as the sheath of the rectus muscle. After piercing the posterior layer of the sheath, the rectus muscle, and the anterior layer of the sheath, it terminates by supplying the skin of the anterior abdominal wall midway between the umbilicus and the os pubis. The branches of the nerve are **muscular** to the transversus, obliqui, rectus, and pyramidalis muscles of the abdominal wall; and **cutaneous branches**, two in number—an *anterior terminal branch*, which supplies the skin of the anterior abdominal wall midway between the umbilicus and the pubis, and a large *lateral cutaneous branch*, which, passing obliquely downwards through the lateral muscles of the abdominal wall, becomes superficial above the iliac crest, a couple of inches behind the anterior superior spine. It supplies the skin of the buttock as far down as a point below and anterior to the greater trochanter of the femur (Fig. 623, p. 715).

The twelfth thoracic nerve, in many cases, receives a **communicating branch** from the eleventh, near its origin, and still more frequently sends a fine branch to join the origin of the first

lumbar nerve in the psoas muscle. It may communicate also with the ilio-hypogastric nerve, as they lie together in the abdominal wall.

Inter-communications of the Thoracic Nerves.—It has been already noted that the belts or areas of skin supplied by the branches of the thoracic nerves are also innervated by adjacent nerves on either side which invade the area supplied by a given nerve. Communications also take place between the branches of the nerves supplying the intercostal muscles, whereby the muscles of a given space derive their innervation from more than one intercostal nerve.

FIG. 624.—NERVES OF THE LUMBO-SACRAL PLEXUS.

PLEXUS LUMBOSACRALIS.

The lumbo-sacral plexus is formed by the union of the anterior rami of the remaining spinal nerves—five lumbar, five sacral, and one coccygeal. Frequently

a fine communicating branch of the twelfth thoracic nerve joins the first lumbar nerve near its origin.

Of the nerves in question the first sacral is generally the largest in size, the nerves diminishing gradually above and rapidly below this nerve. The plexus, for the most part, forms the nerves destined for the supply of the lower limb. In addition, however, nerves arise at its superior limit which are distributed to the trunk above the level of the limb, and at the inferior end of the plexus nerves arise for the supply of the perineum.

Partly for convenience of description, and partly on account of the differences in position and course of some of the nerves emanating from it, the plexus is subdivided into three subordinate parts—lumbar, sacral, and pudendal plexuses. There is, however, no strict line of demarcation between the three parts.

Plexus Lumbalis.—The lumbar plexus is formed by the first four lumbar nerves, and is often joined by a branch from the twelfth thoracic nerve as well. It is limited below by the fourth lumbar nerve (*n. furcalis*), which enters also into the composition of the sacral plexus. The nerves of the lumbar plexus are formed in the loin, and supply that region as well as part of the lower limb. They are separated from the nerves of the sacral portion of the plexus by the articulation of the hip bone with the sacrum.

Plexus Sacralis.—The sacral plexus is formed by the fourth and fifth lumbar, and the first two or three sacral nerves. It is generally limited below by the third sacral nerve (*n. bigeminus*), which assists also in forming the pudendal plexus. The nerves of the sacral plexus are placed on the posterior wall of the pelvis, and are destined almost entirely for the lower limb.

Plexus Pudendus.—The pudendal plexus is formed by the second, third, fourth, and fifth sacral nerves, and the minute coccygeal nerve. It is placed on the posterior wall of the pelvis and supplies branches mainly to the perineum.

Communications with the Sympathetic.—Each of these nerves has communications with the gangliated trunk of the sympathetic in the abdomen and pelvis.

Gray Rami Communicantes.—From the lumbar and sacral ganglia long slender *gray rami communicantes* are directed posteriorly and laterally over the bodies of the vertebræ, and (in the lumbar region) beneath the origins of the psoas muscle, to reach the spinal nerves. These branches are irregular in their arrangement. A given nerve may receive branches from two ganglia, or one ganglion may send branches to two nerves. The rami are longer in the loin than in the pelvis, owing to the projection of the lumbar portion of the vertebral column.

White Rami Communicantes.—Certain lumbar and sacral nerves are also connected with the abdominal and pelvic sympathetic by means of *white rami communicantes*. From the first two, and possibly in some cases also the third and fourth lumbar nerves, white rami communicantes are directed forwards, either independently or incorporated with the corresponding gray rami, to join the upper part of the lumbar sympathetic trunk. The fifth lumbar nerve and the first sacral nerves are unprovided with white rami communicantes. From the anterior rami of the second and third, or third and fourth sacral nerves, white rami (visceral or splanchnic branches) pass medially, and, crossing over (without joining) the sympathetic trunk, enter the pelvic plexus of the sympathetic. The fifth sacral and coccygeal nerves possess no white rami communicantes.

PLEXUS LUMBALIS.

The **lumbar plexus** is formed by the anterior rami of the first three and a part of the fourth lumbar nerves, with the addition, in some cases, of a small branch from the twelfth thoracic nerve. The nerves increase in size from above downwards (Fig. 624).

Position and Constitution.—The plexus is formed in the substance of the psoas muscle, in front of the transverse processes of the lumbar vertebræ. The nerves, on emerging from the intervertebral foramina, are connected as above described with the sympathetic system, and then divide in the following manner in the substance of the psoas major muscle. The first and second nerves divide into superior

and inferior branches. The superior branch of the first nerve (which may be joined by the branch from the twelfth thoracic nerve) forms two nerves, the **ilio-hypogastric** and **ilio-inguinal**. The inferior branch of the first joins the superior branch of the second nerve, to produce the **genito-femoral nerve** (O.T. **genito-crural**). The inferior branch of the second nerve, the whole of the third, and that part of the fourth nerve engaged in the constitution of the plexus divide each into two unequal parts—smaller *anterior* and larger *posterior parts*. The smaller anterior portions combine together to form the **obturator nerve**, which is thus formed by the second, third, and fourth lumbar nerves. The root from the second nerve is not always present. The larger posterior portions of the same nerves combine together to form the **femoral nerve** (O.T. **anterior crural**). From the posterior aspect of the posterior parts of the second and third nerves the **lateral cutaneous nerve of the thigh** (O.T. **external cutaneous**) arises. The nerves also provide, near their origins, irregular **muscular branches** for the psoas and quadratus lumborum muscles. The following is a list of the nerves which spring from the lumbar plexus (Figs. 624 and 625):—

(1) Muscular branches to the quadratus lumborum and psoas muscles.	(4) Genito-femoral.
(2) Ilio-hypogastric.	(5) Lateral cutaneous.
(3) Ilio-inguinal.	(6) Obturator.
	(7) Femoral.

Muscular Branches.—The nerves to the **quadratus lumborum muscle** arise independently from the first three or four lumbar nerves (and sometimes also from the twelfth thoracic nerve). The nerves to the **psoas muscles** arise from the second and third lumbar nerves, with additions, in some cases, from the first or fourth. They are often associated in their origin with the nerve to the iliacus from the femoral nerve. The **psoas minor**, when present, is innervated by the first or second lumbar nerve.

The ilio-hypogastric and ilio-inguinal nerves closely resemble, in their course and distribution, the lower thoracic nerves, with which they are in series.

N. Iliohypogastricus.—The **ilio-hypogastric nerve** is the highest branch of the first lumbar nerve. It receives fibres also from the twelfth thoracic, when that nerve communicates with the first lumbar nerve. After traversing the psoas muscle obliquely, it appears at its lateral border on the surface of the quadratus lumborum and behind the kidney. It courses through the loin, lying between the transversus and obliquus abdominis internus muscles, above the crest of the ilium. About an inch in front of the anterior superior spine it pierces the obliquus internus, and continues its course in the groin beneath the aponeurosis of the obliquus externus. It finally becomes cutaneous in the anterior abdominal wall, by piercing the aponeurosis of the obliquus externus about an inch and a half above the sub-cutaneous inguinal ring (Fig. 623, p. 715).

Its **branches** are—(1) *muscular* to the muscles of the abdominal wall; and (2) *cutaneous branches*, two in number. The **lateral cutaneous branch** corresponds with the lateral branch of an intercostal nerve, and, after piercing the obliquus internus and obliquus externus, becomes cutaneous just above the iliac crest, below and behind the iliac branch of the last thoracic nerve. It is small, and may be absent. It is distributed to the skin over the superior part of the lateral side of the buttock, in continuity with the cutaneous branch of the posterior ramus of the first lumbar nerve. The **anterior cutaneous branch** is the anterior terminal branch of the nerve. It supplies the skin of the anterior abdominal wall below the level of the last thoracic nerve and above the os pubis.

N. Ilioinguinalis.—The **ilio-inguinal nerve** is the second branch given off from the first lumbar nerve. It also may receive fibres from the last thoracic nerve. Not infrequently the ilio-hypogastric and ilio-inguinal nerves are represented for a longer or shorter part of their course by a single trunk. When separate the nerve takes a course similar to that of the ilio-hypogastric nerve, but at a lower level, as far as the anterior abdominal wall. It then pierces the obliquus internus farther forward and lower down than the ilio-hypogastric; and coursing forwards beneath the aponeurosis of the obliquus externus, just

above the inguinal ligament, it becomes superficial after passing through the subcutaneous inguinal ring and external spermatic fascia (Fig. 623, p. 715).

Its branches are *muscular* to the muscles of the abdominal wall, among which it passes, and *cutaneous branches* (*anterior scrotal*, or *labial nerves*), which innervate

FIG. 625.—THE MUSCLES AND NERVES ON THE POSTERIOR ABDOMINAL WALL.

the skin (1) of the anterior abdominal wall over the symphysis pubis, (2) of the thigh over the superior and medial part of the femoral triangle, and (3) of the superior part of the scrotum, and root and dorsum of the penis (of the mons Veneris and labium majus in the female). These last-named branches are contiguous to branches of the perineal and pudendal nerves. No lateral cutaneous branch arises from the ilio-inguinal nerve. It thus corresponds, like the anterior cutaneous part of the ilio-hypogastric nerve, to the anterior trunk of a typical thoracic nerve.

N. Genitofemoralis.—The **genito-femoral nerve** (O.T. **genito-crural**) usually arises by two independent roots from the front of the first and second lumbar nerves, which unite in the substance of the **psoas major** to form a slender trunk. It appears on the posterior abdominal wall, lying on the **psoas major**, medial to the **psoas minor**, and, piercing the **psoas fascia**, it extends downwards on the lateral aspect of the common and external iliac vessels and behind the ureter to the inguinal ligament (Fig. 625, p. 721). At a variable point above that ligament it divides into two branches. 1. The **external spermatic branch** is a minute nerve. It crosses the terminations of the external iliac vessels, and, along with the ductus deferens and testicular and external spermatic vessels, enters the inguinal canal through the abdominal inguinal ring. It terminates by supplying small branches to the skin of the scrotum and adjacent part of the thigh. In the female it accompanies the round ligament to the labium majus. This nerve gives off in its course the following small branches: (1) to the external iliac artery; (2) to the cremaster muscle; (3) to communicate with the spermatic plexus of the sympathetic. 2. The **lumbo-inguinal branch** continues the course of the parent nerve into the thigh, lying on the lateral aspect of the femoral artery. It becomes cutaneous by passing through the fossa ovalis or through the iliac portion of the fascia lata, and supplies an area of skin over the femoral triangle, lateral to that supplied by the ilio-inguinal nerve (Fig. 623, p. 715). It communicates in the thigh with the intermediate cutaneous branch of the femoral nerve. Before piercing the deep fascia it gives a minute branch to the femoral artery.

N. Cutaneus Femoris Lateralis.—The **lateral cutaneous nerve of the thigh** is only distributed to the skin (Fig. 625). It arises from the back of the lumbar plexus, and usually from the second and third lumbar nerves. Emerging from the lateral border of the **psoas major** muscle, the nerve crosses the **iliacus** muscle, beneath the fascia iliaca, to reach the anterior superior iliac spine. It enters the thigh beneath the lateral end of the inguinal ligament, and either over, under, or through the origin of the sartorius muscle. It extends distally along the front of the thigh for a few inches, lying at first beneath the fascia lata, and afterwards in a tubular investment of the fascia. It gives off small branches in this part of its course, and finally, piercing the fascia about four inches distal to the anterior superior iliac spine, it separates into anterior and posterior terminal branches. The **anterior branch** is the larger, and is distributed on the lateral aspect of the front of the thigh almost to the knee. The smaller **posterior branch** supplies the skin of the lateral side of the buttock distal to the greater trochanter and of the proximal two-thirds of the lateral aspect of the thigh (Fig. 625, p. 721).

NERVUS OBTURATORIUS.

The **obturator nerve** supplies the muscles and skin on the medial side of the thigh. It arises in the substance of the **psoas major** muscle by three roots placed in front of those of the femoral nerve, and derived from the second, third, and fourth lumbar nerves (Fig. 624, p. 718). Sometimes the root from the second nerve is absent. Passing vertically downwards, the nerve emerges from the **psoas major** at its medial border, behind the common iliac, and on the lateral side of the hypogastric vessels. It passes forwards below the pelvic brim in company with the obturator artery to the obturator groove of the obturator foramen, through which it reaches the thigh. While in the obturator groove it separates into its two main branches, named anterior and posterior (Fig. 626, p. 723).

The **anterior (O.T. superficial) branch** enters the thigh in front of the obturator externus and adductor brevis muscles, and beneath the pectineus and adductor longus. In the middle third of the thigh it is found coursing along the medial border of the adductor longus, anterior to the gracilis; and it finally divides into two slender terminal filaments, of which one enters the adductor canal and ends on the femoral artery, while the other supplies the skin for a variable distance on the medial side of the thigh and joins in the obturator plexus.

The branches of the anterior part of the nerve are:—

1. An **articular branch** to the hip-joint which arises from the nerve as soon as it enters the thigh, and supplies the joint through the acetabular notch.

2. **Muscular branches** to the adductor longus, gracilis, adductor brevis (usually), pectineus (occasionally). The last-named muscle is not usually supplied from the obturator nerve.

3. A **cutaneous branch** of very variable size forms one of the terminal branches (Fig. 626). It becomes superficial between the gracilis and adductor longus, in the middle third of the thigh, and may supply the skin of the distal two-thirds of the thigh in its medial side. It is generally of small size, and is connected with branches of the medial cutaneous and saphenous nerves behind the sartorius muscle to form the **obturator (O.T. sub-sartorial) plexus**. The branch from the saphenous nerve to the plexus passes medially behind the sartorius after piercing the

FIG. 626.—SCHEME OF THE COURSE AND DISTRIBUTION OF THE OBTURATOR NERVE.

aponeurotic covering of the adductor canal. The branch from the medial cutaneous nerve is generally superficial at the point of formation of the plexus.

4. The **branch to the femoral artery** is the other terminal branch of the nerve. It enters the adductor canal along the medial border of the adductor longus, and ramifies over the distal part of the artery.

5. A **fine communicating branch** sometimes joins the femoral nerve in front of the hip-joint.

The **posterior (O.T. deep) branch** of the obturator nerve reaches the thigh by piercing the obturator externus muscle. It passes distally between the adductor brevis and adductor magnus muscles. After passing obliquely through the adductor magnus, it appears in the popliteal fossa on the popliteal vessels, and terminates by piercing the oblique ligament of the knee and supplying the knee-joint.

Its branches are:—(1) **muscular branches** to the obturator externus, adductor magnus, and (when the muscle is not supplied by the superficial part of the nerve)

the adductor brevis. The branch to the obturator externus arises before the nerve enters the muscle, in the obturator groove. The nerve to the adductor magnus is given off as the obturator nerve passes through the substance of the muscle.

(2) An articular terminal branch is supplied to the posterior aspect of the knee-joint.

NERVUS FEMORALIS.

The **femoral nerve** (O.T. **anterior crural**) is the great nerve for the muscles and skin of the front of the thigh. It arises in the substance of the psoas major muscle, from the back of the second, third, and fourth lumbar nerves, posterior to the obturator nerve. Passing obliquely through the psoas major muscle, it emerges from its lateral border in the large pelvis (Fig. 625, p. 721). Passing downwards in the groove between the psoas and iliacus, it enters the thigh beneath the inguinal ligament, lateral to the femoral sheath and femoral vessels. In the femoral triangle it breaks up into a large number of branches, among which the lateral circumflex artery of the thigh passes.

The **branches** of the femoral nerve, which are (1) muscular, (2) articular, and (3) cutaneous, arise in the following way:—

In the abdomen a muscular branch arises from the lateral aspect of the nerve and enters the iliacus muscle.

In the femoral triangle the terminal muscular, articular, and cutaneous branches arise in the form of a large bundle of nerves.

1. **Rami Musculares.**—The **muscular branches** supply the pectineus, sartorius, and quadriceps. The nerve to the *pectineus* arises close to the inguinal ligament, and, coursing obliquely distally and medially behind the femoral vessels, enters the muscle at its lateral border. It is not infrequently double. It sometimes gives off a fine communicating branch to the anterior part of the obturator nerve. The nerves to the *sartorius* are in two sets: a lateral short set of nerves associated with the lateral part of the intermediate cutaneous nerve, which supply the proximal part of the muscle; and a medial longer set which are associated with the medial part of the intermediate cutaneous nerve, and enter the middle of the muscle. The parts of the *quadriceps* are supplied by several branches. The vastus lateralis and rectus femoris are supplied on their deep surface by separate nerves which are accompanied by branches of the lateral circumflex artery of the thigh. The vastus intermedius muscle is supplied superficially by a nerve which passes through the muscle, and innervates also the muscle of the knee-joint (subcrureus). It also receives fibres from one of the nerves to the vastus medialis. The vastus medialis muscle is supplied by two nerves: a proximal trunk, which supplies the proximal part of the muscle, and sends fibres to the vastus intermedius as well; and a distal trunk, which descends on the lateral side of the femoral artery along with the saphenous nerve, and passing beneath the sartorius, over or under the aponeurotic covering of the adductor canal, enters the medial side of the muscle. This nerve gives off a small branch which enters the medullary canal of the femur.

2. The **articular branches** supply the hip and knee-joints. The articular branch to the hip-joint arises from the nerve to the rectus femoris, and is accompanied by branches from the lateral circumflex artery of the thigh. The articular branches to the knee-joint are four in number. Three of them arise from the nerves to the vastus lateralis, vastus intermedius, and vastus medialis, which, after the muscular nerves are given off, are continued downwards to the knee-joint along the front of the femur. A fourth articular branch arises (sometimes) from the saphenous nerve.

3. **Rami Cutanei Anteriores.**—The **cutaneous branches** are the intermediate and medial cutaneous, and the saphenous nerves (Fig. 627).

The **intermediate cutaneous nerve** arises in two parts, a *lateral* and a *medial branch*, in the proximal part of the femoral triangle. The two branches descend vertically and become cutaneous by piercing the fascia lata over the proximal third of the sartorius muscle. They carry muscular branches to the sartorius, and the lateral branch in many cases pierces the muscle. These two nerves supply the skin of the distal three-fourths of the front of the thigh, between the lateral cutaneous nerve of the thigh laterally and the medial cutaneous on the medial side. They

reach to the front of the patella, and there assist in the formation of the patellar plexus. The lateral branch communicates in the proximal third of the thigh with twigs from the lumbo-inguinal branch of the genito-femoral nerve.

The **medial cutaneous nerve** lies at first in the femoral triangle on the lateral side of the femoral vessels. At the apex of the triangle it crosses over the femoral vessels, and is directed distally over or through the sartorius muscle, and beneath

FIG. 627.—DISTRIBUTION OF CUTANEOUS NERVES ON THE FRONT OF THE LOWER LIMB.

On the left side the distribution of the several nerves is represented in colour.

On the right side a schematic representation is given of the areas supplied by the above nerves, the figures indicating the spinal origin of the branches of distribution to each area.

the fascia lata, to the distal third of the thigh. It is distributed to the skin of the distal two-thirds of the thigh on the medial side by means of three branches—proximal, middle, and distal.

The *proximal branch* may be represented by two or more twigs. It arises from the main nerve near its origin, and pierces the fascia lata near the apex of the femoral triangle. It is distributed to the skin of the proximal part of the thigh, along the line of the great saphenous vein. The *middle* or *anterior branch* is a larger nerve. It separates from the distal branch at the apex of the femoral triangle, and passing over the sartorius muscle becomes cutaneous in the middle

third of the thigh on the medial side. It supplies the skin of the distal half of the thigh, extending as far as the knee, where it joins in the formation of the patellar plexus.

The *distal branch* represents the termination of the nerve. It passes along the medial side of the thigh over the sartorius muscle, and communicates in the middle third of the thigh with the saphenous and obturator nerves to form the obturator plexus. Piercing the fascia lata on the medial side of the thigh in the distal third, it ramifies over the side of the knee, and assists in the formation of the patellar plexus.

The size of the medial cutaneous nerve varies with the size of the cutaneous part of the obturator, and of the saphenous nerve.

N. Saphenus.—The **saphenous nerve** may be regarded as the terminal branch of the femoral nerve. It is destined for the skin of the leg and foot. From its origin in the femoral triangle it extends distally alongside the femoral vessels to the adductor canal. In the canal it crosses obliquely over the femoral sheath from lateral to medial side. At the distal end of the canal, accompanied by the saphenous branch of the *arteria genu suprema*, it passes over the tendon of the adductor magnus, and opposite the medial side of the knee-joint becomes cutaneous by passing between the sartorius and gracilis muscles. The nerve then extends distally in the leg along with the great saphenous vein, and coursing over the front of the ankle it terminates at the middle of the medial border of the foot.

Branches.—1. A **communicating branch** arises in the adductor canal, and passing medially beneath the sartorius joins with branches of the obturator nerve in forming the obturator plexus.

2. **Ramus Infrapatellaris.**—The **infra-patellar branch** arises at the distal end of the adductor canal, and piercing the sartorius muscle is directed distally and forwards below the patella, and over the medial condyle of the tibia to the front of the knee and proximal part of the leg. It enters into the formation of the patellar plexus.

3. An **articular branch** sometimes arises from the nerve at the medial side of the knee.

4. **Rami Cutanei Cruris Mediales.**—The **terminal branches** of the saphenous nerve are distributed to the skin of the front and medial side of the leg and the posterior half of the dorsum and medial side of the foot.

Plexus Patellaris.—The **patellar plexus** consists of fine communications beneath the skin in front of the knee, between the branches of the cutaneous nerves supplying that region. The nerves which enter into its formation are the infra-patellar branch of the saphenous, medial and intermediate cutaneous nerves, and sometimes the lateral cutaneous nerve of the thigh.

The **accessory obturator nerve** (*n. obturatorius accessorius*) is only occasionally present (29 per cent, Eisler). It arises from the third, or third and fourth lumbar nerves, between the roots of the obturator and femoral nerves. Associating itself with the obturator, from which, however, it is quite separable, it appears in the abdomen at the medial side of the psoas muscle, and coursing over the pelvic brim behind the external iliac vessels, it leaves the obturator nerve, and enters the thigh in front of the os pubis.

In the thigh, behind the femoral vessels, it usually ends in three branches: a nerve which replaces the branch from the femoral nerve to the pectineus, a nerve to the hip-joint, and a nerve which communicates with the superficial part of the obturator nerve. In some cases it only supplies the nerve to the pectineus; more rarely it is of considerable size, and reinforces the obturator nerve in the innervation of the adductor muscles.

The accessory obturator nerve was first described by Winslow as the *n. accessorius anterioris cruralis*. Schmidt later described it in great detail, and gave it the name it now bears. It is more closely associated with the femoral than with the obturator. Its origin is behind the roots of the obturator: it is separated, like the femoral, from the obturator by the pubic bone, and its chief branch, to the pectineus muscle, replaces the normal branch from the femoral nerve. On the other hand, for a part of its course it accompanies the obturator, and in rare cases it may replace branches of that nerve.

PLEXUS SACRALIS.

The sacral portion of the lumbo-sacral plexus is destined almost entirely for the lower limb. It is usually formed by the anterior rami of a part of the fourth lumbar nerve (n. furcalis), the fifth lumbar, the first, and parts of the second, and third sacral nerves (n. bigeminus).

Communications with the Sympathetic.—Each of the nerves named is connected to the lumbar or pelvic sympathetic by *gray rami communicantes*, as already described; and *white rami communicantes* pass usually from the third and usually also from the second or fourth sacral nerves to join the pelvic plexus of the sympathetic.

Position and Constitution.—The plexus is placed on the posterior wall of the pelvis between the parietal pelvic fascia and the piriformis muscle. In front of it are the pelvic colon, the hypogastric vessels, and the ureter.

The plexus is constituted by the convergence of the nerves concerned towards the inferior part of the greater sciatic foramen, and their union to form a broad triangular band, the apex of which is continued through the greater sciatic foramen below the piriformis muscle into the buttock, as the **sciatic nerve**. From the anterior and posterior surfaces of this triangular band numerous small branches arise, which are distributed to the parts in the neighbourhood of the origin of the nerve.

The sciatic nerve ends in the thigh by dividing into two large nerves, the **tibial** (O.T. **internal popliteal**), and **common peroneal** (O.T. **external popliteal**). In many cases these two nerves are distinct at their origin, and are separated sometimes by fibres of the piriformis muscle. In all cases on removal of the sheath investing the sciatic nerve the tibial and peroneal nerves can be traced up to the plexus, from which they invariably take origin by distinct and separate roots.

Formation.—The descending branch of the fourth lumbar nerve (n. furcalis) after emerging from the border of the psoas major muscle, medial to the obturator nerve, divides behind the iliac vessels into anterior and posterior (ventral and dorsal) parts, each of which joins a corresponding part of the fifth lumbar nerve. The anterior ramus of the fifth lumbar nerve descends over the ala of the sacrum, and divides into anterior and posterior parts, which are joined by the corresponding parts of the fourth lumbar nerve. The two resulting trunks are sometimes called the **truncus lumbosacralis** or **lumbo-sacral trunk**. The first and second sacral nerves pass almost horizontally laterally from the anterior sacral foramina, and divide in front of the piriformis into similar anterior and posterior parts. The third sacral nerve (n. bigeminus) divides into superior and inferior parts. The inferior part is concerned in forming the pudendal plexus. The superior part is directed laterally, and slightly upwards, towards the second nerve, and does not separate into two parts, but remains undivided.

These trunks combine to form the sacral plexus, and its main subdivisions, in the following way. Lying in apposition, and converging to the lower part of the greater sciatic foramen, the *posterior* (dorsal) *trunks* of the fourth and fifth lumbar nerves (lumbo-sacral trunks), and of the first and second sacral nerves, combine to form the **common peroneal nerve** and the subordinate nerves which arise from the posterior aspect of the plexus. The *anterior* (ventral) *trunks* of the fourth and fifth lumbar nerves (lumbo-sacral trunk), and of the first and second sacral nerves, together with that part of the third sacral nerve which is contributed to the plexus, unite to form the **tibial nerve** and the subordinate nerves arising from the front of the plexus.

Of these nerves the fifth lumbar and first sacral are the largest; the others diminishing in size as they are traced upwards and downwards. There is no distinct demarcation between the sacral and pudendal plexuses. The second and third sacral nerves (and in some cases the first sacral also) are concerned in the formation of both plexuses.

Branches.—The nerves of distribution derived from the sacral plexus are divided according to their origin into an *anterior* (ventral) and a *posterior* (dorsal)

series. Each set comprises one of the two essential terminal parts of the sciatic—peroneal and tibial nerves—and numerous smaller collateral branches.

NERVUS ISCHIADICUS.

It has already been shown how the sciatic nerve is formed. It comprises the two main nerves of the sacral plexus, bound together by an investing sheath, which contains, in addition to the common peroneal and tibial nerves, a subordinate branch of each, the nerve to the hamstring muscles, from the tibial, and the nerve to the short head of the biceps femoris, from the peroneal nerve. A thick band about half an inch in breadth is formed, consisting, from medial to lateral side, of (1) **nerves to the hamstring muscles**, (2) **tibial**, (3) **common peroneal**, (4) **nerve to the short head of the biceps muscle**. The sciatic nerve extends through the buttock into the back of the thigh. Forming a continuation of the sacral plexus, it enters the buttock by passing through the greater sciatic foramen, in the interval between the piriformis and superior gemellus. Concealed by the gluteus maximus muscle, it passes distally to the thigh, accompanied by the inferior gluteal artery, and the arteria comitans nervi ischiadici. It lies in the hollow between the greater trochanter of the femur and the tuberosity of the ischium, and enters the thigh beneath the fold of the nates at the lower border of the gluteus maximus. At this spot it is comparatively superficial, lying in the angle between the edge of the gluteus maximus above and laterally, and the origins of the hamstring muscles medially. In the thigh it is placed upon the adductor magnus, beneath the hamstring muscles, and it terminates at a variable point by dividing into the tibial and common peroneal nerves. As already stated, these two nerves may be separate from their origins, and their separation may occur at any point between the greater sciatic foramen and the proximal part of the popliteal fossa.

THE NERVES OF DISTRIBUTION FROM THE SACRAL PLEXUS.

These are divisible into two series—**collateral** and **terminal branches**. Each subdivision consists of a series of *anterior* and *posterior trunks*.

1. Collateral Branches.—The *anterior branches* are (a) muscular branches (to the quadratus femoris, gemelli, obturator internus, and hamstring muscles); and (b) articular branches (to the hip-joint). These nerves all arise from the anterior aspect of the sacral plexus.

The nerve to the quadratus femoris (and inferior gemellus) arises from the front of the fourth and fifth lumbar and first sacral nerves. It passes downwards over the back of the capsule of the hip-joint (to which it sends a fine branch) beneath the sacral plexus, gemelli, and obturator internus muscles. It supplies a nerve to the inferior gemellus, and terminates in the deep surface of the quadratus femoris.

The nerve to the obturator internus (and superior gemellus) arises from the anterior aspect of the fifth lumbar and first two sacral nerves. In the buttock it lies medial to the sciatic nerve on the lateral side of the pudendal vessels; crossing the ischial spine, it enters the ischio-rectal fossa through the lesser sciatic foramen. The nerve supplies in the buttock a branch to the superior gemellus, and terminates by entering the pelvic surface of the obturator internus.

The nerve to the hamstring muscles forms the most medial part of the sciatic trunk in the lower part of the buttock. It arises from all the roots of the tibial nerve on their anterior aspect, viz., from the fourth and fifth lumbar and

the first three sacral nerves. These roots unite to form a cord which is closely associated with the tibial nerve and is placed in front of it and afterwards on its medial side. Extending into the thigh, the trunk is distributed to the hamstring muscles by means of two sets of branches. Just distal to the ischial tuberosity a proximal set of nerves enters the proximal part of the semitendinosus and the ischial head of the biceps. More distally in the thigh the remaining portion of the nerve separates off from the tibial part of the sciatic trunk and supplies branches to the semimembranosus, the distal part of the semitendinosus, and the adductor magnus.

Articular branches for the hip-joint arise from the nerve to the quadratus femoris, and often directly from the anterior surface of the tibial part of the sciatic nerve near its origin. They enter the back of the capsule of the joint in the region of the buttock.

The *posterior branches* are: (a) muscular branches—a nerve to the piriformis, the superior gluteal nerve, the inferior gluteal nerve, and a nerve to the short head of the biceps; (b) articular branches (to the knee-joint).

These nerves all arise from the posterior aspect of those roots of the sacral plexus, which are associated with the origin of the common peroneal nerve.

The **nerve to the piriformis muscle** may be double. It arises from the back of the second, or first and second sacral nerves, and at once enters the anterior surface of the muscle.

N. Glutæus Superior.—The superior gluteal nerve arises from the posterior surface of the fourth and fifth lumbar and first sacral nerves, and is directed backwards and laterally into the buttock, above the piriformis muscle, along with the superior gluteal artery. Under cover of the glutæus maximus and glutæus medius, it passes over the glutæus minimus, along with the inferior branch of the deep division of the superior gluteal artery, to the deep surface of the tensor fasciæ latæ, in which it ends. On its way it supplies branches to the glutæus medius and glutæus minimus muscles.

N. Glutæus Inferior.—The inferior gluteal nerve arises from the posterior surface of the fifth lumbar and first two sacral nerves. It appears in the buttock at the lower border of the piriformis muscle, superficial to the sciatic nerve, and at once breaks up into a number of branches for the supply of the glutæus maximus. In its course in the buttock it is closely associated with the posterior cutaneous nerve of the thigh. Its origin is sometimes combined with that of the following nerve.

The **nerve to the short head of the biceps** springs from the lateral side of the common peroneal trunk in the proximal part of the thigh. When traced to its origin, it is found to arise (sometimes in combination with the inferior gluteal nerve) from the fifth lumbar and first two sacral nerves. In its course it is closely applied to the common peroneal nerve, from which it separates in the middle third of the thigh, usually in combination with the articular branches of that nerve for the knee-joint. In some cases it has an independent course in the thigh, and it may be associated in the buttock with the inferior gluteal nerve.

An **articular branch** for the lateral and anterior aspects of the knee-joint generally arises from the common peroneal nerve in common with the nerve to the short head of the biceps. When traced up to the plexus, it is found to arise from the posterior surface of the fourth and fifth lumbar and first sacral nerves. It passes through the proximal part of the popliteal fossa concealed by the biceps muscle, and separates into proximal and distal branches, which accompany the superior and inferior lateral articular arteries to the knee-joint.

Terminal Branches.—The common peroneal (O.T. external popliteal) and tibial (O.T. internal popliteal) nerves are the two main trunks resulting from the combination of the posterior and anterior cords of the sacral plexus respectively. The common peroneal nerve is homologous with the radial nerve of the upper limb; the tibial nerve represents a medio-ulnar trunk; and, as already stated, the two nerves, constituting the sciatic nerve, are enveloped in a common sheath for a variable distance before pursuing an independent course in the leg.

NERVUS PERONÆUS COMMUNIS.

The **common peroneal** (O.T. **external popliteal**) nerve arises from the posterior part of the sacral plexus from the fourth and fifth lumbar and first two sacral nerves. Incorporated with the sciatic nerve in the buttock and proximal part of the thigh, it passes distally from the bifurcation of that nerve through the popliteal fossa, to its termination at a point about an inch distal to the head of the fibula. It is concealed at first by the biceps muscle. Following the tendon of that muscle, it passes obliquely through the proximal and lateral part of the popliteal fossa and over the lateral head of the gastrocnemius muscle to the posterior aspect of the head of the fibula. In the distal part of its course and at its termination it is uncovered by muscle.

Collateral Branches.—These are divided into two sets: (*a*) Nerves arising from the roots or trunk of the nerve while it is in combination with the tibial nerve in the sciatic trunk. These have been already described, as a **muscular branch** to the short head of the biceps, and an **articular branch** to the knee-joint. (*b*) Nerves arising in the popliteal fossa. These are **cutaneous branches**, viz., the lateral sural nerve or lateral cutaneous nerve of the calf and the peroneal anastomotic ramus.

N. Cutaneus Suræ Lateralis.—The **lateral sural branch** is irregular in size and distribution, and may be represented by two or more branches (Fig. 628, p. 731). Arising from the common peroneal nerve in the popliteal fossa, often in common with the succeeding nerve, it pierces the deep fascia over the lateral head of the gastrocnemius, and is distributed to the skin on the lateral aspect of the back of the leg in the proximal two-thirds. The extent of its distribution varies with that of the posterior cutaneous nerve of the thigh and the nervus suralis.

Ramus Anastomoticus Peronæus.—The **peroneal anastomotic nerve** (O.T. **communicans fibularis**), arising in the popliteal fossa, passes over the lateral head of the gastrocnemius beneath the deep fascia to the middle third of the leg, where it assists in forming the nervus suralis by its union with an anastomotic (communicating) branch of the tibial nerve called the medial sural nerve or medial cutaneous nerve of the calf. In many cases the two branches do not unite. In such cases the peroneal anastomotic nerve may be limited in its distribution to the skin of the lateral side of the leg, heel, and ankle, or it may be distributed to the area usually supplied by the nervus suralis.

Terminal Branches.—The terminal branches of the common peroneal nerve are three in number:—recurrent tibial, deep peroneal (O.T. anterior tibial), and superficial peroneal (O.T. musculo-cutaneous). They arise just distal to the head of the fibula, and are directed forwards, diverging in their course, beneath the peroneus longus muscle.

The **recurrent tibial nerve** is the smallest branch. Passing forwards beneath the origin of the peronæus longus and the extensor digitorum longus muscles, it divides distal to the lateral condyle of the tibia into branches which supply the proximal fibres of the tibialis anterior muscle, the proximal tibio-fibular articulation, and the knee-joint.

NERVUS PERONÆUS PROFUNDUS.

The **deep peroneal nerve** (O.T. **anterior tibial**) passes obliquely distally, beneath the peronæus longus, extensor digitorum longus, and extensor hallucis longus muscles, to the front of the leg. In its course it is deeply placed upon the interosseous membrane and the distal part of the tibia, in company with the anterior tibial artery. At the ankle it lies beneath the transverse ligament of the leg and the tendon of the extensor hallucis longus, and crossing over the ankle-joint, it divides on the dorsum of the foot into its terminal branches.

1. **Collateral Branches** (in the leg).—These are given off to the muscles between which the deep peroneal nerve passes, namely: tibialis anterior, extensor hallucis longus, extensor digitorum longus, and peronæus tertius. A fine articular branch supplies the ankle-joint.

2. **Terminal Branches** (on the foot).—The terminal branches are medial and lateral. The **medial branch** passes along the dorsum of the foot on the lateral side of the dorsalis pedis artery to the first interosseous space, where it divides into two dorsal digital branches for the supply of the skin of the lateral side of the great toe and the medial side of the second toe (*nervi digitales dorsales hallucis lateralis et digiti secundi medialis*). Each of these branches communicates with branches of the superficial peroneal (O.T. musculo-cutaneous) nerve. It gives off one or two *dorsal interosseous branches*, which supply the medial tarso-metatarsal and metatarso-phalangeal articulations, and enter the first dorsal interosseous muscle.

The **lateral branch** passes obliquely over the tarsus beneath the extensor digitorum brevis, and ends in a gangliform enlargement (similar to the gangliform enlargement on the dorsal interosseous nerve of the forearm at the back of the wrist). From this enlargement muscular branches arise for the supply of the extensor digitorum brevis, along with branches for the tarsal, tarso-metatarsal, and metatarso-phalangeal articulations. Its *dorsal interosseous branches* may be as many as four in number. Of these the lateral two, extremely small, may only reach the tarso-metatarsal articulations. The medial two are fine branches, which, besides supplying the articulations, may give branches to the second and third dorsal interosseous muscles.

The branches from the nerve to the interosseous muscles are probably sensory, the motor supply of these muscles being certainly derived from the lateral plantar nerve.

NERVUS PERONEUS SUPERFICIALIS.

The **superficial peroneal nerve** (O.T. *musculo-cutaneous*), the last of the branches of the common peroneal nerve, passes distal to the head of the fibula and beneath the proximal fibres of the peronæus longus muscle. Lying in a sheath in the intermuscular septum, between the peronæi and the extensor digitorum longus, it proceeds distally in front of the fibula to the distal third of the leg, where it pierces the deep fascia in two branches, medial and lateral.

Its branches are: (1) *collateral* muscular branches distributed to the peronæus longus and peronæus brevis, as the nerve lies in relation to these muscles; (2) *terminal* cutaneous branches, medial and lateral.

Nn. Cutanei Dorsales Medialis et Intermedius.—The **medial terminal branch** (n. cutaneus dorsalis medialis) courses distally over the transverse ligament of the leg, and after supplying offsets to the distal third of the leg and dorsum of the foot, divides into three branches. (1) The most medial branch supplies the skin of the dorsum of the foot and the medial side of the great toe, and communicates with the saphenous nerve. (2) The intermediate branch passes to the interval between the great toe and the second, and divides into two branches which communicate with the medial branch of the deep peroneal nerve. (3) The lateral branch passes to the interval between the second and third toes, and divides into dorsal digital branches to supply the adjacent sides of these toes.

The **lateral terminal branch** (n. cutaneus dorsalis intermedius) of the nerve passes over the transverse ligament of the leg, and after supplying branches to the distal part of the leg and the dorsum of the foot, divides into two parts, which, passing to the intervals between the third and fourth, and fourth and fifth toes respectively, divide into dorsal digital branches for the adjacent sides of these toes. These branches communicate with offsets of the nervus suralis (nerve of the calf).

FIG. 628.—DISTRIBUTION OF CUTANEOUS NERVES ON THE DORSUM OF THE FOOT.

I.S. Saphenous nerve; M.C. Superficial peroneal nerve; A.T. Deep peroneal nerve; E.S. Nervus suralis. The extremities of the toes are supplied by the medial and lateral plantar nerves (I.P., E.P.).

The arrangement of the cutaneous branches of the superficial peroneal nerve is liable to considerable variation. The lateral division of the nerve may be increased in size, and may supply the nerve to the adjacent sides of the second and third toes; or it may be reduced in size, in which case the *nervus suralis* takes its place on the dorsum of the foot, often supplying as many as two and a half toes on the lateral side.

The cutaneous nerves on the dorsum of the toes are much smaller than the corresponding plantar digital nerves. They are reinforced on the dorsum of the terminal phalanges by twigs from the plantar nerves, which supply the tips of the toes and the nails.

NERVUS TIBIALIS.

The **tibial nerve** (O.T. **internal popliteal**) arises from the anterior surface of the sacral plexus, usually from the fourth and fifth lumbar and first three sacral nerves (Fig. 631, p. 736). It is incorporated in the sciatic trunk in the buttock and proximal part of the thigh. At the bifurcation of the sciatic nerve it passes onwards through the popliteal fossa and the back of the leg. The part of the nerve from its origin from the plexus or the bifurcation of the sciatic nerve to the distal border of the popliteus muscle, was formerly called **internal popliteal**; the part of the nerve in the back of the leg being then designated **posterior tibial**. The course of the nerve through the buttock and thigh has already been described (p. 728). In the popliteal fossa it is concealed at first by the *semimembranosus* and other hamstring muscles. It passes to the medial side of the popliteal vessels, and is thereafter found upon the popliteus muscle, under cover of the *gastrocnemius* and *plantaris*. In the back of the leg, from the distal border of the popliteus muscle to the ankle, the tibial (O.T. **posterior tibial**) nerve lies on the *tibialis posterior* muscle and the tibia, and, along with the posterior tibial vessels, occupies a sheath in the intermuscular septum separating the superficial and deep muscles of the back of the leg. In the proximal part of the leg the nerve is medial to the vessels, but, crossing over them, it lies on their lateral side in the distal portion of its course. It terminates beneath the *ligamentum laciniatum* by dividing into the lateral and medial plantar nerves.

The **collateral branches** may be divided into three series arising respectively in the region of the thigh, the popliteal fossa, and the back of the leg:—

(a) *Branches arising from the Roots or Trunk of the Nerve while it is incorporated with the Sciatic Nerve.*—These have been already described as **muscular branches** to the *quadratus femoris*, *gemelli*, *obturator internus*, and the hamstring muscles, and an **articular branch** to the hip-joint (Fig. 631, p. 736).

(b) *Branches arising in the Popliteal Fossa proximal to the Knee-Joint.*—These are in three sets—**articular**, **muscular**, **cutaneous**.

1. The **articular branches** are slender nerves, variable in number. There are usually two, an *azygos* branch which pierces the oblique ligament of the knee-joint, and a *medial* branch, a long fine nerve which, crossing the popliteal vessels, runs distally on the medial side of the fossa to accompany the distal medial articular artery to the knee-joint. In its course it gives off a branch, often absent, which accompanies the proximal medial articular artery.

2. The **muscular branches** are five in number. Nerves for the two heads of the *gastrocnemius*, and the *plantaris* enter these muscles at the borders of the popliteal fossa. A nerve for the *soleus* enters the superficial surface of the muscle. A nerve for the *popliteus* muscle passes over the surface of that muscle, and after winding round its distal border, supplies it on its deep (anterior) surface. As this nerve passes beneath the popliteus it supplies branches to the *tibialis posterior*, an *interosseous* branch for the interosseous membrane, which can be traced as far as the tibio-fibular syndesmosis, an *articular* branch for the proximal tibio-fibular joint, and a *medullary* branch for the shaft of the tibia.

3. **N. Cutaneous Suræ Medialis** (O.T. **N. Communicans Tibialis**).—The cutaneous branch is the **medial cutaneous nerve of the leg**. This nerve passes from the popliteal fossa in the groove between the two heads of the *gastrocnemius* muscle, and afterwards lies upon the *tendo calcaneus*. It pierces the deep fascia in the middle third of the back of the leg, and is joined immediately afterwards by the peroneal anastomotic ramus from the common peroneal nerve. From

their union the nerve of the calf (n. suralis) results, which reaches the foot, winding round the back of the malleolus along with the small saphenous vein. The nervus suralis supplies cutaneous branches to the lateral side and back of the distal third of the leg, the ankle and heel, and the side of the foot and little toe, as well as articular branches to the ankle and tarsal joints.

FIG. 629.—DISTRIBUTION OF CUTANEOUS NERVES ON THE BACK OF THE LOWER LIMB.

In A the distribution of the several nerves is represented, their names being given.

In B a schematic representation is given of the areas supplied by the above nerves, the figures indicating the spinal origin of the branches of distribution to each centre.

The n. suralis communicates on the foot with the superficial peroneal nerve, and its size varies with the size of that nerve. It may extend on to the dorsum of the foot for a considerable distance, and may either reinforce or replace the branches of the above-named nerve to the intervals between the fourth and fifth and the third and fourth toes. The mode of formation of the nervus suralis is very variable. The usual arrangement is that described. Frequently the peroneal anastomotic nerve and the medial sural nerve (medial cutaneous nerve of the leg) do not unite, and in such cases the more usual arrangement is for the tibial trunk to form alone the nervus suralis (nerve of the calf),

the peroneal anastomotic ramus extending only to the ankle and heel. It is less usual for the peroneal anastomotic ramus to form alone the nervus suralis, the medial sural nerve in these cases ending at the heel.

(c) *Branches arising in the Back of the Leg distal to the Knee-Joint.*—These branches are mainly muscular and cutaneous.

The **muscular branches** are four in number, comprising nerves to the soleus (entering its deep surface) and tibialis posterior, often arising by a common trunk, and nerves to the flexor digitorum longus and flexor hallucis longus, the latter generally accompanying the peroneal artery for some distance.

Rami Calcanei Mediales.—The cutaneous branches are the **medial calcanean rami**, which pierce the ligamentum laciniatum, and is distributed to the skin of the heel and posterior part of the sole of the foot.

In addition, a *medullary nerve* to the fibula, and a small *articular branch* to the ankle-joint, are supplied by the tibial nerve.

The **terminal branches of the tibial nerve** are the *medial and lateral plantar nerves*.

NERVUS PLANTARIS MEDIALIS.

N. Plantaris Medialis.—The **medial plantar nerve** is homologous with the median nerve in the hand (Fig. 629, p. 733). It is rather larger than the lateral plantar. It courses forwards in the sole of the foot beneath the ligamentum laciniatum and abductor hallucis to the interval between that muscle and the flexor digitorum brevis, in company with the medial plantar artery.

The **collateral branches** are muscular, cutaneous, and articular. The *muscular* branches supply the abductor hallucis and the flexor digitorum brevis. The *plantar cutaneous* branches are small twigs which pierce the plantar aponeurosis in the interval between these muscles to supply the medial part of the sole of the foot. The *articular* branches are minute twigs which supply the tarsal and tarso-metatarsal articulations.

Nn. Digitales Plantares Communes.—The **terminal branches** are four in number, the *common plantar digital nerves*, and may be designated first, second, third, and fourth, from medial to lateral side.

The **first** (most medial) branch separates from the nerve before the others, and pierces the plantar aponeurosis behind the ball of the great toe. It supplies a muscular branch to the flexor hallucis brevis, and cutaneous branches to the medial side of the foot and ball of the great toe. It terminates as the plantar digital nerve for the medial side of the great toe.

The **second branch** arises along with the third and fourth; after supplying a branch to the first lumbrical muscle, it becomes superficial in the interval between the first and second toes, and terminates by dividing into two *proper digital nerves* for the supply of the adjacent sides of these toes.

The **third and fourth branches** are entirely cutaneous in their distribution. They become superficial in the intervals between the second and third and the third and fourth toes, respectively, and there divide into proper digital branches for the supply of the adjacent sides of these toes.

Nn. Digitales Plantares Proprii.—The **plantar proper digital nerves** supply the whole length of the toes on the plantar aspect, and, in relation to the terminal phalanges, furnish minute dorsal offsets for the supply of the nails and tips of the toes on their dorsal surface. The medial plantar nerve thus supplies the skin of the three and a half medial toes in the sole of the foot; and four muscles:—the abductor hallucis and flexor digitorum brevis, the flexor hallucis brevis, and the first lumbrical muscle.

NERVUS PLANTARIS LATERALIS.

The **lateral plantar nerve** is homologous with the ulnar nerve in the hand. From its origin beneath the ligamentum laciniatum it extends forwards

and laterally in the sole, in company with the lateral plantar artery, between the flexor digitorum brevis and quadratus plantæ, towards the base of the fifth metatarsal bone. Here it terminates by dividing into superficial and deep branches.

Collateral Branches.—*Muscular branches* are given off from the undivided nerve to the quadratus plantæ and abductor digiti quinti muscles. *Cutaneous branches* pierce the plantar fascia at intervals along the line of the intermuscular septum, between the flexor digitorum brevis and abductor digiti quinti.

Terminal Branches—Ramus Superficialis.—The superficial branch is mainly cutaneous. Passing forwards between the flexor digitorum brevis and abductor digiti quinti, it divides into lateral and medial parts.

The *lateral branch*, after supplying the flexor quinti digiti brevis muscle, and sometimes one or both interossei of the fourth space, becomes superficial behind the ball of the little toe, and supplies cutaneous twigs to the sole of the foot and ball of the toe. It terminates as the proper digital branch for the lateral side of the little toe.

The *medial branch* passes forwards to the interval between the fourth and fifth toes, where it becomes cutaneous, and divides into two proper digital branches for the supply of the adjacent sides of these toes. It communicates with the fourth terminal branch of the medial plantar nerve.

Ramus Profundus.—The deep branch of the lateral plantar nerve, passing deeply along with the lateral plantar artery, extends medially towards the great toe, beneath the quadratus plantæ and oblique head of the adductor hallucis. It gives off *articular branches* to the tarsal and tarso-metatarsal articulations, and *muscular branches* to the interossei of each space (except in some cases the muscles of the fourth space): to the adductor hallucis, and the lateral three lumbrical muscles. These nerves enter the deep surface of the muscles, that to the second lumbrical reaching its muscle after passing forwards beneath the transverse head of the adductor hallucis.

FIG. 630.—SCHEME OF DISTRIBUTION OF THE PLANTAR NERVES.

In green, lateral plantar nerve, and its cutaneous and muscular branches; Quad. P., Quadratus plantæ; A.D.Q., Abductor digiti quinti; F.B.D.Q., Flexor brevis digiti quinti.

PLEXUS PUDENDUS.

The pudendal plexus constitutes the third and last subdivision of the lumbosacral plexus. It is composed for the most part of the spinal nerves below those which form the sacral plexus; but, as already stated, there is no distinct point of separation between the two plexuses. On the contrary, there is considerable overlapping, so that two and sometimes three of the principal nerves derived from the pudendal plexus have their origin in common with nerves of the sacral plexus.

The plexus is formed by fibres from the anterior rami of the first three sacral nerves, and by the whole of the anterior rami of the fourth and fifth sacral and coccygeal nerves. The size of the nerves diminishes rapidly from the first sacral to the coccygeal, which is extremely slender.

Position and Constitution.—The plexus is formed on the posterior wall of the pelvis. Of the nerves forming it, the upper ones emerge from the anterior sacral foramina; the fifth sacral nerve appears between the last sacral and first coccygeal vertebra; and the coccygeal nerve appears below the transverse process of that vertebra. The nerves of distribution derived from the plexus are the following:—

1. Visceral branches.
2. Posterior cutaneous nerve of the thigh.
3. Perforating cutaneous nerve.
4. Pudendal nerve.
5. Muscular branches.
6. Ano-coccygeal nerve.

Omitting the visceral branches, all the nerves are distributed to the perineum.

FIG. 631.—NERVES OF THE LUMBO-SACRAL PLEXUS.

Only two, the posterior cutaneous nerve of the thigh and the perforating cutaneous nerve, send branches to the lower limb.

Visceral Branches.—Like the other spinal nerves, the fourth and fifth sacral and coccygeal nerves are provided with fine *gray rami communicantes* from the sacral sympathetic trunk, which join them after a short course on the front of

the sacrum. The third (along with the second or fourth) sacral nerve, in addition, sends a considerable *white ramus communicans* or **visceral branch** direct to the pelvic plexus and viscera.

N. Cutaneus Femoris Posterior—**Posterior Cutaneous Nerve of the Thigh** (O.T. **Small Sciatic**).—This nerve is complex both in origin and distribution (Fig. 631, p. 736). Springing from the junction of the sacral and pudendal plexuses, it is derived from the first three or second and third sacral nerves. It is distributed to the lower limb and perineum, and is associated with other nerves belonging to both regions. It arises from the back of the roots of the sacral plexus in the pelvis. Its higher roots from the first and second sacral nerves are intimately associated with the origin of the inferior gluteal nerve; its lowest root from the third sacral nerve is associated with the origins of the perforating cutaneous or of the pudendal nerve. It enters the buttock through the greater sciatic notch below the piriformis, along with the inferior gluteal artery and nerve. Proceeding distally posterior to the sciatic nerve, it enters the thigh at the lower border of the gluteus maximus muscle, where it gives off considerable branches. Becoming gradually smaller as it courses distally over the hamstring muscles to the popliteal fossa, it finally pierces the popliteal fascia in one or more cutaneous branches, which supply the skin over the calf of the leg for a variable distance (Fig. 629, p. 733).

Branches.—The nerve is purely cutaneous. It supplies branches to the perineum, buttock, thigh, and leg.

Rami Perineales.—The **perineal branch** arises at the lower border of the gluteus maximus muscle (Fig. 631, p. 736). It sweeps in a medial direction to the perineum, lying on the origin of the hamstring muscles distal to the ischial tuberosity; and becoming subcutaneous after passing over the pubic arch, its terminal branches supply the skin of the scrotum and root of the penis, or in the female the labium majus and clitoris, some of them being directed backwards towards the anus and central point of the perineum. They communicate with the inferior hæmorrhoidal and perineal branches of the pudendal nerve, and with the ilio-inguinal nerve. In its course to the perineum the nerve gives off *collateral branches* to the skin of the proximal and medial part of the thigh.

Nn. Clunium Inferiores.—The **inferior gluteal branches** are large and numerous (Fig. 631, p. 736). They arise from the nerve beneath the gluteus maximus, and become subcutaneous by piercing the fascia lata at different points along its lower border. They supply the skin of the lower half of the buttock. The most lateral branches, reaching to the back of the greater trochanter, overlap the terminal filaments of the gluteal branches of the lateral cutaneous nerve of the thigh, and the posterior rami of the first three lumbar nerves. The most medial branches, which may pierce the sacro-tuberous ligament, reach nearly to the coccyx, and are co-extensive in their distribution with the branches of the perforating cutaneous nerve, which they reinforce and not infrequently replace.

The **femoral branches** are divisible into two sets—*medial* and *lateral*. They pierce the fascia lata of the thigh at intervals, and supply the skin of the back of the thigh.

The **sural branches** are two or more slender nerves which pierce the fascia over the popliteal fossa, and are distributed for a variable extent to the skin of the back of the leg. They may stop short over the popliteal fossa, or may extend as far as the ankle. Usually they innervate the skin as far as the middle of the calf. They communicate with the nervus suralis.

In cases where the sciatic nerve is naturally divided at its origin into tibial and common peroneal nerves (*e.g.* by the piriformis muscle), this nerve is also separated into two parts: a **posterior part**, associated with the common peroneal nerve and arising in common with the lower roots of the inferior gluteal nerve (usually from the first and second sacral nerves), and comprising the gluteal and lateral femoral branches; and an **anterior part**, associated with the tibial nerve and arising usually from the second and third sacral nerves, along with the perforating cutaneous and pudendal nerves, and comprising the perineal and medial femoral branches.

Perforating Cutaneous Nerve (n. perforans ligamenti tuberoso-sacri (Schwalbe), n. cutaneus clunium inferior medialis (Eisler)).—This nerve arises

from the back of the second and third sacral nerves (Fig. 631, p. 736). At its origin it is associated with the lower roots of the posterior cutaneous nerve of the thigh. Passing distally it pierces the sacro-tuberous ligament, along with the coccygeal branch of the inferior gluteal artery; and after winding round the lower border of the glutæus maximus muscle, or in some cases piercing its lower fibres, it becomes cutaneous a little distance from the coccyx, and supplies the skin over the lower part of the buttock and the medial part of the fold of the nates.

The perforating cutaneous nerve is not always present. In a minority of cases it is associated at its origin with the pudendal nerve. When absent as a separate nerve, its place is taken by (1) gluteal branches of the posterior cutaneous nerve of the thigh, or (2) a branch from the pudendal nerve, or (3) a small nerve (n. perforans coccygeus major, Eisler), arising separately from the posterior part of the third and fourth sacral nerves.

Muscular Branches.—Between the third and fourth sacral nerves (occasionally reinforced by the second, Eisler) a plexiform loop is formed, from which muscular nerves are given off to the levator ani (supplying the muscle on its pelvic surface), coccygeus, and external sphincter. The nerve to the external sphincter (*perineal branch of fourth sacral*) pierces the sacro-tuberous ligament and the coccygeus muscle, to which it gives offsets, and appears in the ischio-rectal fossa between the glutæus maximus and the external sphincter. Besides supplying the posterior fibres of the external sphincter, it distributes cutaneous offsets to the skin of the ischio-rectal fossa and the fold of the nates behind the anus. This nerve replaces in some instances the perforating cutaneous nerve.

Nn. Anococcygei (Ano-coccygeal Nerve).—By the union of the remaining part of the fourth with the fifth sacral and coccygeal nerves, the so-called **plexus coccygeus (coccygeal plexus)** is formed. A fine descending branch of the fourth sacral nerve passes over or through the sacro-tuberous ligament, to join the fifth sacral nerve. This fifth sacral nerve, joined by the descending branch of the fourth, descends alongside the coccyx and is again joined by the coccygeal nerve, so that a plexiform cord, the *ano-coccygeal nerve* results, homologous with the inferior caudal trunk of tailed animals. Fine twigs arise from it, which pierce the sacro-tuberous ligament and supply the skin in the neighbourhood of the coccyx, medial to the branches of the perforating cutaneous nerve and behind the anus.

NERVUS PUDENDUS.

The **pudendal nerve (O.T. pudic)** is the principal nerve for the supply of the perineum. It arises in the pelvis usually by three roots from the second, third, and fourth sacral nerves (Fig. 631, p. 736). (Frequently one of its branches, the inferior hæmorrhoidal nerve, arises independently from the third and fourth sacral nerves.) The nerve passes to the buttock through the greater sciatic foramen below the sciatic nerve, and lies on the sacro-spinous ligament, or the spine of the ischium, medial to the internal pudendal artery. It enters the perineum along with the artery through the lesser sciatic foramen. In the perineum it is deeply placed in the lateral wall of the ischio-rectal fossa, enclosed in a special sheath derived from the parietal pelvic fascia covering the medial surface of the obturator internus muscle. At the anterior limit of the ischio-rectal fossa, the nerve approaches the surface and divides at the base of the urogenital diaphragm into its terminal branches, the perineal nerve and the dorsal nerve of the penis.

The branches of the nerve are essentially the same in the two sexes. As a rule no branches are given off till it enters the perineum, but sometimes the inferior hæmorrhoidal nerve has an independent origin from the plexus, merely accompanying the pudendal nerve in the first part of its course; and in exceptional cases the perforating cutaneous nerve of the buttock is a branch of the pudendal nerve.

Nn. Hæmorrhoidales Inferiores.—The inferior hæmorrhoidal nerve arises from the nerve under cover of the glutæus maximus, at the posterior part of the ischio-rectal fossa. In cases in which it has an independent origin from the plexus, it arises from the third and fourth sacral nerves. It crosses the ischio-rectal fossa

in company with the inferior hæmorrhoidal vessels, and separates into numerous branches—muscular, cutaneous, and communicating.

The **muscular branches** end in the external sphincter ani muscle. The **cutaneous branches** supply the skin around the anus. The **communicating branches** connect the inferior hæmorrhoidal with three other nerves—the perineal branches of the posterior cutaneous nerve of the thigh, pudendal, and fourth sacral nerves.

Nervus Perinei.—The **perineal nerve**, one of the two terminal branches of the pudendal nerve, arises near the base of the urogenital diaphragm. It almost immediately divides into two parts, superficial and deep.

The **superficial part** is purely cutaneous and consists of two nerves, the posterior

FIG. 632.—DISTRIBUTION OF THE PUDENDAL NERVE.

or lateral and the anterior or medial superficial perineal nerves (nn. scrotales posteriores or nn. laterales posteriores), which pass, along with the superficial perineal vessels, to the anterior part of the perineum. The **posterior or lateral superficial perineal nerve**, at the anterior limit of the ischio-rectal fossa, usually passes over the base of the urogenital diaphragm and over the (superficial) transversus perinei muscle. The **anterior or medial superficial perineal nerve**, lying more deeply, pierces the base of the fascia inferior of the urogenital diaphragm and goes underneath or through the transversus perinei muscle. Becoming superficial in the anterior (urethral) triangle of the perineum, they are distributed to the skin of the scrotum (or labium majus), and communicate with the perineal rami of the posterior cutaneous nerve of the thigh and with the inferior hæmorrhoidal nerve.

The **deep part** of the perineal nerve is mainly but not entirely muscular

Coursing forwards through the anterior part of the ischio-rectal fossa, it passes between the two layers of fascia of the urogenital diaphragm towards the urethra. It supplies muscular branches to the anterior parts of the levator ani and external sphincter, to the transversus perinei, superficialis and profundus, ischio-cavernosus, bulbo-cavernosus (or sphincter vaginæ), and sphincter urethræ membranaceæ. It terminates as the nerve to the bulb, which, piercing the urogenital diaphragm, enters the bulb of the urethra and supplies the erectile tissue of the bulb and corpus cavernosum urethræ, as well as the mucous membrane of the urethra as far as the glans penis (or clitoridis).

N. Dorsalis Penis vel Clitoridis.—The dorsal nerve of the penis or clitoris, the other terminal branch of the pudendal nerve accompanies the internal pudendal artery beneath the fascia inferior of the urogenital diaphragm. It passes forward close to the pubic arch, lying beneath the crus and ischio-cavernosus, and fascia inferior of the urogenital diaphragm, and upon the sphincter urethræ membranaceæ muscle; piercing the fascia inferior of the urogenital diaphragm near

FIG. 633.—THE ORIGIN AND COURSE OF THE PUDENDAL NERVE.

its apex, at the lateral side of the dorsal artery of the penis (or clitoris), it passes on to the dorsum of the penis or clitoris, to which it is distributed in its distal two-thirds, sending branches round the sides of the organ to reach its under surface. In the female the nerve is much smaller than in the male. The dorsal nerve of the penis supplies one branch, the **nerve to the corpus cavernosum penis**, as it lies beneath the inferior fascia of the urogenital diaphragm. This is a slender nerve, which, piercing the fascia inferior, supplies the erectile tissue of the crus and corpus cavernosum penis.

Morphology of the Pudendal Plexus.—The structures occupying the perineum are placed in the ventral axis of the body, and comprise from before backwards, the penis and scrotum, or mons Veneris and vulva, the central point of the perineum, the anus and ischio-rectal fossa, and the coccyx. They are placed on the medial side of the attachment of the lower limbs—the penis or mons Veneris in relation to the preaxial border; the coccyx in relation to the postaxial border of the limb.

The nerves of the perineum, thus reaching the ventral axis of the trunk, are homologous with the anterior (ventral) terminations of other nerves. They are separable into two series. Mainly supplied through the pudendal plexus by the last four sacral and the coccygeal nerves, the perineum is also innervated to a minor extent by the first lumbar nerve through the ilio-inguinal nerve, which reaches the root of the penis and the scrotum. The region is thus supplied by two series of widely separated nerves, which have their meeting-place on the dorsum and side of the penis and scrotum. This junction of the ilio-inguinal and pudendal nerves constitutes the beginning of the **ventral axial line**, which extends peripherally along

the medial side of the lower limb. Apart from this break in their distribution, a definite numerical order may be followed in the arrangement of the perineal nerves. The higher parts of the perineum are innervated by the higher spinal nerves; the lower parts, by the lower nerves. This is best exemplified in the distribution of the cutaneous nerves. The base of the penis and scrotum (or mons Veneris) is supplied by the first lumbar nerve (ilio-inguinal). The dorsal nerve of the penis (or clitoris), when traced back to the pudendal plexus, is found to come from the second, and to a less extent from the third sacral nerves; the scrotal nerves (perineal branches of the pudendal and posterior cutaneous nerve of the thigh) similarly arise from the third, and to a less extent from the second sacral nerves; the skin of the ischio-rectal fossa and anus is innervated by the inferior hæmorrhoidal (third and fourth sacral nerves), and the perineal branch of the fourth sacral nerve. The ano-coccygeal nerve (coccygeal plexus), lastly, supplies the skin round the coccyx (fourth and fifth sacral and coccygeal nerves). Judged from its nerve supply the perineum is to be regarded as occupying, for the most part, a position behind or more caudal than that of the lower limb in relation to the trunk. There is here a remarkable gap in the numerical sequence of the nerves supplying the ventral axis of the body. All the nerves between the first lumbar and the second sacral fail to reach the mid ventral line of the trunk and are wholly concerned in the innervation of the lower limb.

At the preaxial border of the limb (groin) the first lumbar nerve, the highest nerve supplying the perineum, is concerned also in innervating the skin of the limb. At the postaxial border of the limb (fold of the nates and back of the thigh), the nerves which are the highest of those constituting the pudendal plexus (the second and third sacral nerves) are also implicated in innervating that border of the limb. The fourth sacral nerve is only concerned to a very slight extent in the innervation of the limb by means of the perineal branch, which reaches the beginning of its postaxial border; the last two spinal nerves are wholly unrepresented in the limb proper and end entirely in the trunk behind the limb.

FIG. 634.—SCHEME of the innervation of the hinder portion of the trunk and of the perineum, and the interruption of the segmental arrangement of the nerves associated with the formation of the limb.

MORPHOLOGY OF THE LIMB-PLEXUSES.

The arrangement of the limb nerves is rendered complex and the significance of the plexuses is obscured by the changes through which, coincidentally, the nerves on the one hand and the parts supplied by them on the other hand have passed in the course of development.

Nature of the Limbs.—As already described, the mammalian limbs arise as flattened buds from the extremities of the **Wolffian ridge**. Each bud possesses a *preaxial* and a *postaxial* border, and a *dorsal* and a *ventral* surface, continuous with the dorsal and ventral aspects of the trunk and homologous with its lateral and ventral surfaces. Each bud consists at first of a mass of undifferentiated, unsegmented mesoderm, covered with epithelium. Around the central core of mesoderm which produces the skeletal axis, the vessels and muscles of the limb are formed *in situ*, the muscles as double dorsal and ventral strata, beneath the corresponding surfaces of the bud.

Each limb bud is connected to the lateral and ventral aspects of the trunk, and is associated with a number of body segments, varying in the two extremities and in different animals. Although the mesodermal material of which the limb bud is composed exhibits in itself no segmental divisions at any period of its development, a clear indication of the segmental relations of the limbs is obtained from the arrangement of the limb nerves. Taking the nerves which supply the limbs in man as a guide, the segments engaged in the formation of the upper extremity are the last five cervical and first two thoracic. The lower extremity is related by its nerves to all the lumbar and the first three sacral segments. In each limb, the segments at the preaxial and postaxial borders are only partially concerned in limb formation.

It has been already shown that the somatic branches of the nerves enter the substance of the embryonic limb and divide in their course into dorsal and ventral trunks, which supply the dorsal and ventral surfaces of the limb bud. The higher nerves supply the preaxial border, the lower nerves supply the postaxial border, while the nerves most centrally situated extend furthest towards the periphery of the limb.

In order to understand properly the constitution of the limb-plexuses, it is necessary further to make a comparison of the surfaces and borders of the embryonic and adult limbs.

Upper Limb.—(A) **Borders.**—The preaxial border of the upper extremity extends from the

middle of the clavicle, in the line of the cephalic vein, distally along the front of the shoulder, the lateral border of the arm, forearm and hand, to the lateral border of the thumb. The **postaxial border** extends from the middle of the axilla along the medial side of the arm (in the line of the basilic vein), the medial side of the forearm and hand, to the medial border of the little finger.

(B) **Surfaces.**—The areas of the limb between these lines, anteriorly and posteriorly, correspond to the ventral and dorsal surfaces of the embryonic limb bud. The **ventral surface** is represented by the front of the chest, arm, and forearm, and the palm of the hand. The **dorsal surface** is represented by the scapular and deltoid regions, the back of the arm, forearm, and hand.

Lower Limb.—(4) **Borders.**—The **preaxial border** of the lower limb extends from the middle of the inguinal ligament distally along the medial side of the thigh and leg in the line of the great saphenous vein, to the medial side of the great toe. The **postaxial border**, beginning at the coccyx, extends along the fold of the nates and the lateral border and back of the thigh and leg (in the line of the small saphenous vein) to the lateral border of the foot and little toe.

(B) **Surfaces.**—The areas between these lines correspond to the primitive dorsal and ventral surfaces of the embryonic limb bud. The unequal amount of rotation in the parts of the lower limb obscures the relation of foetal and adult surfaces, which are most easily made out in the infantile position of the limbs, with the thighs and knees flexed and the soles of the feet inverted. The **ventral surface** of the embryonic limb is represented by the medial side and posterior part of the thigh, the back of the leg, and the sole of the foot. The **dorsal surface** is represented by the front of the thigh and buttock, the front of the leg, and the dorsum of the foot.

Composition of the Limb-plexuses.—In all mammals the same definite plan underlies the constitution of the limb-plexuses. The nerves concerned are the anterior rami of certain segmental spinal nerves, which (with certain exceptions at the preaxial and postaxial borders) are destined wholly and solely for the innervation of the limb. Each of the anterior rami engaged divides into a pair of **secondary trunks**, named **dorsal** or **posterior**, **ventral** or **anterior**. The dorsal and ventral trunks again subdivide into **tertiary trunks**, which combine with the corresponding subdivisions of neighbouring dorsal and ventral trunks to form the **nerves of distribution**. The combinations of *dorsal trunks* provide a series of nerves for the supply of that part of the limb which is derived from the *dorsal surface* of the embryonic limb bud; the combinations of *ventral trunks* give rise to nerves of distribution to the regions corresponding to its *ventral surface*. The relation of the nerves derived from the limb-plexuses to the areas of the limbs is given in the accompanying tables :—

I. Upper Limb.

Origin.		Nerves.		Distribution.							
Brachial Plexus	Dorsal trunks (<i>Posterior cord</i>)	{	Dorsal scapular }	{	Scapular region and shoulder	{	Dorsal surface				
			Long thoracic }

					Medial cutaneous nerve of the forearm }						
					Median }					{	Front of forearm and hand
Ulnar }											

II. Lower Limb.

Origin.	Nerves.	Distribution.	
Lumbo-sacral Plexus	Dorsal trunks	Ilio-hypogastric (lateral branch) Superior gluteal Inferior gluteal Nerve to piriformis Posterior cutaneous nerve of the thigh Lateral cutaneous nerve of the thigh Genito-femoral (lumbo-inguinal branch) Femoral Peroneal	Dorsal surface
		Buttock	
		Buttock and thigh, lateral side and front	
		Front of thigh	
		Front and medial side of thigh, leg, and foot	
		Front of leg and foot	
	Ventral trunks	Ilio-hypogastric (anterior branch) Ilio-inguinal Genito-femoral (external spermatic branch) Obturator Nerve to obturator internus and superior gemellus Nerve to quadratus femoris and inferior gemellus Nerve to hamstrings Posterior cutaneous nerve of the thigh Tibial	Ventral surface
		Abdominal wall (ventral surface)	
		Abdominal wall, thigh, and perineum	
		Groin	
		Thigh (medial side) and knee (back)	
		Buttock and back of thigh	
		Back of thigh and perineum	
		Back of knee, leg, and sole of foot	

In the regions of the limbs no anterior cutaneous branches, derived from the limb nerves, supply the trunk. The whole of the nerve is carried into the limb and is absorbed in its innervation, and the dorsal and ventral trunks forming the limb-plexuses are to be looked upon as homologous with the lateral and anterior trunks of an intercostal nerve. Two series of anomalies in relation to the formation and distribution of the nerves to the limbs must, however, be considered, because it has been suggested (Goodsir) that the nerves of the limbs are serially homologous not with the whole, but only with the lateral branches of the anterior rami of the intercostal nerves.

(1) **Nerves in connexion with the primitive borders of the Limbs.**—At the preaxial border of the upper limb, at its root, the fourth cervical nerve, which supplies the anterior and lateral surfaces of the neck, is also distributed through the supraclavicular nerves to the skin of both ventral and dorsal surfaces of the limb. The nerves and surfaces are here not merely homologous, but in actual continuity.

At the preaxial border of the lower limb, similarly, the first lumbar nerve, by means of the ilio-hypogastric and ilio-inguinal branches, supplies on the one hand the buttock, in series with the lateral branches of the lower thoracic nerves, and, on the other hand, the lower part of the abdominal wall and the adjacent medial side of the thigh, in series with the anterior terminal branches of the lower thoracic nerves.

At the postaxial border of the upper limb the first and second thoracic nerves are concerned in supplying trunk segments as well as parts of the limb. The first thoracic nerve, besides supplying the limb through the medial cord of the plexus, also innervates at least the muscles of the first intercostal space; the second thoracic nerve is concerned in the innervation of the limb, principally by means of its lateral branch only, which, as the intercosto-brachial nerve, supplies the skin along the postaxial border of the limb and on its *dorsal side*. At the postaxial border of the lower limb, in the same way, the third and fourth sacral nerves, partially implicated in the innervation of the limb (through the tibial, posterior cutaneous nerve of the thigh, perforating cutaneous nerve, and perineal branch of the fourth sacral nerve), are also engaged in supplying the trunk (perineum) through the pudendal nerve. These peculiarities of arrangement of the nerves at the borders of the limbs may be explained on the supposition that the segment corresponding to the nerve named is only partially concerned in limb formation, and is, at the same time, implicated to a greater or less extent in the formation of structures belonging to the trunk.

(2) **The origin and distribution of the nerves at the postaxial border of the limbs** present

a special difficulty. In the composition of the brachial plexus the first thoracic nerve is almost wholly engaged in forming the ventral series of nerves. It only gives a minute nerve to join the posterior cord, and this is not always present. In the case of the lumbo-sacral plexus the third sacral nerve does not as a rule divide into ventral and dorsal trunks, but contributes only to the formation of the ventral series of nerves. A solution of this difficulty may be found in the examination of the areas of distribution of the nerves derived from the first thoracic and third sacral nerves respectively. In the case of the brachial plexus (the medial cord of which receives normally the whole contribution of the first thoracic nerve) the medial cutaneous nerve of the arm, the ulnar branch of the medial cutaneous nerve of the forearm, and the dorsal branch of the ulnar nerve supply the dorsal aspect of the limb on its postaxial border. These nerves are in serial homology with the intercosto-brachial and lateral trunks of intercostal nerves. In the case of the lumbo-sacral plexus similarly, in which the third sacral nerve does not divide into ventral and dorsal trunks, the posterior cutaneous nerve of the thigh and tibial nerves containing the contribution from the third sacral nerves innervate, by means of the gluteal and lateral femoral branches of the former and the medial sural nerve (medial cutaneous nerve of the calf) of the latter, the dorsal surface of the limb along the postaxial border, in series with the perforating cutaneous nerve and the perineal branch of the fourth sacral.

These apparent anomalies appear to indicate that, instead of dividing into its proper dorsal and ventral trunks, the entire contribution of the spinal nerve concerned, is in these instances carried undivided along the postaxial border of the limb in association with the ventral trunks, and that the dorsal subdivisions are thrown off successively as the plexus cords approach the periphery. Indeed, in the case of the posterior cutaneous nerve of the thigh, Eisler has shown that, when the common peroneal and tibial nerves are separated at their origin, its gluteal and lateral femoral branches arise from and are connected with the dorsal, and the perineal and medial femoral branches with the ventral trunk.

THE DISTRIBUTION OF THE SPINAL NERVES TO THE MUSCLES AND SKIN OF THE LIMBS.

By dissection, experiment, and clinical observation, it is conclusively proved that as a rule each nerve of distribution in the limb, whether to muscle or skin, is made up of fibres derived from more than one spinal nerve ; and, further, that in cutaneous distribution a considerable overlapping occurs in the course of the several peripheral nerves. Moreover, the arrangement of the distribution of the nerves to skin and to muscles is not identical. In the case of the skin of the limbs, by the covering of the limb being drawn on to it from adjacent parts in the process of growth, cutaneous nerves are engaged, which are derived from sources not represented in the muscular innervation of the limbs. Again, among the muscles, some have undergone fusion, others have become rudimentary, and others again have altered their position in the limb. Bearing these qualifications in mind, it is possible to formulate a definite plan for the innervation of the skin and muscles of the upper and lower limb. The accompanying tables give an analysis of the distribution of the spinal nerves to the skin and muscles of the upper and lower limb respectively :—

A. **Innervation of the Muscles of the Limbs.**—The following laws appear to be applicable to the upper and lower limbs alike :—

1. *No limb-muscle receives its nerve-supply from posterior rami.*
2. *The dorsal and ventral strata of muscles are always supplied by the corresponding dorsal and ventral branches of the nerves concerned. The ventral muscular stratum is more extensive than the dorsal; the ventral nerves are the more numerous, and the additional nerves are postaxially placed. The spinal nerves supplying muscles of the upper limb are C. 5, 6, 7, 8 (dorsal), and C. 5, 6, 7, 8, T. 1 (ventral); the nerves for the muscles of the lower limb are L. 2, 3, 4, 5, S. 1, 2 (dorsal), and L. 2, 3, 4, 5, S. 1, 2, 3 (ventral).*
3. *The dorsal and ventral trunks of the nerves are distributed in the limb in a continuous, segmental manner; so that, "of two muscles, that nearer the head end of the body tends to be supplied by the higher nerve, and that nearer the tail end by the lower nerve" (Herringham).*
4. *The nerves placed most centrally in the plexus extend furthest into the limb, and the more preaxial nerves terminate sooner in the limb than the more postaxial nerves.*

Upper Limb.

Dorsal Surface.	Ventral Surface.
Muscles of shoulder . C. 3, 4, 5, 6, 7, 8.	Muscles of chest . C. 5, 6, 7, 8, T. 1.
„ arm . C. 6, 7, 8.	„ arm . C. 5, 6, 7.
„ forearm . C. 6, 7.	„ forearm . C. 6, 7, 8, T. 1.
	„ hand . C. 6, 7, 8 (T. 1).

Lower Limb.

Dorsal Surface.	Ventral Surface.
Muscles of thigh and buttock . L. 2, 3, 4, 5, S. 1, 2.	Muscles of thigh . L. 2, 3, 4, 5, S. 1, 2, 3.
Muscles of leg and foot L. 4, 5, S. 1.	„ leg . L. 4, 5, S. 1, 2.
	„ foot . L. 5, S. 1, 2.

The only exception to this rule is on the ventral (anterior) surface of the arm, where a suppression of the muscle elements leads to an absence of the regular series of segmental nerves (C. 8, T. 1) on its postaxial border. These nerves reappear in the forearm, and the occasional

DIAGRAM of the segmental distribution of the muscular nerves of the upper and lower limbs.

“axillary arches” may be regarded as the muscular elements usually suppressed, and, when present, supplied by these nerves.

Muscles with a Double Nerve-supply.—The existence of more than one nerve to a muscle indicates usually that the muscle is composite and is the representative of originally separate elements, belonging to more than one segment or to both surfaces of the limb. In the case of the pectoralis major, subscapularis and flexor digitorum profundus, adductor magnus, and soleus, parts of the same (ventral or dorsal) stratum have fused, to form muscles innervated from the corresponding ventral or dorsal nerves. The other muscles having a double nerve-supply—brachialis, biceps femoris, and (sometimes) pectineus—are examples of fusion at the preaxial or postaxial border of muscular elements derived from the dorsal and ventral surfaces of the limb, which are correspondingly innervated by branches from both dorsal and ventral series: *e.g.* the brachialis is innervated by the musculo-cutaneous and radial nerves; the biceps femoris by the peroneal (short head) and tibial nerves (long head); and the pectineus, by the femoral and (sometimes) obturator nerves.

B. Innervation of the Skin of the Limbs.—While the scheme of cutaneous innervation of the limbs is fundamentally segmental, yet the arrangement is confused and complicated by various causes. The growth of the limb from the trunk has caused the skin to be drawn out over it like a stretched sheet of india-rubber (Herringham), and at the same time the extent of the dorsal area of the limb is increased at the expense of the ventral area. The central nerves of the plexus remain buried deeply in the substance of the limb, only coming to the surface towards the periphery. The proximal parts of both surfaces of the limb thus become innervated by cutaneous nerves otherwise not necessarily concerned in the innervation of the limbs. Herringham has shown that—(A) *Of two spots on the skin, that nearer the preaxial border tends to be supplied by the higher nerve.* (B) *Of two spots in the preaxial area, the lower tends to be supplied by*

the lower nerve; and of two spots in the postaxial area, the lower tends to be supplied by the higher nerve. In other words, from the root of the limb along the preaxial border to its distal extremity, and along the postaxial border to the root of the limb again, there is a definite numerical sequence of spinal nerves supplying skin areas through nerves of the limb-plexuses. A similar numerical sequence in the arrangement of the nerves is also found extending over the dorsal and ventral surfaces of the limbs from preaxial to postaxial border, except in certain situations.

On the dorsal and ventral surfaces of both upper and lower limbs there is a hiatus, for a certain distance, in the numerical sequence of the spinal nerves in their cutaneous distribution, explicable on the ground that the central nerves of the plexus, which fail to reach the surface in these situations, are replaced by cutaneous branches from neighbouring nerves. This hiatus has been named the *axial area or line*.

In the upper limb, the dorsal axial area or line extends from the median line of the back, opposite the vertebra prominens, to the insertion of the deltoid.

The ventral axial area or line extends anteriorly from the median plane of the trunk, at the sternal synchondrosis, across the chest, distally along the front of the arm and forearm to the wrist.

In the lower limb, the dorsal axial area or line may be traced from the median plane of the back over the posterior superior iliac spine, across the buttock and thigh, to the head of the fibula.

A ventral axial area or line can also be traced from the root of the penis along the medial side of the thigh and knee, and along the back of the leg to the heel.

These areas or lines represent the meeting-place and overlapping of nerves, which are not in numerical sequence; and it is only at the peripheral parts of the limbs, on the dorsal and ventral surfaces, that the nerves appear in numerical sequence from the preaxial to the postaxial border. In the case of the upper limb the hiatus is caused, in both surfaces of the limb, by the absence of cutaneous branches of the seventh cervical nerve; in the case of the lower limb the hiatus is due to the absence of branches from the fifth lumbar nerve on both surfaces of the limb, and the absence of branches from the fourth lumbar nerve, in addition, on the dorsal surface.

Understanding the significance of these dorsal and ventral axial areas or lines, and at the same time bearing in mind the overlapping which occurs in the cutaneous distribution of each spinal nerve, the areas of skin supplied through the limb-plexuses can be mapped out with considerable precision, as indicated in the following tables:—

A. Cutaneous Distribution. Upper Limb.

Nerves.		Spinal Origin.	Distribution.
Preaxial border from neck to hand ↓	Supraclavicular nerves	C. 3. 4.	Chest, shoulder, deltoid, and scapular regions.
	Axillary	C. 5. 6.	Deltoid region, lateral side of arm.

VARIATIONS IN THE POSITION OF THE LIMB-PLEXUSES.

Two different kinds of variations occur in relation to the limb-nerves.

(1) **Individual variations**, both in the extent of origin and in the area of distribution of a given nerve, are not uncommon; these variations are usually concomitant with compensatory variations in adjacent nerves, and are due to the fibres of a given spinal nerve taking an abnormal course in the trunk of another nerve of distribution and effecting a communication with the proper nerve peripherally. In this way the variations in the origin and distribution of the intercosto-brachial nerve may be explained; and, similarly, the ulnar nerve may have some of its fibres carried as far as the forearm, incorporated with the median and transferred to it by a communication between the two nerves in that region.

(2) **Variations in the limb-plexus**, in relation to the vertebral column, are the chief cause of variations in the constitution of the limb-nerves. These variations affect more or less the whole series of nerves in the plexus.

The **brachial plexus** is subject only to very slight variation in position and arrangement. It may be reinforced at the upper end by a slender trunk from the fourth cervical nerve, and, more frequently, by an intra-thoracic communication between the second and first thoracic nerves. The presence of one or other of these nerves is an indication of a slight tendency towards a cephalic or caudal shifting of the whole plexus in relation to the spinal medulla. It is, however, never sufficient to cause the exclusion to any extent of the nerves normally implicated. The presence of a cervical rib may coincide with little or no change in the relation of the nerves. Indeed, the inclusion of the second thoracic nerve in the plexus may be, as already stated, merely an individual variation, a change in the path to the limb of the intercosto-brachial nerve. Concomitant variations occur among groups of nerves, however, which indicate a certain tendency to variation in the position of the whole plexus. At one end, the suprascapular and musculo-cutaneous nerves may arise from the fourth and fifth, fifth alone, or fifth and sixth cervical nerves. At the other end of the plexus, the radial may or may not receive a root from the first thoracic nerve, and this addition is rather more likely to occur when the second thoracic nerve is implicated in the plexus.

The **lumbo-sacral plexus** shows a very considerable variability in position and constitution. Eisler records concomitant variations in the plexus in 18 per cent of the cases examined by him. The variations occur within wide limits. The plexus may begin at the eleventh or twelfth

thoracic or first lumbar nerve. The last nerve in the sciatic cord may be the second, third, or fourth sacral nerve. The position of the *n. furcalis* is a guide to the arrangement of the plexus. It may be formed by the third, third and fourth, fourth, fourth and fifth, or fifth lumbar nerves. The resulting variations are illustrated by the following extreme cases:—

	(1) <i>Prefixed Variety.</i>	(2) <i>Postfixed Variety.</i>
Nervus furcalis	L. 3 and 4 (double).	L. 5.
Obturator	L. 1, 2, 3.	L. 2, 3, 4, 5.
Femoral	T. 12, L. 1, 2, 3, 4.	L. 2, 3, 4, 5.
Tibial	L. 3, 4, 5, S. 1, 2.	L. 5, S. 1, 2, 3, 4.
Common peroneal	L. 3, 4, 5, S. 1.	L. 5, S. 1, 2, 3.

Those variations in the constitution of the lumbo-sacral plexus are most numerous which are due to the inclusion of nerves more caudally placed. Thus, out of twenty-two variations in the position of the *n. furcalis*, in nineteen Eisler found it formed by the fifth lumbar nerve; in two cases only, by the third lumbar nerve. There is further evidence that variations in the position of the plexus are accompanied by variations in the vertebral column itself. Out of the twenty-two abnormal plexuses examined by Eisler, sixteen were coincident with abnormal arrangement of the associated vertebrae.

SIGNIFICANCE OF THE LIMB-PLEXUSES.

From the above considerations, it is obvious that something more than convenience of transit for the spinal nerves to skin and muscles is secured by the formation of the limb-plexuses. It has been shown that by their combinations in the plexuses, every spot or area of skin in the limbs is innervated by more than one spinal nerve; and generally, also, each limb-muscle is supplied by more than one spinal nerve. Each cutaneous area and each limb-muscle is thus brought into relationship with a wider area of the spinal medulla than would occur if the plexuses were non-existent. A simultaneous record of sensation is thus transmitted from any given point on the surface of the limb through more than one posterior root; and a more ready co-ordination of muscular movement is brought about by the transmission of motor impulses from the anterior root of a given spinal nerve to more than one muscle at the same time. In a word, a plexus exists to supply the whole limb and the limb as a whole, as an organ which has its different active parts connected with the central nervous system by means of the limb-plexus.

SYSTEMA NERVORUM SYMPATHICUM.

The **sympathetic nervous system** comprises a pair of elongated gangliated trunks, extending through the whole length of the body from the base of the skull to the coccyx, connected to the peripheral spinal nerves by one series of nerves, and to the viscera by another series. At its cephalic end each sympathetic trunk passes into the cranial cavity along with the internal carotid artery, on which it forms plexuses, and thereby forms complex relations with certain cerebral nerves. At their caudal ends the two sympathetic trunks are joined together by fine filaments and unite with the coccygeal ganglion (*g. impar*).

The sympathetic system is essentially dependent on and subservient to the spinal nervous system. It distributes efferent fibres from the peripheral spinal nerves to (*a*) the viscera and vessels of the splanchnic area, and (*b*) through recurrent (gray) rami to vessels, glands, and involuntary muscles in the course of the somatic divisions of the spinal nerves. It further collects and transmits to the cerebro-spinal system afferent fibres from the viscera (Fig. 635).

General Structure of the Sympathetic System.—The sympathetic system is composed of two elements—ganglia and nerve fibres.

Ganglia Trunci Sympathici.—The ganglia are variable in number, form, size, and position. They are not definitely segmental in position, but they are always connected together by a system of narrow commissural cords of nerve fibres. A ganglion (Fig. 635) consists of a larger or smaller number of multipolar nerve cells, enclosed in a capsule of connective tissue. Each cell is provided with one *axon* and a number of *dendrites*. The axon may enter into the composition of (*a*) the commissural cord; (*b*) a central branch (gray ramus communicans); or (*c*) a peripheral branch from the sympathetic trunk. These axons are commonly medullated at their origin, but become non-medullated in their course from the parent cell. Besides these ganglia, two other series of ganglia are present in connexion with the peripheral branches of the sympathetic: **ganglia plexuorum sympathicorum**,

intermediate or collateral ganglia, on the branches or in the sympathetic plexuses; and terminal ganglia, in close relation to the endings of the nerves in the viscera.

The nerve-fibres in the sympathetic system are of two classes, medullated and non-medullated. The distinction is not absolute. The medullated fibres may lose their medullary sheaths before reaching their terminations; and the non-medullated fibres may at their origin possess a medullary sheath. The medullated fibres form the series of *white rami communicantes* (the visceral branches of the spinal nerves). They take origin from the anterior rami of certain spinal nerves in two streams: thoracico-lumbar from the second thoracic to the second lumbar nerve inclusive, and pelvic, or sacral, from the second and third, or third and fourth sacral nerves. The roots of these rami arise from both posterior and anterior roots of the spinal nerves,

FIG. 635.—SCHEME OF THE CONSTITUTION OF THE WHITE RAMUS COMMUNICANS OF THE SYMPATHETIC.

The roots and trunks of a spinal nerve are shown, with the white ramus passing between the spinal nerve and a sympathetic ganglion (Sy.). The splanchnic efferent fibres (in red) are shown, partly ending in the ganglion, and partly passing beyond the ganglion into a peripheral branch. The splanchnic afferent fibres (in blue) are shown, partly entering the ganglion, and passing upwards or downwards in the gangliated cord; partly passing over the cord into peripheral branches.

The non-medullated fibres in the sympathetic system are derived from the axons of the sympathetic ganglion cells. They have different destinations. (a) Some fibres appear to contribute to the formation of the commissural cord connecting the ganglia together, and to end in arborisations round the cells of a neighbouring ganglion. (b) Non-medullated fibres form a large part of the system of peripheral (splanchnic efferent) branches, streaming into the splanchnic area in an irregular manner, both from the ganglia and the connecting commissures. (c) The gray rami communicantes form a series of non-medullated fibres (with a small number of medullated fibres intermingled) proceeding centrally from the ganglia to the spinal nerves. These gray rami are found in connexion with each and all of the spinal nerves. Their origin from the gangliated trunk is quite irregular: they may come from the ganglia or the commissure; they may divide after their origin, so

but in largest numbers from the anterior root. The fibres from the anterior root are of very small size. They are the axons of nerve cells within the spinal medulla, which enter the sympathetic trunk through the white ramus, and end by forming arborisations around the cells of a sympathetic ganglion. There are three known courses for such a fibre to take in relation to the sympathetic system—(a) It may end in the ganglion with which the ramus is immediately related; (b) it may course upwards or downwards in the commissural cord to reach a neighbouring ganglion; (c) it may pass beyond the sympathetic trunk to end in relation to cells of the peripheral (collateral) ganglia along with fibres of distribution from the sympathetic ganglia. These fibres are splanchnic efferent fibres; motor fibres for the unstriated muscular tissue of the vessels and viscera, and secretory fibres for the glands in the splanchnic area. The fibres from the posterior root of the spinal nerve entering into the composition of the white ramus communicans are the axons of spinal ganglion cells. They constitute the splanchnic afferent fibres, and probably traverse the sympathetic gangliated trunk, passing upwards, downwards, and peripherally, without being connected with its cells. They are the sensory fibres from the viscera, with which they are associated along with the peripheral branches arising from the sympathetic trunk itself. It is not certain that fibres from the spinal ganglia are only found in connexion with nerves provided with distinct white rami. Similar medullated fibres are found also in the gray rami communicantes.

that two spinal nerves are supplied from one ganglion ; or two ganglia may supply branches to a single spinal nerve. The gray ramus is distributed along the somatic divisions of the spinal nerves, supplying branches to unstriated muscular fibres (vaso-motor, pilo-motor) and glands (secretory). They also provide small recurrent branches, ending in the membranes enveloping the spinal nerve-roots. Mingled with the non-medullated fibres of the gray rami are a small number of medullated fibres, regarded as afferent fibres—axons passing to the spinal ganglia which are incorporated with the gray rami.

The **commis-**
sural cords of the
sympathetic system
are composed of white
and gray fibres. The
white fibres are: (1)
splanchnic efferent
fibres, passing to a
ganglion above or
below the point of
entrance into the
sympathetic system ;
(2) splanchnic affer-
ent fibres, guided
along the commis-
sure and over or
through the ganglia.
The *gray fibres* are
the axons of sympa-
thetic ganglion cells:
(1) true commissural
fibres passing into
connexion with the
cells of a neighbour-
ing ganglion ; (2)
fibres passing along
the commissure for a
certain distance up-
wards or downwards
before entering the
splanchnic area as
peripheral branches.

The **peripheral**
branches of the
sympathetic trunk
consist of—(1) **white**
fibres, which may be
either splanchnic afferent fibres on their way from the viscera through the gangliated trunk to the spinal ganglia, or splanchnic efferent fibres which, after traversing the gangliated trunk, proceed to join and end in collateral or terminal ganglia in relation to viscera ; (2) **gray fibres**, efferent branches, the axons of the ganglion cells, distributed on the one hand peripherally to the vessels and viscera of the splanchnic area, and on the other hand centrally through the gray rami communicantes and the somatic divisions of the spinal nerves, to the glands and involuntary muscles in the somatic area, as secretory, and vaso-motor and pilo-motor fibres.

Although forming always one continuous cord, the sympathetic system may

FIG. 636.—SCHEME OF THE CONSTITUTION AND CONNEXIONS OF THE GANGLIATED CORD OF THE SYMPATHETIC.

The gangliated cord is indicated on the right, with the arrangement of the fibres arising from the ganglion cells. On the left the roots and trunks of spinal nerves are shown, with the arrangement of the white ramus communicans above and of the gray ramus below.

for convenience of description be dealt with in four parts—cephalic and cervical, thoracic, lumbar, and pelvic.

I. PARS CEPHALICA ET CERVICALIS SYMTEMATIS SYMPATHICI.

The **cephalic and cervical part of the sympathetic trunk** is to be regarded as an upward prolongation of the primitive sympathetic system along the great vessels of the neck. It is characterised by the absence of **segmental ganglia** and by the absence of **white rami communicantes** joining it to the spinal nerves. Its connexion with the spinal nervous system is through the white rami communicantes of the upper thoracic nerves, which join the gangliated trunk in the thorax, and stream upwards into the cervical portion of the trunk. The trunk possesses two or three ganglia, from which branches are distributed to structures belonging to head, neck, and thorax: (1) motor fibres to involuntary muscles (*e.g.* dilator of the pupil); (2) vaso-motor fibres for arteries of the head, neck, and upper limbs; (3) pilo-motor fibres (along the cervical spinal nerves) to the skin of the head and neck; (4) cardio-motor fibres; and (5) secretory fibres (*e.g.* submaxillary gland).

The gangliated trunk in the neck is placed upon the prevertebral muscles and behind the carotid vessels. It extends from the root of the neck, where it is continuous behind the subclavian artery with the thoracic portion of the trunk, to the base of the skull, where it ends in the formation of plexiform branches upon the internal carotid artery. It consists of a narrow commissure composed of medullated and non-medullated fibres, with two or three ganglia—a *superior* ganglion at the upper end, an *inferior* ganglion at the point of junction with the thoracic portion of the trunk, and a *middle* ganglion varying in position and often absent.

Ganglion Cervicale Superius.—The superior cervical ganglion situated at the base of the skull, lies between the internal jugular vein and the internal carotid artery. It is the largest of the sympathetic ganglia, measuring an inch or more in length. The commissural cord connects it with the **ganglion cervicale medius** (*middle ganglion*), which is of small size, is frequently absent, and may be divided into two parts. It is usually placed over the inferior thyreoid artery as it passes behind the carotid sheath.

Ganglion Cervicale Inferius.—The inferior ganglion is joined by the commissural cord to the middle (or superior) ganglion above, and is only imperfectly separated from the first thoracic ganglion below. It is of considerable size, irregular in shape, and is placed behind the first part of the subclavian artery in the interval between the last cervical transverse process and the neck of the first rib.

The **branches** from the cervical sympathetic ganglia and commissural cords are divisible into two sets—(A) **Central** communicating branches for other nerves; (B) **Peripheral** branches of distribution, which alone, or along with other nerves, form plexuses, accompanying and supplying vessels and viscera of the head, neck, and thorax. Although this distinction is made, it is to be borne in mind that the branches of communication are as much nerves of distribution as the others.

GANGLION CERVICALE SUPERIUS.

Central Communicating Branches.—1. **Gray rami communicantes** pass from the ganglion to the anterior rami of the first four cervical nerves.

2. **Communications with Cranial Nerves.**—Just outside the skull, in the deep part of the neck, communicating branches pass to the following cerebral nerves: (a) to the petrous ganglion of the glossopharyngeal and the jugular ganglion of the vagus; (b) to the ganglion nodosum of the vagus; (c) to the hypoglossal nerve.

Peripheral Branches of Distribution.—1. **Pharynx.**—**Plexus Pharyngeus Ascendens.**—A pharyngeal branch passes behind the carotid sheath to reach the wall of the pharynx, where it joins (along with the pharyngeal branches of the glossopharyngeal and vagus nerves) in the formation of the **ascending pharyngeal plexus**, and assists in supplying the muscles and mucous membrane of the pharynx.

2. Heart.—N. Cardiacus Superior.—The superior cardiac branch is a slender nerve which, on the *right side*, descends behind the large vessels into the thorax to join the deep cardiac plexus. On the *left side* the course of the nerve is similar in the neck, but in the superior mediastinum it passes between the left carotid and subclavian arteries, and over the aortic arch, to join with the inferior cervical cardiac branch of the vagus in the formation of the superficial cardiac plexus. In their course both nerves form connexions with the other cardiac nerves of the sympathetic, and with cardiac and other branches of the vagus (recurrent and external laryngeal).

3. Vessels.—(a) The nn. carotici externi (external carotid branches) pass

FIG. 637.—DISTRIBUTION OF THE SYMPATHETIC IN THE NECK.

forwards to the external carotid artery, and form the **plexus caroticus externus** (external carotid plexus), which supplies offsets to that artery and its branches, as well as to the **glomus caroticum** (inter-carotid body). From the subordinate plexuses on the external maxillary and middle meningeal branches of the artery sympathetic fibres are supplied to the submaxillary and otic ganglia, respectively.

(b) N. Caroticus Internus.—The internal carotid branches form an upward prolongation of the ganglion, which applies itself in the form of bundles of nerve-fibres to the internal carotid artery as it enters the carotid canal in the temporal bone. The branches separate into lateral and medial parts, which form plexuses investing the artery in the cranium. The lateral division forms the inferior or internal carotid plexus (pl. caroticus internus); the medial division gives rise to the superior

or cavernous plexus (pl. cavernosus). Both plexuses supply offsets to the artery and its branches, and form communications with certain cerebral nerves.

Pl. Caroticis Internus.—The internal carotid plexus communicates by fine

FIG. 638.—THE SYMPATHETIC TRUNK IN THE THORAX.

branches with (a) the abducens nerve, and (b) the semilunar ganglion, and gives off (c) the great deep petrosal and (d) the carotico-tympanic nerves. The deep petrosal nerve joins the larger superficial petrosal nerve from the genicular ganglion

of the facial, over the foramen lacerum. By their union the **pterygoid nerve** is formed, which, after traversing the pterygoid canal, ends in the sphenopalatine ganglion. The **carotico-tympanic nerves** pass to the **tympanic plexus**. This plexus, formed by the carotico-tympanic nerves, the tympanic branch of the glossopharyngeal, and a twig from the genicular ganglion of the facial nerve, is placed on the labyrinthine wall of the tympanum. It supplies the mucous lining of the tympanum and auditory tube; and the **smaller superficial petrosal nerve** passes from it to the otic ganglion.

Plexus Cavernosus.—The cavernous plexus communicates with (*a*) the oculo-motor, (*b*) the trochlear nerve, and (*c*) the ophthalmic division of the trigeminal nerve; it also (*d*) supplies twigs to the hypophysis (pituitary body), and (*e*) forms the sympathetic root of the ciliary ganglion. This may pass to the ganglion independently, or it may be incorporated in the long root of the ganglion from the naso-ciliary branch of the ophthalmic nerve.

GANGLION CERVICALE MEDIUS.

Central Communicating Branches.—1. **Gray rami communicantes** arise from the ganglion or from the commissural cord for the anterior rami of the fifth and sixth cervical nerves. 2. The **ansa subclavia (ansa Vieussensii)** is a loop of communication from this ganglion, which, after passing over and supplying offsets to the subclavian artery and its branches, joins the inferior cervical ganglion.

Peripheral Branches of Distribution.—1. **Heart.**—A slender middle cardiac branch descends, either separately or in company with other cardiac nerves, behind the large vessels into the thorax, where it ends in the deep part of the cardiac plexus on each side.

2. **Thyroid Gland.**—Branches extend inwards along the inferior thyroid artery to supply the thyroid gland.

When the middle ganglion is absent the branches described arise from the commissural cord.

GANGLION CERVICALE INFERIUS.

Central Communicating Branches.—1. **Gray rami communicantes** arise from this ganglion for the anterior rami of the seventh and eighth cervical nerves. 2. The **ansa subclavia** already mentioned connects the middle and inferior ganglia over the front of the subclavian artery. 3. A communication frequently occurs with the recurrent nerve.

Peripheral Branches of Distribution.—1. **Heart.**—An inferior cardiac branch is given off on each side to enter the deep cardiac plexus.

2. **Vessels.**—(*a*) The **vertebral plexus** is a dense plexus of fibres surrounding the vertebral artery and accompanying its branches in the neck and the cranial cavity. (*b*) The **subclavian plexus** is derived from the ansa subclavia (subclavian loop), and supplies small offsets to the subclavian artery. It gives branches to the **internal mammary artery**, and communicates with the **phrenic nerve**.

II. PARS THORACALIS SYSTEMATIS SYMPATHICI.

The **thoracic part of the sympathetic trunk** lies behind the pleura, in front of the necks of the ribs, and the intercostal vessels and nerves. It consists of a number of ganglia of an irregularly angular or fusiform shape, joined together by commissural bands of considerable thickness. The number of ganglia is usually ten or eleven; but the first and sometimes others may be so fused with the neighbouring ganglia as to still further reduce the number.

This part of the sympathetic trunk is characterised by its union with the thoracic spinal nerves. Each thoracic nerve, with the probable exception of the first, sends a **visceral branch** (white ramus communicans) to join the gangliated trunk in the thorax. These white rami separate into two main streams in relation to the sympathetic trunk. Those of the *upper five* nerves are for the most part directed upwards to be distributed through the cervical part of the sympathetic trunk

in the manner already described. The white rami of the *lower thoracic* nerves are for the most part directed downwards in the inferior part of the sympathetic trunk and its branches, to be distributed in the abdomen; at the same time some of their fibres are directly supplied to certain thoracic viscera,—lungs, aorta, cesophagus.

These white rami are composed of (1) **splanchnic afferent fibres** passing from its peripheral branches through the sympathetic trunk into the ganglia of the

FIG. 639.—THE CARDIAC PLEXUSES.

spinal nerves—medullated nerve-fibres unconnected with sympathetic ganglion cells; and (2) **somatic and splanchnic efferent fibres**, small medullated nerves which, after a longer or shorter course in the gangliated trunk or its peripheral branches, become connected with the sympathetic ganglion cells, or with the cells of peripheral (collateral or terminal) ganglia, from which again (non-medullated) axons proceed to supply branches to viscera and vessels. The ultimate destination of the *upper* stream of white rami from the thoracic nerves has been mentioned in the description of the cervical sympathetic.

The peripheral branches supplying *thoracic organs* contain vaso-motor fibres for the lungs and aorta. The peripheral branches from the *lower* part of the sympathetic trunk in the thorax, receiving white rami from the lower thoracic nerves, are mainly distributed to structures below the diaphragm. They comprise (a) visceroinhibitory fibres for the stomach and intestines; (b) motor fibres for part of the rectum; (c) pilo-motor fibres for the lower part of the body; (d) vaso-motor fibres for the abdominal aorta and its branches, and for the lower limbs; (e) secretory, and (f) sensory fibres for the abdominal viscera.

The branches from the gangliated trunk are, as in the neck, divisible into two sets—(A) Central branches, communicating with other nerves, and (B) peripheral branches, distributed in a plexiform manner to the thoracic and abdominal viscera.

(A) **Central Communicating Branches.**—The white rami communicantes from the thoracic nerves have already been described. Passing forwards from the anterior rami of the nerves, they become connected with the ganglia or the commissural cord of the sympathetic.

The gray rami communicantes are branches arising irregularly from each thoracic ganglion; passing backwards along with the white rami, they join the anterior rami of the thoracic nerves, and are distributed in a manner already described (p. 754).

(B) **Peripheral Branches of Distribution.**—These branches arise irregularly from the ganglia and the commissural cord. They are composed of non-medullated (splanchnic efferent) fibres derived from the ganglion cells, and medullated fibres (splanchnic efferent and afferent) derived directly from the white rami, without the intervention of the cells of the ganglia.

1. **Rami Pulmonales.**—**Pulmonary Branches.**—From the gangliated trunk opposite the second, third, and fourth ganglia fine filaments arise which join the posterior pulmonary plexus.

2. **Rami Aortici.**—**Aortic Branches.**—The upper part of the thoracic aorta receives five branches from the upper five thoracic ganglia.

3. **Nn. Splanchnici.**—**Splanchnic Nerves.**—Three nerves arise from the inferior part of the gangliated trunk, partly from the ganglia themselves, and partly from the commissural cord between the ganglia. Passing downwards over the bodies of the thoracic vertebræ they pierce the diaphragm, to end in the abdomen.

(a) **N. Splanchnicus Major.**—The greater splanchnic nerve arises from the gangliated trunk between the fifth and ninth ganglia. By the union of several irregular strands a nerve of considerable size is formed, which descends in the posterior mediastinum, and piercing the crus of the diaphragm, joins at once the anterior end of the *celiac ganglion*. In its course in the thorax the splanchnic ganglion is formed upon the nerve. It is more prominent in the fetus than in the adult. From both nerve and ganglion branches arise in the thorax, for the supply of the œsophagus and descending thoracic aorta (Fig. 638).

(b) **N. Splanchnicus Minor.**—The smaller splanchnic nerve arises from the gangliated trunk opposite to the ninth and tenth ganglia. It passes over the bodies of the lower thoracic vertebræ, pierces the diaphragm near or along with the greater splanchnic nerve, and ends in the *celiac plexus* (*aortico-renal ganglion*).

(c) **N. Splanchnicus Imus.**—The lowermost splanchnic nerve arises from the last thoracic ganglion of the sympathetic, or it may be a branch of the smaller splanchnic nerve. It pierces the diaphragm, and ends in the *renal plexus*.

III. PARS ABDOMINALIS SYSTEMATIS SYMPATHICI.

The abdominal part of the sympathetic trunk is placed upon the bodies of the lumbar vertebræ, medial to the origins of the psoas major muscle, and in front of the lumbar vessels. It is connected with the thoracic portion of the trunk by an attenuated commissure, which either pierces or passes behind the diaphragm. It is continuous below with the pelvic portion of the trunk by a commissure, which passes behind the common iliac artery.

It is joined by medullated fibres (white rami communicantes) from the first two

lumbar spinal nerves, and it contains as well medullated fibres continued down from the lower part of the thoracic sympathetic trunk, and derived from the visceral branches (white rami communicantes) of the lower thoracic nerves.

This part of the trunk is characterised by great irregularity in the number of the ganglia. They are usually four in number, but there are frequently more (up to eight); and in extreme cases fusion may occur to such an extent that the separation of individual ganglia becomes impossible.

FIG. 640.—THE LUMBAR PORTION OF THE SYMPATHETIC GANGLIATED CORD AND LUMBAR PLEXUS. (From a dissection.)

T.11, T.12, L.1, L.2, L.3, L.4, L.5, Anterior rami of spinal nerves, with white and gray rami communicantes.

Sy, Sympathetic trunk; Va, Vagus nerve; G.S, Greater splanchnic nerve, joining celiac ganglion; S.R.C, Suprarenal gland and plexus; R.PL, Renal plexus; Ao.PL, Aortic plexus; S.M, Superior mesenteric plexus; I.M, Inferior mesenteric plexus; Hy.PL, Hypogastric plexus; Q, Nerves to quadratus lumborum; I.H, Ilio-hypogastric nerve; I.L, Ilio-inguinal nerve; G.C, Genito-femoral nerve; E.C, Lateral cutaneous nerve; A.C, Femoral nerve; Acc. Obt, Accessory obturator nerve; Obt, Obturator nerve; 4, 5, Lumbo-sacral trunk.

1. Central Communicating Branches.—White rami communicantes.—Only the first two (or three) lumbar spinal nerves send visceral branches (white rami communicantes) to the upper lumbar ganglia or to the sympathetic trunk. These nerves form the lower limit of the thoracic-lumbar visceral branches of the spinal nerves. They comprise vaso-motor fibres (for the genital organs), and motor fibres for the bladder and uterus.

Gray rami communicantes pass from the gangliated trunk to the anterior rami of the lumbar nerves in an irregular manner. One ramus may divide so as to supply branches to two adjacent spinal nerves; or one spinal nerve may be joined by several (two to five) gray rami from the sympathetic trunk.

The rami course beneath the origin of the psoas major muscle and over the bodies of the vertebrae. Gray rami sometimes pierce the fibres of the psoas muscle.

2. Peripheral Branches of Distribution.—From the lumbar sympathetic trunk numbers of small branches arise irregularly, and supply the abdominal aorta, reinforcing the aortic plexus (derived from the celiac plexus).

IV. PARS PELVINA SYSTEMATIS SYMPATHICI.

The pelvic part of the sympathetic trunk, like the cervical and lower abdominal portions of

this system, receives no *white rami communicantes* from the spinal nerves. The visceral branches (*pelvic splanchnic*) of the third, and usually, also, the second or fourth sacral nerves, enter the *pelvic plexus* without being directly connected with the sympathetic trunk. These nerves, however, are to be regarded as homologous with the white rami communicantes of the thoracic-lumbar nerves (*abdominal splanchnic*). They convey to the pelvic viscera—(1) motor and inhibitory fibres for rectum, uterus, and bladder, (2) vaso-dilator fibres for the genital organs, and (3) secretory fibres for the prostate gland.

This portion of the sympathetic trunk is placed on the pelvic surface of the sacrum, medial to the anterior sacral foramina. It is connected above by a commissural cord with the abdominal portion of the sympathetic, and below it ends in a plexiform union over the coccyx with the trunk of the other side, the two being frequently connected by the **ganglion impar** or **coccygeal ganglion**. The number of ganglia is variable; there are commonly four. They are of small size, gradually diminishing from above downwards.

Central communicating branches arise irregularly in the form of **gray rami communicantes** from the sacral ganglia, which join the anterior rami of the sacral and coccygeal nerves.

Peripheral Branches of Distribution.—(1) **Visceral branches** of small size arise from the upper part of the pelvic sympathetic trunk, and join the **pelvic plexus** (see below).

(2) **Parietal branches**, also of small size, ramify over the front of the sacrum, and form, in relation to the middle sacral artery, a plexiform union with branches from the sympathetic trunk of the other side.

PLEXUS SYMPATHICI.

Sympathetic Plexuses.—It has already been seen that the peripheral branches of the sympathetic trunk throughout its length are characterised by forming or joining plexuses in their neighbourhood.

The **cervical sympathetic ganglia** and nerves give rise to the carotid and cavernous plexuses; the external carotid, pharyngeal, thyreoid, vertebral, and subclavian plexuses; and they send important branches to the *cardiac plexuses* (described with the vagus nerve).

The **thoracic ganglia** send branches to join the *pulmonary* and *œsophageal plexuses* (described with the vagus nerve). They form plexuses on the thoracic aorta, and by means of the splanchnic nerves they form the chief source of the cœliac plexus.

THE CÆLIAC AND PELVIC PLEXUSES.

These great plexuses serve to distribute nerves to the viscera and vessels of the abdominal and pelvic cavities. Taken together they include three plexuses—the cœliac plexus, the hypogastric plexus, and the pelvic plexus. They are constituted by peripheral branches of the lower thoracic, abdominal, and upper pelvic parts of the sympathetic trunk; and they are related to the central nervous system by means of the visceral branches (white rami communicantes) of the lower thoracic and upper lumbar nerves on the one hand, and by the visceral branches of the second and third, or third and fourth sacral nerves, on the other hand. The thoracico-lumbar series join the sympathetic trunk, and reach the cœliac plexus mainly through the splanchnic nerves, and to a lesser extent through the abdominal part of the sympathetic trunk. The sacral series enter the pelvic plexus without connexion with the sympathetic trunk. The hypogastric plexus serves as a connecting link between the cœliac and pelvic plexuses.

PLEXUS CÆLIACUS.

The **cœliac plexus** lies on the posterior abdominal wall in relation to the abdominal aorta and behind the stomach. It is composed of three elements: the cœliac plexus surrounding the origin of the cœliac artery, between the crura of the diaphragm; and two cœliac ganglia, each lying on the corresponding crus of the diaphragm, and overlapped by the suprarenal gland, and on the right side by the inferior vena cava. The plexus is continuous with subordinate plexuses, diaphragmatic, suprarenal, renal, superior mesenteric and aortic; and by means of the **hypogastric nerves** the aortic plexus is continued into the **hypogastric plexus**, which again forms the chief origin of the **pelvic plexuses**.

The cœliac ganglia constitute the chief ganglionic centres in the solar plexus. They are irregular in form. They are often partially subdivided, and one

detached portion at the lower end is named the **aortico-renal ganglion**. Other small scattered masses of cells are present in the coeliac plexus. At the upper end the coeliac ganglion receives the *greater splanchnic nerve*. The aortico-renal ganglion

FIG. 641.—THE SYMPATHETIC IN THE ABDOMEN AND PELVIS.

at its lower end receives the *smaller splanchnic nerve*. Branches from the ganglion radiate in all directions—medially to join the coeliac plexus, upwards to form the diaphragmatic plexus, laterally to the suprarenal plexus, downward to the renal, superior mesenteric, and aortic plexuses.

The **coeliac plexus** forms a considerable plexiform mass surrounding the coeliac artery. It consists of a dense meshwork of fibres with ganglia intermingled, joined by numerous branches from the coeliac ganglion on each side, and by branches from the right vagus nerve. It is continuous below with the superior mesenteric and aortic plexuses. Investing the coeliac artery, it forms subsidiary plexuses which are distributed along the branches of the artery. The **coronary plexus** supplies branches to the œsophagus and stomach; the **hepatic plexus** supplies branches to the liver and gall-bladder, stomach, duodenum, and pancreas; and the **splenic plexus** sends offshoots to the spleen, pancreas, and stomach.

Subordinate plexuses are formed on the aorta and its branches by nerves derived from the coeliac ganglia and coeliac plexus.

a. Plexus Phrenicus.—The **phrenic plexus** consists of fibres arising from the coeliac ganglion, and accompanies the inferior phrenic artery. Besides supplying the diaphragm, it gives branches to the suprarenal plexus, and—on the right side to the inferior vena cava—on the left side to the œsophagus. It communicates on each side with the phrenic nerve. At the junction of the plexus and the phrenic nerve of the right side a ganglion is formed (**phrenic ganglion**).

b. Plexus Suprarenalis.—The **suprarenal plexus** is of considerable size. It is mainly derived from branches of the coeliac ganglion, reinforced by nerves from the inferior part of the coeliac plexus which stream laterally on the suprarenal arteries. It is joined by branches from the phrenic plexus above and from the renal plexus below. The nerves enter the substance of the suprarenal gland.

c. Plexus Renalis.—The **renal plexus** is derived from (1) branches of the coeliac ganglion, and (2) fibres from the aortic plexus, extending laterally along the renal artery to the hilus of the kidney. It receives also the lowermost splanchnic nerve, and is connected by numerous branches to the suprarenal plexus.

d. Plexus Mesentericus Superior.—The **superior mesenteric plexus** is inseparable above from the coeliac plexus, and is joined on either side by fibres from the coeliac and aortico-renal ganglia. It is continuous below with the aortic plexus. A separate detached ganglionic mass (**superior mesenteric ganglion**) is present in the plexus. Accompanying the superior mesenteric artery it forms subordinate plexuses around the branches of the vessel. The plexuses at first surround the intestinal arteries, but near the intestine they form fine plexuses between the layers of the mesentery, from which branches pass to the wall of the gut. This plexus supplies the small intestine, cæcum, vermiform process, ascending and transverse portions of the colon.

e. Plexus Aorticus Abdominalis.—The **aortic plexus** is the continuation downwards of the coeliac plexus around the abdominal aorta. It is continuous above with the coeliac and superior mesenteric plexuses; it is reinforced by the peripheral branches of the lumbar sympathetic trunk; and it is connected with the hypogastric plexus below by the **hypogastric nerves**. Besides investing and supplying the aorta, the plexus is connected with various subordinate plexuses on the branches of the artery. It contributes to the suprarenal and renal plexuses, and it gives rise to the spermatic or ovarian, and the inferior mesenteric plexuses.

Plexus Spermaticus.—The **spermatic plexus** invests and accompanies the spermatic artery. It is derived from the aortic plexus, and receives a contribution from the renal plexus. It supplies the spermatic cord and testis.

Plexus Arteriæ Ovaricæ.—The **plexus of the ovarian artery** in the female arises like the spermatic plexus. It accompanies the ovarian artery to the pelvis, and supplies the ovary, broad ligament, and uterine tube. It forms communications in the broad ligament with the **uterine plexus** (from the pelvic plexus), and sends fibres to the uterus.

Plexus Mesentericus Inferior.—The **inferior mesenteric plexus** is a derivative from the aortic plexus, prolonged along the inferior mesenteric artery. It forms subordinate plexuses on the branches of the artery (colic, sigmoid, and superior hæmorrhoidal), and is distributed to the descending colon, iliac colon, pelvic colon, and upper part of the rectum.

PLEXUS PELVINI.

The **hypogastric nerves** form the continuation of the aortic plexus into the pelvic cavity. They consist of numerous plexiform bundles of nerve-fibres which descend along the front and back of the bifurcation of the aorta and the origin of the common iliac arteries, and over the sacral promontory, where, becoming inextricably mingled, they constitute the hypogastric plexus.

The **hypogastric plexus** is continued downwards in front of the sacrum on either side of the rectum, and ends in the pelvic plexuses.

The **pelvic plexuses** are formed by the separation of the hypogastric plexus into two halves on either side of the rectum. Each is joined by fibres from the upper portion of the pelvic part of the sympathetic trunk, and by the **visceral branches** (white rami communicantes) from the second and third or third and fourth sacral nerves. Accompanying the hypogastric artery and its branches, each pelvic plexus gives off subordinate plexuses for the pelvic viscera.

a. Plexus Hæmorrhoidalis.—The **hæmorrhoidal plexus** supplies the rectum, and joins the superior hæmorrhoidal plexus from the inferior mesenteric plexus.

b. Plexus Vesicalis.—The **vesical plexus** accompanies the vesical arteries to the bladder-wall. Besides supplying the muscular wall and mucous membrane of the bladder, it forms subordinate plexuses for the lower part of the ureter, the vesicula seminalis, and the ductus deferens.

c. Plexus Prostaticus.—The **prostatic plexus** is of considerable size. It is placed on either side of the gland, and in addition to supplying its substance and the prostatic urethra, it sends offsets to the neck of the bladder and the vesicula seminalis. It is continued forwards on each side to form the **plexus cavernosus penis** (cavernous plexus of the penis). Bundles of nerves pierce the layers of the fascia of the urogenital diaphragm, and after supplying the membranous urethra, give off branches which enter and supply the corpus cavernosum penis. The cavernous nerves communicate with branches of the pudendal nerve and give offsets to the corpus cavernosum urethræ and the penile portion of the urethra.

d. Plexus Uterovaginalis.—The **uterine plexus** passes upwards with the uterine artery between the layers of the broad ligament, and is distributed to the surfaces and substance of the organ. It communicates between the layers of the broad ligament with the plexus of the ovarian artery.

The **vaginal plexus** is formed mainly by the visceral branches of the sacral nerves entering the pelvic plexus. It supplies the wall and mucous membrane of the vagina and urethra, and provides a **cavernous plexus** for the clitoris. The uterine and vaginal plexuses of the female correspond to the prostatic plexus of the male.

THE MORPHOLOGY OF THE SYMPATHETIC SYSTEM

FIG. 642.—SECTION THROUGH THE SYMPATHETIC TRUNK OF AN EMBRYO.

Showing the connexion with the ganglion (Sy) of the white ramus communicans (Spl); (α) a portion of the ramus joining the ganglion; (β) fibres passing over the trunk, accompanied by a stream of cells; (γ) continuous with those of the ganglion; (Ao) Aorta.

distinct elements—fibres of cerebro-spinal origin and “sympathetic” cells and fibres. While the function of the sympathetic trunk and its branches seems to be absolutely dependent upon the

cerebro-spinal nervous system, it is certain that the cells and fibres of the sympathetic system possess a vital activity apart from their connexion with the central nervous system. In the development of the sympathetic it is at least highly probable that a mesoblastic rudiment or precursor forms the basis of the sympathetic system, which is secondarily joined by nerve-fibres from the roots of the spinal nerves.

Morphologically this part of the nervous system is essentially a longitudinal cord or column, associated with involuntary muscles and glandular tissues, and particularly related to the organs in the splanchnic area. Like other longitudinal structures in the body, and especially like the organs of the splanchnic area, the sympathetic system is not truly segmental. The sympathetic trunk is only quasi-segmental, the segmentation being attributable to its junction with the visceral branches of the spinal nerves. The peripheral branches from the sympathetic trunk are by no means segmental; even the gray rami are not properly metameric, but, like the ganglia, assume a segmental character in consequence of their connexions with the spinal nerves.

The phylogenetic relation of the sympathetic and the cerebro-spinal elements in the system it is impossible to determine. It may be that the sympathetic system is the representative of an ancient architecture independent of the cerebro-spinal nervous system, the materials of which are utilised for a more modern nervous system; or it may be that the correlation of spinal nerves and sympathetic are both the consequences of the formation of new organs and structures in the splanchnic area. Examined in every light, it possesses features which effectually differentiate it from the cerebro-spinal system, although it has become inextricably united with it and subservient to it.

THE CEREBRAL NERVES.

Number.	Name.	Function.	Superficial Attachment to Brain.
I.	Olfactory . . .	Smell	Olfactory bulb.
II.	Optic	Sight	Optic chiasma.
III.	Oculo-motor . . .	Motor to muscles of eyeball and orbit	Cerebral peduncle.
IV.	Trochlear	Motor to superior oblique muscle of eyeball	Anterior medullary velum.
V.	Trigeminal	Sensory to face, tongue, and teeth; motor to muscles of mastication	Pons.
VI.	Abducent	Motor to lateral rectus muscle of eyeball	Junction of pons and medulla oblongata.
VII.	Facial	Motor to muscles of scalp and face, sensory to tongue	Medulla oblongata.
VIII.	Acoustic	Hearing and equilibrium	Medulla oblongata.
IX.	Glossopharyngeal . . .	Sensory to tongue and pharynx	Medulla oblongata.
X.	Vagus	Sensory to pharynx, œsophagus and stomach, and respiratory organs	Medulla oblongata.
XI.	Accessory	(a) Accessory to vagus. —Motor to muscles of palate, pharynx, œsophagus, stomach and intestines, and respiratory organs; inhibitory for the heart (b) Spinal part. —Motor to trapezius and sterno-mastoid	Medulla oblongata. Spinal medulla.
XII.	Hypoglossal	Motor to muscles of the tongue	Medulla oblongata.

The deep connexions of the cerebral nerves are dealt with in the section which treats of the Brain (pp. 592 to 607). Certain general points in connexion with these nerves are also touched upon in the chapter introductory to the Nervous System (p. 500). Their development is given on p. 501 *et seq.*

NERVI OLFACTORII.

The first or olfactory nerves consist of several parts: (1) a series of fine nerves, which arise from (2) the olfactory bulb. This again is connected by (3) the olfactory tract with the brain, to which it is attached by (4) two *striæ* or roots (Fig. 643).

The anatomy of the roots, tract, and bulb of the olfactory nerve are described elsewhere (pp. 623 to 628).

The **olfactory nerves**, about twenty in number, arise from the under surface of the olfactory bulb. The fibres are non-medullated. Piercing the cribriform plate of the ethmoid bone, enveloped in sheaths of dura mater, they are distributed in the nasal cavity as the nerves of smell. The fibres form fine plexuses over a limited area on the superior portion of the nasal septum, and to a less extent over the lateral wall of the nose.

FIG. 643.—VIEW OF THE INFERIOR SURFACE OF THE BRAIN,

With the lower portion of the temporal and occipital lobes, and the cerebellum on the left side removed, to show the origins of the cerebral nerves.

NERVUS OPTICUS.

The **second or optic nerve** arises from the brain by means of the **optic tract** (Fig. 643). This takes origin from the pulvinar of the thalamus, from the lateral and medial geniculate bodies, and from the brachium of the upper of the two corpora quadrigemina (*vide* pp. 619 and 620). The optic tract reaches the base of the brain after sweeping round between the cerebral peduncle and the gyrus hippocampi. The two optic tracts converge in front of the inter-peduncular fossa, medial to the anterior perforated substance and the termination of the internal carotid artery, and unite to form the **optic chiasma**. This adheres to the inferior surface of the floor of the third ventricle in front of the tuber cinereum, and gives rise at each end to the **optic nerve**. The optic nerve, directed laterally and forward, pierces the dura mater, and passes from the cranial cavity into the orbit through the optic foramen in company with the ophthalmic artery. In the orbit the nerve is embedded in the fat behind the eyeball, and is

surrounded by the ocular muscles. It is connected with the globe of the eye at a point one-eighth of an inch on the medial side of the axis of the eyeball. After piercing the fibrous and vascular coats, the nerve spreads out at the **optic papilla** to form the innermost layer of the **retina**. In the orbit the nerve is crossed by the ophthalmic artery and the naso-ciliary nerve, and nearer to its termination it is surrounded by the ciliary vessels and nerves, and by the fascia bulbi. It is pierced obliquely on its inferior surface by the arteria centralis retinae.

FIG. 644.—CENTRAL CONNEXIONS OF THE OPTIC NERVE AND OPTIC TRACTS.

Decussation in the Optic Chiasma.—In the optic chiasma the fibres of the two optic tracts separate, the medial part of each tract decussating to form the medial half of the opposite optic nerve. The other, lateral, part of each tract, continues its course to form the lateral half of the optic nerve on the same side. At the back of the chiasma another bundle of fibres is found passing from tract to tract behind the decussating fibres, and known as **Gudden's commissure** (see p. 619).

NERVUS OCULOMOTORIUS.

The **third** or **oculo-motor nerve** arises from the brain, in the region of the posterior perforated substance, by several *fila radicularia* (radicles) emerging from the **oculo-motor sulcus**, on the medial side of the cerebral peduncle, just in front of the pons (Fig. 643). Passing forwards between the posterior cerebral and

superior cerebellar arteries, the nerve pierces the dura mater beside the posterior clinoid process, in a small triangular space between the free and attached borders of the tentorium cerebelli. Beneath the dura mater the nerve courses through the

FIG. 645.—RELATIONS OF STRUCTURES IN THE CAVERNOUS SINUS AND SUPERIOR ORBITAL FISSURE.

lateral wall of the cavernous sinus, and enters the orbit through the superior orbital fissure and between the two heads of the lateral rectus muscle. As it enters the orbit it divides into upper and lower branches, separated by the naso-ciliary nerve.

Branches.—The superior branch of the nerve supplies two muscles of the orbit—the superior rectus and the levator palpebræ superioris.

The inferior branch passes forwards, and after giving branches to the medial and inferior recti, ends in the inferior oblique muscle. The *short root of the ciliary ganglion* arises from the terminal branch which goes to the inferior oblique muscle.

FIG. 646.—DORSAL SURFACE OF THE MID-BRAIN, to show the origin of the trochlear (fourth) nerve.

Communications.—1. In the cavernous sinus the oculo-motor nerve communicates with the cavernous plexus on the internal carotid artery. 2. In the cavernous sinus it also receives a slender communication from the ophthalmic division of the trigeminal nerve. 3. The *short root of the ciliary ganglion* passes upwards from the branch of the nerve which supplies the inferior oblique muscle.

NERVUS TROCHLEARIS.

The **fourth** or **trochlear nerve** emerges from the dorsal surface of the mid-brain. It arises at the side of the *frenulum veli* from the anterior end of the anterior medullary velum, just behind the corpora quadrigemina. It is extremely slender, and of considerable length. Passing round the cerebral peduncle, the nerve appears in the base of the brain behind the optic tract, in the interval between the cerebral peduncle and the temporal lobe of the brain. Continued forwards to the base of the skull, it pierces the free border of the tentorium cerebelli, lateral to the oculo-motor nerve, and proceeds forwards in the lateral wall of the cavernous sinus, to the superior orbital fissure, lying between the oculo-

motor nerve and the ophthalmic division of the trigeminal nerve. It enters the orbit above the muscles of the eyeball, and terminates in the orbital (superior) surface of the superior oblique muscle.

Communications.—In the cavernous sinus the nerve receives (1) a communicating

FIG. 647.—THE BASE OF THE SKULL, to show the dura mater, sinuses, arteries, and nerves.

branch from the cavernous or carotid plexus on the internal carotid artery, and (2) a slender filament from the ophthalmic division of the trigeminal nerve.

NERVUS TRIGEMINUS.

The **fifth** or **trigeminal nerve** arises from the inferior surface of the pons in its lateral part by two roots, a large **sensory root** and a small **motor root** (Fig. 643, p. 768). The two roots proceed forwards in the posterior fossa of the skull, and piercing the dura mater beneath the attachment of the tentorium cerebelli to the superior angle of the petrous part of the temporal bone, enter a cavity in the dura mater (*cavum Meckelii*) over the apex of the petrous bone.

The large sensory root gradually conceals the small motor root in its course forwards, and expands beneath the dura mater into a large flattened ganglion—the **semilunar ganglion**. This ganglion occupies an impression on the apex of the petrous portion of the temporal bone, and from it three large trunks arise—the ophthalmic or first, the maxillary or second, and the mandibular or third divisions of the nerve. The small motor root of the nerve passes forward beneath the ganglion, and is incorporated wholly with the mandibular division of the nerve.

NERVUS OPHTHALMICUS.

The **ophthalmic nerve** passes forwards to the orbit through the middle fossa of the skull, beneath the dura mater. It lies in the lateral wall of the cavernous sinus, at a lower level than the trochlear nerve, and reaches the orbit through the superior orbital fissure (Fig. 645).

In the wall of the cavernous sinus the ophthalmic nerve gives off (1) a small recurrent branch to the dura mater (*n. tentorii*), (2) communicating branches to the cavernous plexus of the sympathetic on the internal carotid artery, and (3) small communicating twigs to the trunks of the oculo-motor, trochlear, and abducent nerves.

In the superior orbital fissure the nerve divides into three main branches—lacrimal, frontal, and naso-ciliary (Fig. 645).

N. Lacrimalis.—The lacrimal nerve enters the orbit through the lateral angle of the superior orbital fissure, above the orbital muscles. Passing forwards between the periosteum and the orbital contents to the anterior part of the orbit, the nerve ends by supplying branches (*a*) to the lacrimal gland, (*b*) to the conjunctiva, and (*c*) to the skin of the lateral commissure of the eye.

FIG. 648.—DISTRIBUTION OF SENSORY NERVES TO THE HEAD AND NECK.

The lacrimal nerve communicates in the orbit with the zygomatic branch of the maxillary nerve, and on the face, by its terminal branches, with the temporal branches of the facial nerve (Fig. 653).

N. Frontalis.—The frontal nerve, entering the orbital cavity through the superior orbital fissure, courses forwards above the ocular muscles, and divides at a variable point into two branches—a larger supra-orbital and a smaller supra-trochlear nerve.

N. Supraorbitalis.—The supra-orbital nerve passes directly forwards, and leaves the orbit through the supra-orbital groove or foramen to reach the forehead. It gives off the following secondary branches: (1) the principal (**frontal**) branches (**rami frontales**) are distributed to the forehead and scalp, reaching backwards as far as the vertex; (2) small branches supply the upper eyelid; and (3) twigs are

distributed to the frontal sinus. On the forehead the supra-orbital nerve communicates with the temporal branches of the facial nerve.

N. Supratrochlearis.—The **supra-trochlear nerve** courses obliquely forwards and medially over the tendon of the superior oblique muscle to reach the medial side of the supra-orbital arch. Leaving the cavity of the orbit, the nerve is distributed to the skin of the medial part of the forehead, the root of the nose, and the medial commissure of the eye.

It communicates with the infra-trochlear branch of the naso-ciliary nerve, either before or after leaving the orbital cavity.

N. Nasociliaris.—The **naso-ciliary nerve** (O.T. **nasal**) enters the orbit through the superior orbital fissure, between the heads of the lateral rectus muscle, and between the two divisions of the oculo-motor nerve (Fig. 652, p. 776). It crosses the orbital cavity obliquely to reach the anterior ethmoidal foramen, lying in its course below the superior rectus and superior oblique muscles, and above the optic nerve and medial rectus muscle. The nerve is transmitted, under the name of *anterior ethmoidal*, through the anterior ethmoidal foramen into the cranial cavity, where it lies embedded in dura mater on the lamina cribrosa of the ethmoid bone. It enters the nasal cavity through the nasal fissure, and terminates by dividing into medial and lateral branches. The medial division supplies the mucous membrane over the upper and anterior part of the nasal septum. The lateral branch, after supplying collateral offsets to the lateral wall of the nasal cavity, finally appears on the face as the **external nasal nerve** between the nasal bone and lateral cartilage, and supplies branches to the skin of the lower part and tip of the nose.

The **branches** of the naso-ciliary nerve may be divided into three sets, arising (a) in the orbit, (b) in the nose, and (c) on the face.

In the orbit the branches are given off in three situations—lateral to, above, and medial to the optic nerve. (a) As the nerve lies on the lateral aspect of the optic nerve, it gives off the **radix longa ganglii ciliaris** (**long root of the ciliary ganglion**). (b) As it crosses the optic nerve, **nn. ciliares longi** (**two long ciliary branches**) arise, and pass forwards alongside the optic nerve to the eyeball. (c) On the medial side of the optic nerve the **n. infratrochlearis** (**infra-trochlear nerve**) arises, a slender branch which courses forward beneath the pulley of the superior oblique muscle to the front of the orbit. It ends on the face by supplying the skin of the root of the nose and the eyelids, and communicates either in the orbit or on the face with the supra-trochlear nerve. On the face it also communicates with zygomatic branches of the facial nerve.

In the nose the **rami nasales mediales** (**medial nasal branches**) supply the mucous membrane of the anterior part of the nasal septum; the **rami nasales laterales** (**lateral nasal branches**) supply the anterior part of the lateral wall of the nasal cavity.

On the face the terminal filaments of the nerve are distributed, as the **ramus nasalis externus** (**external nasal branch**), to the skin of the lower half and tip of the nose. The terminal branch communicates with the zygomatic branches of the facial nerve (Fig. 653).

Ganglion Ciliare.—The **ciliary ganglion** is associated with the naso-ciliary branch of the ophthalmic nerve and with the inferior division of the oculo-motor nerve. It is a small reddish ganglion, placed between the lateral rectus muscle and the optic nerve, and in front of the ophthalmic artery. Its **roots** are three in number: (1) **sensory** or long, derived from the naso-ciliary branch of the ophthalmic nerve; (2) **motor** or short, derived from the inferior division of the oculo-motor nerve; and (3) **sympathetic**, a slender filament from the cavernous plexus on the internal carotid artery, which may exist as an independent root or may be incorporated with the long root from the naso-ciliary nerve. The branches from the ganglion are twelve to fifteen **nn. ciliares breves** (**short ciliary nerves**), which pass to the eyeball in two groups above and below the optic nerve. They supply the coats of the eyeball, including the iris and ciliary muscles. *The circular fibres of the iris* and the *ciliary muscle* are innervated by the third nerve; *the radial fibres of the iris* by the sympathetic.

FIG. 649.—INNERVATION OF NASAL SEPTUM AND PALATE.

FIG. 650.—INNERVATION OF LATERAL WALL OF NASAL CAVITY AND PALATE.

NERVUS MAXILLARIS.

The Maxillary Nerve.—This large nerve courses forwards from its origin in the semilunar ganglion through the middle fossa of the skull, beneath the dura mater, and in relation to the lower part of the cavernous sinus (Fig. 647, p. 771). Passing through the foramen rotundum, it traverses the pterygo-palatine fossa. It enters the orbit as the infra-orbital nerve, through the inferior orbital fissure, and occupying successively the infra-orbital groove and canal, it finally appears on the face through the infra-orbital foramen (Fig. 653).

The branches and communications of this nerve occur (*a*) in the cavity of the cranium, (*b*) in the pterygo-palatine fossa, (*c*) in the infra-orbital canal, and (*d*) on the face.

FIG. 651.—THE NERVES OF THE ORBIT FROM ABOVE.

In the cavity of the cranium the nerve gives off a minute (*n. meningeus medius*) middle meningeal (O.T. recurrent nerve) to the dura mater of the middle fossa of the skull.

In the pterygo-palatine fossa the nerve gives off—(1) two short thick *nn. sphenopalatine* (spheno-palatine nerves), the sensory roots of the spheno-palatine ganglion. (2) *Rami alveolares superiores posteriores* (posterior superior alveolar nerves, which may be double), descend through the pterygo-maxillary fissure to the lateral side of the maxilla, and proceed forwards along the alveolar arch, in company with the posterior superior alveolar artery. They supply the gum and the upper molar teeth by branches which perforate the bone to reach the alveoli. The nerves form a fine plexus joined by the middle alveolar nerve before finally reaching the teeth. (3) A small *zygomatic* (O.T. orbital) branch enters the orbital cavity through the inferior orbital fissure, and proceeding along the lateral wall, communicates

with the lacrimal nerve, and passes through the zygomatico-orbital foramen in the zygomatic bone, where it divides into two branches. The **zygomatico-facial** (O.T. malar) branch appears on the face, after traversing the zygomatic bone, and supplies

FIG. 652.—SCHEMATIC REPRESENTATION OF THE NERVES WHICH TRAVERSE THE CAVITY OF THE ORBIT.

the skin over that bone. It communicates with the zygomatic branches of the facial nerve. The **zygomatico-temporal** (O.T. temporal) branch perforates the temporal surface of the zygomatic bone, and is distributed, after piercing the temporal fascia

FIG. 653.—THE COURSE OF THE OPHTHALMIC AND MAXILLARY NERVES.

to the skin over the anterior part of the temple. It communicates with the temporal branches of the facial nerve. It may be very minute, and not pass further than the temporal fascia, between the two layers of which it may form a communication with the facial nerve. (4) The **infra-orbital nerve** (n. infraorbitalis)

is the terminal branch of the maxillary nerve, which enters the orbit through the inferior orbital fissure and traverses the infra-orbital canal to reach the face.

In the *infra-orbital canal* the infra-orbital nerve supplies one and sometimes two branches to the teeth—the middle and anterior superior alveolar nerves (*ramus alveolaris superior medius et rami alveolares superiores anteriores*). The former may be only a secondary branch of the latter nerves, or they may arise independently from the infra-orbital nerve. However formed, the nerves descend in bony canals in the wall of the maxillary sinus (to the lining of which branches are given), and reach the alveolar arch, where they form minute plexuses and supply the teeth (joining posteriorly with the branches of the posterior superior alveolar nerve). The anterior superior alveolar nerve supplies the incisor and canine teeth; the middle superior alveolar nerve supplies the premolar teeth.

After emerging on the face from the infra-orbital foramen, the infra-orbital nerve divides into a number of radiating branches arranged in three sets—(a)

FIG. 654.—COURSE AND BRANCHES OF THE MAXILLARY NERVE.

inferior palpebral (*rami palpebrales inferiores*), for the lower eyelid; (b) external nasal (*rami nasales externi*), for the skin of the side of the nose; and (c) superior labial (*rami labiales superiores*), for the cheek and upper lip. These branches form communications with the zygomatic branches of the facial nerve, and give rise to the *infra-orbital plexus* (Fig. 657, p. 783).

Ganglion Spheno-palatinum.—The *spheno-palatine ganglion* occupies the upper part of the pterygo-palatine fossa. It is a small reddish-gray ganglion, suspended from the maxillary nerve by the two *spheno-palatine branches* which constitute its sensory roots. The motor and sympathetic roots of the ganglion are derived from the nerve of the pterygoid canal. This nerve is formed in the cavity of the skull upon the cartilage filling up the foramen lacerum, by the union of the *greater superficial petrosal nerve* from the genicular ganglion of the facial nerve (emerging from the temporal bone through the hiatus canalis facialis) with the *deep petrosal nerve*, a branch of the carotid plexus of the sympathetic on the internal carotid artery. The nerve of the pterygoid canal passes through the pterygoid canal to the pterygo-palatine fossa, where it joins the spheno-palatine ganglion.

The branches from the ganglion are seven in number.

(a) The **pharyngeal branch** passes backwards through the pharyngeal canal to supply the mucous membrane of the roof of the pharynx.

(b) **Nervi Palatini**.—The **palatine nerves**, three in number, are directed downwards to the palate through the palatine canals. The large **n. palatinus anterior** (**anterior palatine nerve**) emerges on the under surface of the palate through the greater palatine foramen, and at once separates into numerous branches for the supply of the mucous membrane of the soft and the hard palate. Its anterior filaments communicate with branches of the naso-palatine nerve. The main nerve gives off, as it lies in the palatine canal, a small **posterior inferior lateral nasal nerve** (**rami nasales posteriores inferiores laterales**), which enters the nasal cavity and supplies the mucous membrane of the lower part of its lateral wall. The **n. palatinus medius** (**middle palatine nerve**) descends through a small palatine canal, and, piercing the pyramidal process of the palate bone, is distributed to the mucous membrane of the soft palate, uvula, and palatine tonsil. It possibly conveys motor fibres to the levator veli palatini and uvular muscles. The **n. palatinus posterior** (**posterior palatine nerve**) consists of one or more small twigs which pass through lesser palatine canals, and supply branches to the mucous membrane of the tonsil, soft palate, and uvula.

(c) The branches directed medially from the sphenopalatine ganglion enter the nasal cavity through the sphenopalatine foramen. They are two in number—the **posterior superior lateral nasal** and the **naso-palatine**. The **posterior superior lateral nasal branch** (**rami nasales posteriores superiores laterales**) is a small nerve destined for the mucous membrane of the superior and posterior part of the lateral wall of the nasal cavity. The **n. nasopalatinus** (**naso-palatine nerve**), after passing through the sphenopalatine foramen, crosses the roof of the nasal cavity, and extends obliquely downwards and forwards along the nasal septum, grooving the vomer in its course, to reach the incisive foramen near the front of the hard palate. The nerves pass through the subordinate median foramina (of Scarpa), the left nerve in front of the right. In the incisive foramen the two nerves communicate together. They then turn backwards and supply the mucous membrane of the hard palate. They communicate posteriorly with terminal filaments of the anterior palatine nerves. In its course through the nasal cavity the naso-palatine nerve furnishes collateral branches to the mucous membrane of the roof and septum of the nose (*posterior superior medial branches*) (Fig. 649, p. 774).

(d) **Rami Orbitales**.—The **orbital branches**, one or more minute branches, pass upwards to the periosteum of the orbit from the sphenopalatine ganglion.

NERVUS MANDIBULARIS.

The **mandibular nerve** is formed by the union of two roots; a large **sensory root**, from the semilunar ganglion, and the small **motor root** of the trigeminal nerve, which is wholly incorporated with this trunk. The two roots pass together beneath the dura mater of the middle fossa of the base of the skull to the foramen ovale, through which they emerge into the infra-temporal fossa. Outside the skull they combine to form a single trunk, which soon separates into anterior and posterior divisions.

At its emergence from the skull the nerve is deeply placed beneath the middle of the zygomatic arch, and is concealed by the ramus of the mandible, and by the masseter, temporal, and external pterygoid muscles.

The branches of the nerve may be divided into two series—(1) those derived from the undivided nerve, and (2) those derived from its terminal divisions.

The branches of the undivided nerve are two in number. (a) A small **nervus spinosus** (**O.T. recurrent nerve**) arises just outside the skull, and accompanying the middle meningeal artery through the foramen spinosum, supplies the dura mater.

(b) In the infra-temporal region a small branch arises for the supply of the **internal pterygoid muscle**. This nerve forms a connexion with the otic ganglion.

The terminal divisions of the nerve are a small anterior and a large posterior trunk.

The small anterior trunk (**nervus masticatorius** or **masticator nerve**) passes

downwards and forwards beneath the external pterygoid muscle, and separates into the following branches:—(1) A branch for the external pterygoid muscle, which supplies it on its deep surface; (2) a branch to the masseter muscle (*n. massetericus*), which passes over the superior border of the external pterygoid and through the mandibular notch of the mandible; (3) and (4) two deep temporal branches (*nn. temporales profundi*) anterior and posterior to the temporal muscle, which also ascend above the external pterygoid muscle; and (5) the *n. buccinatorius* (*buccinator* (*O.T. buccal*) nerve), which passes obliquely forwards between the two heads of the external pterygoid to reach the buccinator muscle. *This nerve is sensory*, and its fibres are in part distributed to the skin of the cheek (communicating with buccal branches of the facial nerve); they are also in part distributed to the mucous membrane of the inside of the mouth, to reach which they pierce

FIG. 655.—THE MANDIBULAR NERVE.

the fibres of the buccinator muscle. The buccinator nerve usually supplies a third branch to the temporal muscle, after emerging between the two heads of the external pterygoid muscle (Fig. 655).

The large posterior trunk extends downwards a short way beneath the external pterygoid muscle. After giving off by two roots the auriculo-temporal nerve, it ends by dividing into two, the lingual and the inferior alveolar nerves.

N. Auriculotemporalis.—The auriculo-temporal nerve is formed by the union of two roots which embrace the middle meningeal artery. The nerve passes backwards beneath the external pterygoid muscle and between the speno-mandibular ligament and the neck of the mandible. After passing through the parotid gland, it is directed upwards to the temple over the zygoma, in company with the superficial temporal artery. It is finally distributed as a cutaneous nerve of the temple and scalp, and reaches almost to the vertex of the skull.

The auriculo-temporal nerve gives off the following branches:—(1) A small branch to the mandibular articulation. (2) Branches to the parotid gland (*rami*

parotidei). (3) A twig for the supply of the skin of the external acoustic meatus and *membrana tympani* (*n. meatus auditorii externi et ramus membranæ tympani*). (4) Branches to the superior half of the auricle on its lateral aspect. (5) Terminal branches to the skin of the temple and scalp (*rami temporales superficiales*).

It has the following **communications** with other nerves:—(1) Important communications are effected by the roots of the nerve, which are separately joined by small branches from the otic ganglion. (2) The parotid branches of the nerve are connected with branches of the facial nerve in the substance of the gland (*rami anastomotici c. nervo faciali*). (3) The temporal branch of the nerve is in communication superficially with the temporal branches of the facial nerve.

N. Lingualis.—The **lingual nerve** is the smaller of the two terminal branches of the posterior division of the mandibular trunk. It proceeds downwards in front of the inferior alveolar nerve, beneath the external pterygoid muscle, to its inferior border. After passing between the internal pterygoid muscle and the ramus of the mandible, it crosses beneath the mucous membrane of the floor of the mouth in the interval between the mylo-hyoid and hyoglossus muscles and beneath the duct of the submaxillary gland. It sweeps forwards and medially to the side of the tongue, to the mucous membrane over the anterior two-thirds of which it is distributed.

Two nerves communicate with the lingual nerve in its course to the tongue:—(1) The **chorda tympani** branch of the facial nerve joins it beneath the external pterygoid muscle, and is incorporated with it in its distribution to the tongue. (2) The **hypoglossal nerve** forms larger or smaller loops of communication with the lingual nerve as they course forwards together over the hyoglossus muscle (*rami anastomotici cum nervo hypoglosso*).

Besides supplying the aforesaid branches to the mucous membrane over the sides and dorsum of the tongue in its anterior two-thirds, the lingual nerve supplies the mucous membrane of the lateral wall and floor of the mouth. It also assists, along with the chorda tympani nerve, in forming the roots of the submaxillary ganglion.

Ganglion Submaxillare.—The **submaxillary ganglion** is a minute reddish ganglion placed on the hyoglossus muscle, between the lingual nerve and the duct of the submaxillary gland. It is suspended from the former by two trunks, consisting for the most part of fibres of the lingual and chorda tympani nerves, which at this point become separated from the lingual nerve and incorporated with the ganglion. The **roots** of the ganglion are—(1) an afferent root, derived from the lingual nerve; (2) an efferent root, derived from the chorda tympani; and (3) a sympathetic root, from the sympathetic plexus upon the external maxillary artery.

The **branches from the ganglion** are distributed to the submaxillary gland and duct (*rami submaxillares*), and by fibres which become reunited with the trunk of the lingual nerve, to the sublingual gland.

N. Alveolaris Inferior.—The **inferior alveolar nerve** (O.T. **inferior dental**) is larger than the lingual nerve. It passes from beneath the inferior border of the external pterygoid muscle to reach the interval between the ramus of the mandible and the speno-mandibular ligament. Entering the mandibular canal through the mandibular foramen, it traverses the substance of the ramus and body of the mandible, distributing branches in its course to the teeth. A fine plexus is formed by the dental branches before they finally supply the teeth.

Branches and Communications.—(1) **N. Mylohyoideus.**—The **mylo-hyoid nerve** is a small branch arising just before the inferior alveolar nerve passes through the mandibular foramen. Grooving the ramus in its course, it descends into the submaxillary triangle on the superficial aspect of the mylo-hyoid muscle. Concealed in this situation by the submaxillary gland and the external maxillary artery, it is distributed to the mylo-hyoid and anterior belly of the digastric muscles. (2) **N. Mentalis.**—The **mental branch** of the inferior alveolar nerve is a trunk of considerable size arising from the main nerve in the mandibular canal. It emerges from the mandible through the mental foramen, and is distributed by many branches to the chin and lower lip. It communicates beneath the facial muscles with the *ramus marginalis mandibulæ* of the facial nerve (Fig. 657, p. 783). (3) The **incisor**

branch is the terminal part of the inferior alveolar nerve remaining after the origin of the mental branch. It supplies the incisor and canine teeth.

Ganglion Oticum.—The otic ganglion is situated deep to the mandibular nerve just below the foramen ovale. Like the other ganglia described above, it possesses three roots:—(1) A *motor root*, derived from the nerve to the internal pterygoid muscle; (2) a *sensory root*, formed by the *smaller superficial petrosal nerve* from the tympanic plexus (through which communications are effected with the tympanic branch of the glossopharyngeal nerve, and a branch from the genicular ganglion of the facial nerve); (3) a *sympathetic root*, from the plexus on the middle meningeal artery (Fig. 656).

Five branches arise from the ganglion—three communicating and two motor branches. The three **communicating nerves** are fine branches which join respectively the nerve of the pterygoid canal, the roots of the auriculo-temporal, and the chorda tympani nerve. The two **motor nerves** supply the tensor tympani and tensor veli palatini muscles.

Summary.—The trigeminal, the largest and most complex of the cerebral nerves, is (1) the chief sensory nerve for the face, the anterior half of the scalp, the orbit and eyeball, the nose and nasal cavity, the lips, teeth, mouth, and anterior two-thirds of the tongue; (2) the motor fibres of the nerve supply the muscles of mastication, the mylo-hyoid and anterior belly of the digastric, possibly the levator veli palatini and uvular muscle (through the spheno-palatine ganglion), and the tensor tympani and tensor veli palatini muscles (through the otic ganglion); (3) through the ganglia placed on the three divisions of the nerve, not only are important organs, areas, and muscles innervated, but communications are also effected with the sympathetic system, with the oculo-motor nerve (ciliary ganglion), facial nerve (spheno-palatine and otic ganglia), and glossopharyngeal nerve (otic ganglion).

In its distribution to the skin of the face the branches of the fifth nerve present two striking peculiarities:—(1) While the branches to the skin reach the surface at many points and in diverse ways, the three main divisions are severally, by their branches, responsible for the supply of three clearly demarcated cutaneous areas (Fig. 648, p. 772). (2) By numerous communications with the facial nerve, sensory fibres are given to the muscles of expression supplied by the facial nerve.

NERVUS ABDUCENS.

The **sixth or abducens nerve** issues from the brain at the inferior border of the pons, just above the pyramid of the medulla oblongata (for the deep origin, see p. 600). It is directed forwards, and pierces the dura mater in the posterior fossa of the base of the skull alongside the dorsum sellæ (Fig. 647, p. 771). It then occupies the medial wall of the cavernous sinus and is placed on the lateral side of the internal carotid artery. It passes through the superior orbital fissure below the oculo-motor and naso-ciliary nerves and between the two heads of the lateral rectus muscle (Fig. 652, p. 776). In the cavity of the orbit it supplies the lateral rectus muscle on its deep (ocular) surface.

Communications.—In the wall of the cavernous sinus the sixth nerve receives two communicating filaments:—(1) From the carotid plexus of the sympathetic, and (2) from the ophthalmic division of the trigeminal nerve.

NERVUS FACIALIS.

The **seventh or facial nerve** emerges from the brain at the inferior border of the pons, below the trigeminal nerve and medial to the acoustic nerve (for the deep origin, see p. 598). Between it and the latter nerve is the minute *nervus intermedius* (Fig. 656, p. 782). The facial nerve passes through the internal acoustic meatus, and through the canalis facialis in the petrous portion of the temporal bone, emerges at the base of the skull by the stylo-mastoid foramen, and passes forwards through the parotid gland to supply the muscles of the face. In the *internal acoustic meatus* the nerve is placed upon the acoustic nerve, the *nervus intermedius* intervening. In the *canalis facialis* the nerve first passes backwards on the medial side of the tympanum, and then downwards behind the tympanum, in the medial wall of the tympanic antrum. In the *parotid gland* the nerve crosses the external carotid artery and the posterior facial vein superficially. On the face its branches radiate from the anterior border of the parotid gland and enter the deep surface of the facial muscles.

Branches and Communications.—(i.) In the *internal acoustic meatus* the *nervus intermedius*, lying between the facial and acoustic, sends communicating branches to both nerves. The branch to the acoustic nerve probably separates from it again to join the genicular ganglion of the facial nerve.

(ii.) In the *canalis facialis* the **ganglion geniculi** is formed at the point where the facial nerve bends backwards. It is an oval swelling on the nerve, and is joined by a branch from the upper (vestibular) trunk of the acoustic nerve, by which it probably receives fibres of the *nervus intermedius*. From the ganglion three small nerves arise:—(1) The **greater superficial petrosal nerve** passes forwards through the *hiatus canalis facialis* to the middle fossa of the skull. On the upper surface of the foramen lacerum it is joined by the **deep petrosal nerve** from the sympathetic plexus on the internal carotid artery to form the nerve of the pterygoid canal, which, after traversing the pterygoid canal, ends in the sphenopalatine ganglion. (2) A minute nerve (*ramus anastomoticus cum plexu tympanico*) pierces the temporal bone and joins the tympanic branch of the glosso-

FIG. 656.—THE CONNEXIONS OF THE FACIAL NERVE IN THE TEMPORAL BONE.

pharyngeal in the substance of the bone. By their union the **lesser superficial petrosal nerve** is formed, which pierces the temporal bone and ends in the otic ganglion. (3) The **external superficial petrosal nerve** is a minute inconstant branch which joins the sympathetic plexus on the middle meningeal artery.

In the course of the facial nerve in the lower part of the *canalis facialis*, behind the tympanum, three branches arise—(1) **N. Stapedius**.—The small nerve to the *stapedius* muscle, which passes forwards to the tympanum. (2) **Chorda Tympani**.—The *chorda tympani* nerve (probably associated with the *nervus intermedius*), which enters the tympanic cavity through the *tympanic aperture of the canaliculus chordæ*, passes over the *membrana tympani* and the handle of the malleus, and leaves the cavity through the *medial end of the petro-tympanic fissure* to reach the *infra-temporal fossa*. Beneath the external pterygoid muscle it becomes incorporated with the lingual branch of the mandibular nerve, and in its further course is inseparable from that nerve. It supplies a root to the submaxillary ganglion, and is finally distributed to the side and dorsum of the tongue in its anterior two-thirds. The *chorda tympani* nerve receives, beneath the external pterygoid muscle, a fine communicating branch from the otic ganglion. (3) Before it leaves the *canalis facialis* a fine communicating branch arises from the facial nerve to join the auricular branch of the vagus nerve.

(iii.) *In the neck* the facial nerve gives off three muscular branches: (1) and (2) **Ramus Stylohyoideus, Ramus Digastricus.**—Small branches supply the stylo-hyoid and the posterior belly of the digastric, the latter nerve sometimes communicating with the glossopharyngeal. (3) **N. Auricularis Posterior.**—The posterior auricular nerve bends backwards and upwards over the anterior border of the mastoid process along with the posterior auricular artery. It divides into two branches—an *auricular branch* for the posterior auricular muscle and the intrinsic muscles of the auricle, and an *occipital branch* for the occipital belly of the epicranii muscle.

FIG. 657.—THE DISTRIBUTION OF THE TRIGEMINAL AND FACIAL NERVES ON THE FACE.

The posterior auricular nerve communicates with the great auricular, lesser occipital, and auricular branch of the vagus nerves in its course.

(iv.) *In the parotid gland* the facial nerve spreads out in an irregular series of branches (*plexus parotideus*), indefinitely divided into a temporo-facial and a cervico-facial division. Communications occur in the substance of the gland between the main trunks and the great auricular and auriculo-temporal nerves.

The temporo-facial division gives off two series of subordinate branches which radiate forwards and upwards from the parotid gland.

1. **Rami Temporales.**—The temporal branches are of large size, and, sweeping out of the parotid gland over the zygomatic arch, are distributed to the orbicularis oculi, frontalis, corrugator supercilii, auricularis anterior and superior. The temporal branches communicate in their course with the auriculo-temporal, zygomatico-temporal, lacrimal, and supra-orbital branches of the trigeminal nerve.

branch to the genicular ganglion of the facial nerve. It then separates into three terminal branches which pierce the lamina cribrosa. (1) **N. Utricularis**.—The utricular nerve supplies the macula acustica of the utricle. (2) and (3) **N. Ampullaris Superior et Lateralis**.—The superior and lateral ampullary nerves supply the ampullæ of the superior and lateral semicircular ducts.

N. Cochleæ.—The inferior or cochlear nerve gives off (1) *n. saccularis*, a saccular nerve to the macula acustica of the sacculus, (2) *n. ampullaris inferior*, an inferior ampullary nerve to the ampulla of the posterior semicircular duct, and (3) is continued through the lamina cribrosa to the labyrinth as the cochlear nerve, which is distributed through the modiolus and osseous spiral lamina to the organ of Corti in the cochlea.

Both the vestibular and cochlear nerves contain among their fibres collections of nerve cells, forming in each nerve a distinct ganglion—the vestibular ganglion on the vestibular trunk, and the ganglion spirale or spiral ganglion of the cochlea on the cochlear trunk.

NERVUS GLOSSOPHARYNGEUS.

The ninth or glossopharyngeal nerve (Fig. 643, p. 768) arises from the brain by five or six fine fila radicularia (radicles) which emerge from the medulla oblongata between the olive and the restiform body, close to the facial nerve above, and in series with the fila of the vagus nerve below (for the deep connexions, see p. 596). The fila combine to form a nerve which passes through the jugular foramen, along with the vagus and accessory nerves, but enveloped in a separate sheath of dura mater (Fig. 647, p. 771). Reaching the neck, the nerve arches downwards and forwards to the interval between the hyoid bone and the mandible. It lies at first between the internal carotid artery and the internal jugular vein, and then between the internal and external carotid arteries, in its course to the side of the pharynx. It sweeps round the stylopharyngeus muscle and the stylo-hyoid ligament, and disappears beneath the hyoglossus muscle, to reach its termination in the tongue.

The branches of the nerve may be classified in three series according to their origin—(i.) in the jugular foramen; (ii.) in the neck; (iii.) in relation to the tongue.

In the jugular foramen there are two enlargements upon the trunk of the nerve—the superior and petrous ganglia. The superior ganglion (O.T. jugular) is small, does not implicate the whole width of the nerve, and may be fused with the petrous ganglion, or even absent altogether. No branches arise from it.

Ganglion Petrosus.—The petrous ganglion is distinct and constant. It is placed upon the nerve at the lower part of its course through the jugular foramen.

FIG. 659.—SCHEME OF THE DISTRIBUTION OF THE GLOSSOPHARYNGEAL NERVE.

G.Ph, Glossopharyngeal nerve; J, Superior, and P, Petrous ganglia; Ty, Tympanic nerve; Ty. Plex., Tympanic plexus; Fa, Root from genicular ganglion of facial nerve; S.S.P, Lesser superficial petrosal nerve to the otic ganglion; S.D.P, Carotico-tympanic nerve; I.C, Internal carotid artery; Va, Vagus nerve; Aur., Auricular branch of vagus; Sy., Superior cervical sympathetic ganglion; F, Communicating branch to facial nerve; Ph, Pharyngeal branch of vagus; E.C, External carotid artery; Ph.Pl, Pharyngeal plexus; S.Ph, Stylopharyngeus muscle; S.H.L, Stylo-hyoid ligament; H.G, Hyoglossus; S.G, Styloglossus; Ton, Palatine tonsil; S. Pal., Soft palate; G.H.G, Genioglossus; G.H, Genio-hyoid; Hy, Hyoid bone.

Branches and Communications of the Petrous Ganglion.—**N. Tympanicus.**—The **tympanic branch** is the most important offset from this ganglion. It passes through a small canal in the bridge of bone between the jugular foramen and the carotid canal to reach the cavity of the tympanum, where it breaks up into branches, to form, along with branches from the carotid plexus of the sympathetic on the internal carotid artery (*nn. caroticotympanici superior et inferior*, O.T. *small deep petrosal*), the **plexus tympanicus Jacobsoni** (**tympanic plexus**), for the supply of the mucous lining of the tympanum, mastoid cells, and auditory tube (Fig. 656, p. 782). The fibres of the tympanic branch of the glossopharyngeal nerve become reunited to form, by their union with a small nerve from the genicular ganglion of the facial nerve (*anastomotic with the tympanic plexus*), the **lesser superficial petrosal nerve** in the substance of the temporal bone. This passes forwards through the temporal bone, and eventually joins the otic ganglion.

Besides forming the tympanic branch, the petrous ganglion of the glossopharyngeal nerve communicates with three other nerves—(1) with the superior cervical ganglion of the sympathetic; (2) with the auricular branch of the vagus; and (3) sometimes with the jugular ganglion of the vagus.

In the neck the glossopharyngeal nerve gives off two branches. (1) As it crosses over the **stylopharyngeus muscle** it supplies the nerve to that muscle (**ramus stylopharyngeus**), fibres of which pierce the muscle to reach the mucous membrane of the pharynx. (2) **Rami Pharyngei.**—The **pharyngeal branches** of the nerve supply the mucous membrane of the pharynx directly after piercing the superior constrictor muscle, and indirectly after joining, along with the pharyngeal offsets from the vagus and the superior cervical ganglion of the sympathetic, in the formation of the **pharyngeal plexus**.

The **terminal branches** of the nerve supply the mucous membrane of the tongue and adjacent parts. **Rami Tonsillares.**—A **tonsillar branch** forms a plexus to supply the mucous membrane covering the tonsil, the adjacent part of the soft palate, and the palatine arches. **Rami Linguales.**—**Lingual branches** supply the mucous membrane of the dorsal third and lateral half of the tongue, extending backwards to the glosso-epiglottic folds and the front of the epiglottis.

NERVUS VAGUS.

The **tenth or vagus nerve** (O.T. **pneumogastric**) arises from the brain by numerous *fila radicularia* attached to the anterior margin of the restiform body of the medulla oblongata, in series with the glossopharyngeal nerve above and the accessory nerve below it (for the deep connexions, see p. 656). The *fila* of the nerve unite to form a single trunk which emerges in the neck through the jugular foramen.

In the jugular foramen the nerve occupies the same sheath of dura mater as the accessory nerve, and is placed behind the glossopharyngeal nerve. Two ganglia are present on the trunk in this situation. The higher and smaller is the **jugular ganglion**; the lower and larger is the **ganglion nodosum**.

In the neck the vagus nerve pursues a vertical course in front of the vertebral column. It occupies the carotid sheath, lying between and behind the internal and common carotid arteries and the internal jugular vein. It enters the thorax behind the large veins: *on the right side*, after crossing over the subclavian artery; *on the left side*, in the interval between the left common carotid and subclavian arteries.

In the thorax the nerves occupy the superior and posterior mediastinal spaces, and their relations are different on the two sides. (a) *In the superior mediastinum* the **right nerve** continues its course alongside the innominate artery and the trachea, and behind the right innominate vein and superior vena cava, to the posterior surface of the root of the lung. The **left nerve** courses downwards between the left common carotid and subclavian arteries, and behind the left innominate vein and the phrenic nerve. It passes over the aortic arch, and then proceeds to the posterior surface of the root of the left lung. (b) *In the posterior mediastinum* the **vagi nerves** are concerned in the formation of two great plexuses—the pulmonary and the œsophageal. Behind the root of each lung the nerve breaks up to form

FIG. 660.—THE DISTRIBUTION OF THE VAGUS NERVE.

the large posterior pulmonary plexus, from the lower end of which two nerves emerge on each side. These nerves on the right side pass obliquely over the vena azygos; on the left side they cross the descending thoracic aorta. Both series reach the œsophagus, and divide into small anastomosing branches which form the œsophageal plexus. At the œsophageal opening of the diaphragm the two nerves become separated from the plexus, and entering the abdomen—the left nerve in front of the œsophagus, the right nerve behind it—they terminate by supplying the stomach and other abdominal organs.

The communications and branches of the vagus nerve may be described as (i.) ganglionic, (ii.) cervical, (iii.) thoracic, and (iv.) abdominal (Fig. 660).

Ganglion Jugulare.—The jugular ganglion (O.T. ganglion of the root) is small and spherical. It occupies the jugular foramen, and gives off two branches—meningeal and auricular.

Ramus Meningeus.—The meningeal branch passes backwards to supply the dura mater of the posterior fossa of the skull.

Ramus Auricularis.—The auricular branch ascends to the ear in a fissure between the jugular and stylo-mastoid foramina. It receives near its origin a twig from the tympanic branch of the glossopharyngeal nerve, and usually communicates with the facial nerve by a branch arising from the latter in the canalis facialis. The nerve is distributed to the back of the auricle and the external acoustic meatus, and communicates superficially with the posterior auricular nerve.

Communications.—Besides supplying the meningeal and auricular branches, this ganglion receives communications from (1) the superior cervical ganglion of the sympathetic; (2) the accessory nerve; and (3) (sometimes) the petrous ganglion of the glossopharyngeal nerve (*ramus anastomoticus cum nervo glossopharyngeo*).

Ganglion Nodosum.—The ganglion nodosum (O.T. ganglion of the trunk), placed immediately below the preceding, is large and fusiform. Like the jugular ganglion, it supplies two branches—the pharyngeal and superior laryngeal nerves.

Rami Pharyngei.—The pharyngeal branch receives its fibres (through the ganglion) from the accessory nerve. It passes obliquely downwards and medially to the pharynx between the internal and external carotid arteries, and combines with the pharyngeal branches from the glossopharyngeal and superior cervical ganglion of the sympathetic to form the pharyngeal plexus. From this plexus the muscles of the pharynx and soft palate (except the stylopharyngeus and tensor veli palatini) are supplied. The lingual branch is a small nerve which separates itself from the plexus and joins the hypoglossal nerve in the anterior triangle of the neck.

N. Laryngeus Superior.—The superior laryngeal nerve passes obliquely downwards and medially, behind the external and internal carotid arteries, towards the thyroid cartilage. It divides in its course into two unequal parts—a larger internal and a smaller external laryngeal branch.

Ramus Internus.—The internal laryngeal branch passes medially into the larynx between the middle and inferior constrictor muscles of the pharynx and through the thyreo-hyoid membrane. It supplies the mucous membrane of the larynx, reaching upwards to the epiglottis and base of the tongue, and forms communications beneath the lamina of the thyroid cartilage with the branches of the inferior laryngeal nerve (*ramus anastomoticus cum nervo laryngeo inferiore*).

Ramus Externus.—The external laryngeal branch passes downwards upon the inferior constrictor muscle of the pharynx. It supplies branches to that muscle, and ends in the crico-thyroid muscle.

Communications.—Besides supplying these pharyngeal and laryngeal nerves, this ganglion has the following communications with other nerves: (1) with the superior cervical ganglion of the sympathetic; (2) with the hypoglossal; (3) with the loop between the first and second cervical nerves; and (4) with the accessory nerve. This nerve applies itself to the ganglion, and thereby supplies to the vagus nerve the inhibitory fibres for the heart, as well as the motor fibres for the pharynx, œsophagus, stomach and intestines, larynx and respiratory organs.

Branches of the Vagus in the Neck.—In the neck the vagus nerve

supplies cardiac branches and (on the right side) the recurrent (laryngeal) nerve (Fig. 661).

Rami Cardiaci Superiores.—The cardiac branches are superior and inferior. *On the right side* both cardiac branches pass downwards into the thorax behind the subclavian artery, and proceed alongside the trachea to join the deep cardiac plexus. *On the left side* the two nerves separate on reaching the thorax. The *superior nerve* passes deeply alongside the trachea to join the deep cardiac plexus. The *inferior nerve* accompanies the vagus nerve over the aortic arch, along with the superior cervical cardiac branch of the sympathetic, to end in the superficial cardiac plexus.

N. Recurrens.—The right recurrent (laryngeal) nerve arises at the root of the neck, as the vagus crosses over the first part of the subclavian artery. It hooks round the artery, and passes obliquely upwards and medially behind the subclavian, the common carotid, and the inferior thyroid artery and the thyroid gland. It finally disappears beneath the inferior border of the inferior constrictor muscle, and, receiving the name of *inferior laryngeal nerve*, it ends in supplying the muscles of the larynx. In its course it gives off the following branches:—

(1) **Cardiac branches (rami cardiaci inferiores)** arise as the nerve winds round the subclavian artery, and course downwards alongside the trachea to end in the deep cardiac plexus.

(2) **Communicating branches** to the inferior cervical ganglion of the sympathetic arise from the nerve behind the subclavian artery.

(3) **Muscular branches** supply the trachea, œsophagus (*rami tracheales et œsophagei*), and the inferior constrictor of the pharynx.

(4) **Terminal branches** supply the muscles of the larynx (except the crico-thyroid) and communicate beneath the lamina of the thyroid cartilage with branches of the internal laryngeal nerve.

Branches of the Vagus in the Thorax.—In the thorax the vagi form the great pulmonary and œsophageal plexuses. The right nerve, in addition, furnishes cardiac branches; and the left nerve gives off the recurrent (laryngeal) nerve.

N. Recurrens.—The left recurrent (laryngeal) nerve differs from the nerve of the right side mainly in its point of origin and in the early part of its course. It springs from the vagus as it crosses the aortic arch, and, after hooking round the arch, lateral to the *ligamentum arteriosum*, it passes upwards in the superior mediastinum, in the interval between the trachea and œsophagus, to the neck. In the neck its course and relations are similar to those of the nerve of the right side. The branches of the nerve are the same as those of the right nerve. The *cardiac branches* are larger, and, arising below the aortic arch, proceed to the deep cardiac plexus.

Cardiac branches from the right vagus nerve arise in the superior mediastinum, and pass downwards alongside the trachea to join the deep cardiac plexus. *On the right side* thoracic cardiac branches are thus supplied from both the trunk of the nerve and its recurrent branch; *on the left side* the cardiac branches in the thorax arise solely from the recurrent branch.

Abdominal Branches.—After the formation of the œsophageal plexus the two vagi nerves resume their course, and passing along with the gullet through the diaphragm, terminate by supplying the stomach. The *right nerve* enters the abdominal cavity behind the gullet, and is distributed to the posterior surface of the stomach. It sends communicating offsets to the celiac, splenic, and renal plexuses. The *left nerve* applies itself to the anterior surface and small curvature of the stomach, to which it is distributed. It sends communicating offsets along the small curvature of the stomach to the right vagus, and between the layers of the gastro-hepatic ligament to the hepatic plexus.

PLEXUS THORACALES.

Plexus Cardiaci.—The cardiac branches of the vagus nerve (both cervical and thoracic) combine with the cardiac branches of the sympathetic to form the superficial and deep cardiac plexuses.

The **superficial cardiac plexus** is placed in the hollow of the aortic arch, superficial to the pericardium. It contains a small ganglion (**cardiac ganglion of Wrisberg**), and is joined by two small nerves—(1) the cardiac branch from the superior cervical ganglion of the sympathetic, and (2) the inferior cervical cardiac branch of the vagus—both of the left side—which reach it after passing over the arch of the aorta.

FIG. 661.—THE INNERVATION OF THE HEART.

Branches and Communications.—From the plexus branches of communication pass (1) to the left half of the **deep cardiac plexus**, between the aortic arch and the bifurcation of the pulmonary artery; (2) to the **left anterior pulmonary plexus** along the left branch of the pulmonary artery; (3) the branches of distribution to the heart extend along the pulmonary artery to join the **anterior (right) coronary plexus**, which supplies the substance of the heart in the course of the right coronary artery.

Plexus Cardiacus Profundus.—The **deep cardiac plexus** is much larger. It

is placed behind the arch of the aorta, on the sides of the trachea, just above its bifurcation. It consists of two lateral parts, joined together by numerous communications around the termination of the trachea. The two portions of the plexus are different in their constitution and distribution. The *right half* of the plexus is joined by both the cervical and thoracic branches of the right vagus and by the branches of the right recurrent nerve, as well as by branches from the superior, middle, and inferior cervical ganglia of the sympathetic. The *left half* of the plexus is joined by the superior cervical cardiac branch of the left vagus, by branches from the left recurrent nerve, and by branches from the middle and inferior cervical ganglia of the left sympathetic; it also receives a contribution from the superficial cardiac plexus.

The deep cardiac plexus is distributed to the heart and lungs. The *right half* of the plexus for the most part constitutes the **anterior coronary plexus**, reaching the heart alongside the ascending aorta, and is distributed to the heart substance in the course of the right coronary artery. It is reinforced by fibres from the superficial cardiac plexus, which reach the heart along the pulmonary artery. Fibres from the right half of the deep cardiac plexus pass also to join the **posterior coronary plexus**, and others extend laterally to join the **anterior pulmonary plexus** of the right side.

The *left half* of the deep cardiac plexus, reinforced by fibres from the superficial cardiac plexus, is distributed to the heart in the form of the **posterior coronary plexus**, which is joined by a few fibres behind the pulmonary artery from the right half of the plexus, and supplies the heart substance in the course of the left coronary artery. The left half of the plexus contributes also to the **left anterior pulmonary plexus** by fibres which extend laterally to the root of the lung along the left branch of the pulmonary artery.

Plexus Pulmonales (Pulmonary Plexuses).—As already stated, the vagus nerve on each side, on reaching the back of the root of the lung, breaks up into numerous plexiform branches for the formation of the posterior pulmonary plexus. From each nerve a few fibres pass to the front of the root of the lung, above its upper border, to form the much smaller anterior pulmonary plexus.

Plexus Pulmonalis Anterior.—The **anterior pulmonary plexus** on each side is joined by a few fibres from the corresponding part of the deep cardiac plexus, and on the left side from the superficial cardiac plexus as well. It surrounds and supplies the constituents of the root of the lung anteriorly.

Plexus Pulmonalis Posterior.—The **posterior pulmonary plexus**, placed behind the root of the lung, is formed by the greater part of the vagus nerve, reinforced by fine branches from the second, third, and fourth thoracic ganglia of the sympathetic. Numerous branches proceed from it in a plexiform manner along the bronchi and vessels into the substance of the lung.

Plexus Œsophageus Anterior et Posterior (Œsophageal Plexus).—The œsophagus in the thorax is supplied by the vagus nerve both in the superior and posterior mediastina. In the *superior mediastinum* it receives branches from the vagus nerve on the right side, and from its recurrent branch on the left side.

In the *posterior mediastinum* the gullet is surrounded by the œsophageal plexus, formed from the trunks of the vagi nerves emerging from the posterior pulmonary plexuses, which form a large plexus surrounding the gullet. This part of the œsophagus also receives fibres from the greater splanchnic nerve and ganglion. From the œsophageal plexus branches supply the muscular wall and mucous membrane of the œsophagus.

Pericardiac branches are also supplied from the plexus to the posterior surface of the pericardium.

NERVUS ACCESSORIUS.

The **eleventh or accessory nerve (O.T. spinal accessory)** consists of two essentially separate parts, different both in origin and in distribution. One portion is **accessory to the vagus nerve**, and arises, in series with the fila of that nerve, from the side of the medulla oblongata. The other, **spinal portion**, arises from

FIG. 662.—THE DISTRIBUTION OF THE PNEUMOGASTRIC NERVE.

Pl, Coeliac plexus.

the lateral aspect of the spinal medulla, between the anterior and posterior roots of the spinal nerves, its origin extending from the level of the accessory portion as low as the origin of the sixth cervical nerve (for the deep origin, see p. 596). Successively joining together, the fila radicularia (rootlets) form a trunk which ascends in the subdural space of the spinal medulla, posterior to the ligamentum denticulatum, to the foramen magnum. There the two portions unite into a single trunk, which leaves the cranial cavity through the jugular foramen in the same compartment of dura mater as the vagus nerve (Fig. 647, p. 771).

Ramus Internus.—In the jugular foramen the accessory portion of the nerve or internal ramus (after furnishing a small branch to the jugular ganglion of the vagus) applies itself to the ganglion nodosum, and in part joins the ganglion, in part the trunk of the nerve beyond the ganglion. By means of these connexions the vagus receives visceromotor and cardio-inhibitory fibres.

Ramus Externus.—The spinal portion of the nerve, or external ramus, extends into the neck, where at first it lies along with other nerves, in the interval between the internal carotid artery and the internal jugular vein. Passing obliquely downwards and laterally over the vein, it descends close beneath the sterno-mastoid muscle, which it supplies as it pierces it on its deep surface. After crossing the posterior triangle the nerve ends by supplying the trapezius muscle on its deep surface. This portion of the nerve communicates in three situations with nerves from the cervical plexus—(1) in or beneath the sterno-mastoid, with the branch for the muscle derived from the second cervical nerve; (2) in the posterior triangle, with branches from the third and fourth cervical nerves; (3) beneath the trapezius, with the branches for the muscle derived from the third and fourth cervical nerves.

NERVUS HYPOGLOSSUS.

The **twelfth** or **hypoglossal nerve** arises by numerous fila radicularia from the front of the medulla oblongata between the pyramid and the olive (Fig. 643, p. 768) (for the deep origin, see p. 594). The fila arrange themselves in two bundles which separately pierce the dura mater, and unite in the hypoglossal canal, or after emerging from the skull. In the neck the nerve arches downwards and forwards towards the hyoid bone, and then turns medially among the supra-hyoid muscles to the tongue. At first it is placed deeply, along with other cerebral nerves, on the lateral side of the internal carotid artery; it then curves forwards and downwards over the two carotid arteries, lying beneath the digastric and stylo-hyoid muscles. As it crosses the external carotid artery it hooks round the occipital artery. Above the greater cornu of the hyoid bone the nerve conceals the lingual artery; and it then disappears between the mylo-hyoid and hyoglossus muscles to reach the tongue, in the muscular substance of which it terminates.

Communications.—In its course the hypoglossal nerve has the following communications with other nerves:—Near the base of the skull it is connected by small branches with (1) the superior cervical ganglion of the sympathetic; (2) the ganglion nodosum of the vagus; (3) by a larger branch, with the loop between the first two cervical nerves; (4) as it crosses the external carotid artery it receives a communication from the

FIG. 663.—SCHEME OF THE ORIGIN, CONNEXIONS, AND DISTRIBUTION OF THE ACCESSORY NERVE.

Sp. Acc., Accessory nerve; C.1-4, First four cervical nerves (posterior roots); Va., Vagus nerve; R., Ganglion jugulare; T., Ganglion nodosum; G.Ph., Glossopharyngeal nerve; S.M., Nerves to sternocleidomastoid; Tr., Nerves to trapezius; F.M., Foramen magnum; J.F., Jugular foramen.

pharyngeal plexus (*lingual branch of the vagus*); and (5) beneath the mylo-hyoid muscle, at the anterior border of the hyoglossus, it forms loops of communication with the lingual branch of the mandibular nerve.

The **branches** of the nerve are:—(1) Recurrent; (2) Descending; (3) Thyro-hyoid; and (4) Lingual.

Ramus Recurrens.—The **recurrent branch** passes from the nerve near its origin to supply the dura mater of the posterior fossa of the base of the skull. It probably derives its fibres from the communication with the first and second cervical nerves.

FIG. 664.—THE MUSCLES OF THE HYOID BONE AND STYLOID PROCESS, AND THE EXTRINSIC MUSCLES OF THE TONGUE, WITH THEIR NERVES.

Ramus Descendens.—The descending branch of the hypoglossal nerve is the chief branch given off in the neck. It arises from the hypoglossal nerve as it crosses the internal carotid artery, and descends in the anterior triangle in front of the carotid sheath. It is joined about the middle of the neck by the **descending cervical nerve** (from the second and third cervical nerves). By their union the **ansa hypoglossi** (**hypoglossal loop**) is formed, from which branches are distributed to the majority of the infra-hyoid muscles—both bellies of the omo-hyoid, the sterno-hyoid, and the sterno-thyroid. The descending branch of the hypoglossal nerve derives its fibres from the communication to the hypoglossal nerve from the loop between the first and second cervical nerves; so that the **ansa hypoglossi** is made up of fibres of the first three cervical nerves.

Ramus Thyreo-hyoideus.—The nerve to the thyreo-hyoid muscle is a small branch which arises from the hypoglossal nerve before it passes beneath the mylo-hyoid muscle. It descends behind the greater cornu of the hyoid bone to reach the muscle. When traced backwards this nerve is found associated with the loop between the first and second cervical nerves.

Rami Linguales.—The lingual branches of the hypoglossal nerve are distributed to the hyoglossus, genio-hyoid, and genioglossus, and to all the intrinsic muscles of the tongue. The nerve to the genio-hyoid is said to be derived from the loop between the first and second cervical nerves. It is not known if these two cervical nerves are implicated in the innervation of the proper muscles of the tongue, but it appears certain that the muscles named—the genio-hyoid, thyreo-hyoid, sterno-hyoid, omo-hyoid, and sterno-thyreoid—are not supplied by the hypoglossal, but only by cervical nerves, the genio-hyoid and thyreo-hyoid by the first two, the other muscles by the first three cervical nerves.

THE MORPHOLOGY OF THE CEREBRAL NERVES.

The head and face, possibly the oldest, and from every point of view the most fundamental and important portion of the body fabric, present in some respects a more conservative type of

FIG. 665.—COMPARISON OF ORIGINS OF NERVE ROOTS FROM SPINAL MEDULLA AND HIND-BRAIN (after His).
A. Spinal medulla; B. Hind-brain.

structure, and in other aspects have been subject to more profound alterations than other parts of the body. Segmentation is characteristic of the trunk, pervading bones, muscles, vessels, and nerves. An absence of true segmentation is characteristic of the head region—omitting for the moment the cerebral nerves. The head is characterised by the possession of an unsegmented tubular nervous system, enclosed in a bony capsule not obviously segmental, with which the capsules of the sense-organs become united. The pre-oral and post-oral visceral arches and clefts are not truly segmental like the costal arches of the trunk. The branchial clefts are said to be inter-segmental; and their muscles (associated with the myoblast surrounding the developing heart) are described as visceral, and not myotomic, so that the branchial vessels and nerves (similarly) are not to be regarded as comparable to the segmental vessels and nerves of the trunk. The truly segmental structures present are certain persistent myotomes or muscle plates, which give rise to muscles innervated by the third, fourth, sixth, and twelfth cerebral nerves.

Another difficulty in the morphology of the head arises from the absence of body cavity, and the consequent difficulty of differentiating the somatic and splanchnic mesoderm, and the somatic and splanchnic distribution of a given nerve.

Under these circumstances there is little help to be derived from head structures other than the nerves themselves in seeking a solution of the question of the morphological relations of the cerebral nerves. The spinal nerves are, generally speaking, all alike. The cerebral nerves, on the other hand, are all different. Scarcely any two nerves are alike; and no single cerebral nerve possesses in itself all the characteristic features of a spinal nerve. As seen in the account of its development (p. 504), the cranial nervous system possesses a series of dorsal ganglia, comparable in position and development to the spinal ganglia with which afferent nerves are associated; and the efferent roots are developed in the same way, and occupy somewhat the same position

as the anterior roots of the spinal nerves. But there is no single complete segmental nerve in the head. The very essence of the architecture of the head is a want of segmentation; and this character is shared by the cerebral nerves. In addition it must be borne in mind that, in relation to the mammalian head, there are organs which have no homologues in the trunk, and on whose existence the essential arrangement of the cerebral nerves depends—*e.g.* sense-organs and gill-arches.

Among the cerebral nerves there are several which possess a resemblance to one or other of the elements of a typical spinal nerve. In the neck the origin of the fibres of the accessory nerve is from the side of the spinal medulla, and it is in series with the motor roots of the vagoglossopharyngeal, facial, and fifth nerves. His (as shown in the account of the development of the nerves) has described the neuroblastic origin of the motor roots of these nerves from the lateral part of the basal lamina of the primitive brain. They thus form a series apart—lateral motor roots—separable from the series of motor roots originating from the medial part of the basal lamina, comprising those of the third, fourth, sixth, and twelfth nerves; the latter nerve roots being comparable to and in series with the anterior roots of the spinal nerves. The lateral motor roots are not represented in the spinal series except in the neck. It is questionable if there is any fundamental distinction between the lateral and anterior motor roots of the cerebral nerves. The accessory fibres, for example, when traced into the spinal medulla, have an origin from the anterior column of the spinal medulla, and only differ from the motor or anterior root fibres of a spinal nerve in their different course to the surface. The ganglia in association with the cerebral nerves are comparable to the spinal ganglia. The trigeminal nerve, with the semilunar ganglion, the ganglion of the facial, the ganglia of the acoustic, of the glossopharyngeal and the vagus, and the transitory (Froiep's) ganglion of the hypoglossal nerves, arise from the brain in a comparable position, and in the same way as the spinal ganglia. But another series of structures—the sense organs of the lateral line, and the so-called "epibranchial" organs which are highly developed in lower vertebrates (*e.g.* elasmobranchs), and which appear transitorily only, or are absent altogether in mammalian development, may possibly have a share in the formation of certain of these ganglia or parts of them (*e.g.* ciliary ganglion, genicular ganglion, ganglia of the acoustic nerve, petrous ganglion of the glossopharyngeal, and the ganglion nodosum of the vagus).

Certain of the cerebral nerves are apparently distinctly **segmental**, supplying muscles derived from the persisting myotomes of the head. The **first three myotomes** are said to give rise to the muscles of the eyeball. The *first* produces the superior rectus, inferior rectus, medial rectus, and inferior oblique muscles, and its segmental nerve is the **oculo-motor**. The *second myotome* is said to produce the superior oblique muscle, and its segmental nerve is the **trochlear**. The *third myotome* is said to produce the lateral rectus muscle, and its segmental nerve is the **abducent**. It has been asserted that the tongue muscles are derived from the **last three or four cephalic and first cervical myotomes**, and that the **hypoglossal nerve** is the segmental nerve for these myotomes, comprising the motor elements of several (four or five) segmental nerves. The intervening myotomes between the first three and this occipital series disappearing, the corresponding elements of segmental nerves are supposed to be absent also (Fig. 666).

Certain of the cerebral nerves are essentially related to the structures derived from and associated with the pre-oral and post-oral **visceral clefts and arches** (Fig. 667). The **trigeminal nerve** is essentially the nerve of the **mandibular arch**. By its efferent root it supplies the muscles of that arch. By its afferent root and branches it is related to (1) the fronto-nasal process (ophthalmic division and ciliary ganglion); (2) the maxillary arch (maxillary nerve); and (3) the mandibular arch (mandibular nerve). The mandibular is at first the main nerve; and the maxillary division is sometimes regarded as a subordinate branch (præ-branchial, præ-trematic) for the supply of the anterior margin of the cleft (mouth), with which the nerve is in relation. The ophthalmic nerve is sometimes regarded as a morphologically separate nerve. The nerves to these arches have been compared to the anterior rami of spinal nerves, the branches which they supply to the forehead and temple (frontal, zygomatic, and auriculo-temporal) representing the posterior rami. The ganglia on each division of the nerve are formed as extensions from the semilunar ganglion.

The **facial nerve** is essentially the nerve of the **second (hyoid) arch** and the cleft in front of that arch (spiracular cleft, auditory tube). Its motor root supplies the muscles of that arch (stapedius, stylo-hyoid, and digastric), and the epicranial and facial muscles and platysma, which are developments from the hyoid arch (Rabl). The **chorda tympani nerve** is regarded as the subordinate (præ-branchial, præ-trematic) branch to supply the anterior margin of the first post-oral cleft. It is possible that the genicular ganglion, with the *nervus intermedius* and the *chorda tympani*, may, in part at least, represent the ganglionic and afferent element of the nerve. Or the genicular ganglion, and the nerves in relation to it, may be associated with an "epibranchial" sense-organ.

The **acoustic nerve**, on the other hand, may be either the sensory element of the branchial nerve, associated with the **hyoid arch** and first post-oral cleft, or it may represent the nerve or nerves belonging to ancestral sense-organs of the lateral line.

The **glossopharyngeal** is the branchial nerve of the **third post-oral (thyreo-hyoid) arch** and the cleft in front. Its efferent fibres supply the muscle of this arch,—the *stylopharyngeus*. The superior constrictor of the pharynx is also assigned to this arch; the middle and inferior muscles to the fourth (first branchial) arch. The afferent portion of the nerve is possibly composed of two separate parts; the petrous ganglion being associated with an epibranchial or lateral line sense-organ, and the rest of the nerve forming the afferent fibres for the gill-cleft

and arch. The lingual branches are regarded as the main stem (post-trematic), the pharyngeal branches as subordinate branches; the tympanic branch being the præ-brachial or præ-trematic branch for the anterior margin of the third gill-cleft.

The **vagus nerve** is generally regarded as representing the fusion of all the brachial nerves behind the glossopharyngeal. Its efferent fibres are in series with those of the glossopharyngeal above and the accessory nerve below, and belong to the lateral series of His. Its afferent fibres, like those of the glossopharyngeal, represent two elements. The ganglion nodosum has possible connexions with epibranchial sense-organs—the rest of the nerve representing the fused brachial nerves of fishes. The **superior laryngeal nerve** is looked upon as the brachial nerve of the fourth, and the **recurrent nerve** as the brachial nerve of the fifth arch. While the relation of the nerve to the hinder gill-arches and clefts makes it possible to understand the innervation by the vagus of the heart and lungs, no satisfactory explanation is forthcoming of the passage of the nerve into the abdomen, and its distribution to the stomach and other organs below the diaphragm.

FIG. 666.—SCHEME TO ILLUSTRATE THE DISPOSITION OF THE MYOTOMES IN THE EMBRYO IN RELATION TO THE HEAD, TRUNK, AND LIMBS.

A, B, C, First three cephalic myotomes; N, 1, 2, 3, 4, Last persisting cephalic myotomes; C, T, L, S, Co, The myotomes of the cervical, thoracic, lumbar, sacral, and caudal regions; I, II, III, IV, V, VI, VII, VIII, IX, X, XI, XII, refer to the cerebral nerves, and the structures with which they may be embryologically associated.

The **accessory nerve** consists of two parts. The internal ramus (*accessory portion*) of the nerve consists of efferent fibres for the **branchial region**, in series with the lateral motor roots of the glossopharyngeal and vagus nerves. The external ramus (*spinal portion*) of the nerve is also composed of efferent fibres, and represents the only lateral motor elements arising from the spinal medulla.

Olfactory Nerve.—There is complete uncertainty regarding the morphology of this nerve. It consists of three elements: (1) the **olfactory bulb**, derived from the cerebral hemisphere, solid in man, but a hollow cerebral diverticulum in certain animals, and forming the rhinencephalon; (2) the **olfactory ganglion**, with its central and peripheral processes, derived from the ectoderm; (3) the **nasal pit**. Attention has been specially fixed on the olfactory ganglion, which has been compared to (1) a spinal ganglion, derived from the anterior end of the medullary groove; and to (2) a lateral line sense-organ.

The **optic nerve** also presents an insoluble problem in regard to its morphological position

in the series of cerebral nerves. The optic stalk and optic cup have been regarded as a highly modified spinal ganglion; but there is insuperable difficulty in accepting this view. The peripheral processes do not become connected with either ectodermal or mesodermal structures, but become the tissue of the retina; while the central processes, growing backwards, envelop the optic stalk, and obtain connexions with the brain. The retina must be regarded as a highly modified nerve-layer, morphologically in series with the wall of the fore-brain; and the ectodermal structure of superficial origin comparable to the olfactory ganglion or the auditory vesicle is the lens (which may possibly be homologous with a lateral line sense-organ). The optic nerve, optic chiasma, and optic tract are then to be looked upon as cerebral commissures, and not as nerves in the ordinary sense.

The simplest and most primitive condition of the head, in relation to the morphology of the cerebral nerves, is found before the formation of the gill-clefts, when the salient features are

FIG. 667.—THE EMBRYOLOGICAL ARRANGEMENT OF THE CEREBRAL NERVES. (Modified from Mall.)

a tubular and simple brain, and a series of superficial invaginations which pass from the surface inwards to become connected with outgrowths corresponding to them from the primitive brain. On each side of the head three hollow invaginations occur:—(1) The **nasal pit** bearing the olfactory epithelium becomes connected by the olfactory ganglion with the rhinencephalon, an outgrowth from the fore-brain, and so forms the basis of an olfactory organ and nerve; (2) a similar invagination produces the **lens**, connected with a protrusion of the optic vesicle from the fore-brain, by which the basis of the eye and the optic nerve is formed; (3) behind the oral cavity a third invagination forms the **auditory vesicle**, which is connected with the solid extension from the hind-brain of the acoustic ganglia, to form the essentials of the organ of hearing and acoustic nerve.

The trigeminal nerve is essentially the nerve of the buccal cavity and the subordinate cavities, nasal and oral, derived from it. The **branchial arches and clefts** are secondary structures, and their nerves are (1) the trigeminal for the first (mandibular) arch and the cleft in front of it; (2) the facial for the second (hyoid) arch and cleft; (3) the glossopharyngeal for the third (thyreo-hyoid) arch and cleft; and (4) the vagus for the succeeding arches and clefts. The cerebral part of the accessory nerve is inseparable from the motor portion of the vago-glossopharyngeal nerves; the spinal part is beyond the series of the cerebral nerves.

Lastly, there are certain truly **segmental nerve elements**, motor fibres which, remaining associated with certain persistent cephalic myotomes, give rise to the oculo-motor, trochlear, abducent, and hypoglossal nerves.

ORGANA SENSUUM ET INTEGUMENTUM COMMUNE.

By ROBERT HOWDEN, M.D., F.R.S.E.

Professor of Anatomy in the University of Durham.

ORGANA SENSUUM.

THE **organs of the senses** are derived from cells of the ectoderm and constitute the apparatus by which man is made acquainted with his surroundings.

Every sense organ consists of three parts:—(a) a peripheral or receptive, capable of responding to external stimuli, (b) an intermediate or conductive, along which the impulses are conveyed, and (c) a central or perceptive, where the impulses are collected and transformed into sensations. The intermediate and central parts have been described in the section on the Nervous System; the peripheral parts form the subject matter of this chapter, and may be grouped under two headings:—(a) those connected with the *special senses* of smell, sight, hearing, and taste, and located in the nose, eye, ear, and mouth, respectively; and (b) those of *general sensations* (pressure, heat, cold, pain, etc.), which are widely distributed throughout the body.

ORGANON OLFACTUS.

The nose is the peripheral **olfactory organ** and consists of the *nasus externus*, which projects from the face, and the *cavum nasi*, which is divided by a vertical septum into right and left cavities.

Nasus Externus.—The **external nose** forms a more or less triangular pyramid, of which the upper angle is termed the **root**, and is usually separated from the forehead by a depression, while its base, directed downwards, is perforated by the **nares** or **nostrils**. Its free angle is named the **apex**; and the anterior border, joining root and apex, is termed the **dorsum**; the upper part of the dorsum is supported by the nasal bones, and is named the **bridge**. Each side of the nose forms an open angle (*naso-facial angle*) with the cheek, and ends below in a mobile expanded portion, the *ala nasi*, which forms the lateral boundary of the *naris*, and is limited above by a furrow, the *alar sulcus*. The skin of the nose is thin and movable over the root, but thick and adherent over the apex and *alæ*, where it contains numerous large sebaceous glands.

The arterial supply of the external nose is derived from the external maxillary and ophthalmic arteries, and its veins open into the anterior facial vein and communicate with the ophthalmic vein. Its principal lymph vessels follow the course of the anterior facial vein and open into the submaxillary lymph glands. From the root of the nose one or two vessels run laterally in the upper eyelid and end in the upper anterior auricular lymph glands, while a third group runs below the orbit to the lower anterior auricular lymph glands. Its muscles are supplied by the facial nerve, and the skin covering it is supplied by the infra-trochlear and naso-ciliary branches of the ophthalmic nerve and the infra-orbital branch of the maxillary nerve.

The external nose presents great variety as to its size and shape, and certain well-defined types, such as *aquiline*, *Grecian*, etc., are described. The relation which its breadth, measured across the *alæ*, bears to its length, measured from root to apex, is termed the *nasal index*, and is expressed thus:

$$\frac{\text{greatest breadth} \times 100}{\text{greatest length.}}$$

In white races this index is below 70 (leptorhines); in yellow races, between 70 and 85 mesorhines); and in black races, above 85 (platyrhines).

CARTILAGINES NASI.

Five chief cartilages are concerned in the formation of the nose; they are the lateral and greater alar cartilages on each side and the cartilage of the septum.

Cartilago Nasi Lateralis.—The lateral cartilage (Figs. 669, 670) is triangular in shape and is situated immediately below the nasal bone. Its posterior edge is thin and is attached to the maxilla and the nasal bone; its anterior edge is thick and its superior part is directly continuous with the cartilage of the septum; its inferior margin is joined by fibrous tissue to the upper edge of the greater alar cartilage.

Cartilago Alaris Major.—The greater alar cartilage (Figs. 668, 669, 670) encircles the anterior part of the nostril and assists in keeping it open. It consists

FIG. 668.—VIEW OF NASAL SEPTUM FROM THE LEFT SIDE.

of a lateral and a medial crus, which are continuous with each other in a rounded angle at the apex of the nose. The **lateral crus** is oval in shape and is attached to the lateral cartilage and the maxilla by fibrous tissue. Above and behind it are two or three *lesser alar cartilages*, while sometimes a horizontal furrow cuts off a narrow linear part from its superior margin. The inferior edge of the lateral crus does not descend as far as the opening of the nostril, the ala being here devoid of cartilage and composed of fatty and connective tissue covered with skin. The **medial crus** (Fig. 668) bounds the medial wall of the nostril and lies in the septum mobile, below the anterior part of the cartilage of the septum. The medial crura of the two cartilages are separated, in front, by a notch which corresponds with the apex of the nose, and the posterior end of each curves slightly lateralwards and ends in a rounded extremity.

Cartilago Septi Nasi.—The cartilage of the septum (Fig. 668) is of an irregularly quadrilateral form. Its postero-superior edge is attached to the perpendicular lamina of the ethmoid; its postero-inferior margin to the vomer and the maxillæ. Its antero-superior border is thick, and is fixed above to the back of the internasal

suture; immediately below the level of the nasal bones it is continued, on each side, into the lateral cartilages, which may be looked upon as its wing-like expansions. The inferior part of this border is separated by a fissure from the lateral cartilage, and extends downwards between the greater alar cartilages, to which it is attached by fibrous tissue; in this fibrous tissue a small accessory cartilage is usually seen on either side of the median plane. Its antero-inferior border is short, and is attached by fibrous tissue to the medial crura of the greater alar cartilages, while its anterior angle is rounded and does not reach as far as the apex of the nose. The lowest part of the nasal septum is not formed by the septal cartilage, but by the medial crura of the greater alar cartilages and by the integument, and, being freely movable, is termed the *septum mobile nasi*. The cartilage of the septum may be prolonged backwards (especially in children) as a narrow process, the *processus sphenoidalis*, into the angle between the vomer and ethmoid; this process varies from 4 to 6 mm. in width, and sometimes reaches as far as the body of the sphenoid.

FIG. 669.—PROFILE VIEW OF THE BONY AND CARTILAGINOUS SKELETON OF THE EXTERNAL NOSE.

sometimes reaches as far as the body of the

On either side of the inferior edge of the cartilage of the septum, and seen best in a frontal section of the nose, is a narrow band of cartilage, the *vomero-nasal cartilage*; it measures from 6 to 12 mm. in length, and is attached to the vomer.

CAVUM NASI.

The **nasal cavity** (Fig. 672) is divided by the nasal septum into a right and a left nasal cavity, which extend from the nostrils in front to the choanæ behind, and open, through the choanæ, into the nasal part of the pharynx. Their bony boundaries are described in the section on Osteology (p. 183). On the lateral wall of each are found the orifices of the frontal, ethmoidal, sphenoidal, and maxillary sinuses, together with that of the naso-lacrimal duct.

Immediately above the aperture of the nostril is a slightly

FIG. 670.—FRONT VIEW OF THE BONY AND CARTILAGINOUS SKELETON OF THE EXTERNAL NOSE.

expanded area, the **vestibule**; this is bounded laterally by the lateral crus of the greater alar cartilage, and medially by the lower part of the septum; it is prolonged as a small recess towards the apex of the nose. Partly subdivided by a curved ridge, the vestibule is lined with skin and, in its lower half, there are hairs and sebaceous glands; the hairs are curved downwards to guard the entrance to the nostril. The superior part of the vestibule is smooth, and is limited above and posteriorly by a slightly marked arched prominence, the **limen nasi**, beyond which the nasal cavity is lined with mucous membrane.

FIG. 671.—CARTILAGES OF NOSE FROM BELOW.

slit-like space, and comprises the middle of the superior nasal concha and the corresponding portion of the septum. The **respiratory region** includes the remaining part of the cavity.

Septum Nasi (Fig. 668).—Where the bony septum of the nose is deficient, below and in front, the gap is filled by the septal cartilage. Until the seventh year the nasal septum lies, as a rule, in the median plane, but after this age it is very often bent to one or other side—more frequently to the right—the deflection being greatest usually along the line of junction of the vomer with the perpendicular lamina of the ethmoid. Deflection of the septum is more common in European than in non-European skulls—occurring in about 53 per cent of the former and in about 28 per cent of the latter (Zuckerkandl). Associated with, or apart from, this deviation, crests or spurs of bone are found, projecting from the septum into one or other nasal cavity, in about 20 per cent of skulls. In the septum, a little above and in front of the naso-palatine recess, is a minute orifice, not always recognisable, from which a blind pouch extends upwards and backwards for a distance of from 2 to 9 mm. This is the **vomero-nasal organ of Jacobson**, and is supported by the vomero-nasal cartilage. In man this organ is rudimentary, but in many of the lower animals it is well developed (Fig. 673), and probably plays a part in the sense of smell, since it is lined with epithelium similar to that covering the olfactory region, and is supplied by branches of the olfactory nerve.

Lateral Wall (Fig. 674).—In the lateral wall of the nasal cavity, above the superior nasal concha, is a narrow recess, the **recessus sphenothmoidalis**, into the posterior

FIG. 672.—FRONTAL SECTION THROUGH NASAL CAVITIES; ANTERIOR HALF OF SECTION VIEWED FROM BEHIND.

nasal cavity, is a narrow recess, the **recessus sphenothmoidalis**, into the posterior

part of which the sphenoidal air-sinus opens. The **superior meatus** of the nose is a short oblique fissure, directed downwards and backwards under cover of the superior nasal concha; into it the posterior ethmoidal cells open by one or more orifices. A small meatus, bounded superiorly by a concha suprema, frequently exists above the superior meatus. The narrow slit-like interval between the nasal septum and the medial surface of the middle nasal concha is named the **olfactory cleft** or **sulcus**.

The **middle meatus**, situated below and lateral to the middle nasal concha, is a roomy passage, and is continued forwards into a slightly depressed area, termed the **atrium meatus nasi**, which lies immediately above the vestibule. The atrium is limited superiorly and anteriorly by a low ridge, the **agger nasi**, the representative of the *naso-turbinal* found in many animals. When the middle nasal concha has been removed the lateral wall of the meatus is exposed. On it is seen a narrow semilunar cleft, the **hiatus semilunaris**, bounded above by a rounded elevation, the **bullae ethmoidalis**, and below by the sharp edge of the **processus uncinatus** of the

FIG. 673.—SECTION THROUGH NOSE OF A KITTEN, showing position of the vomero-nasal organs.

FIG. 674.—VIEW OF THE LATERAL WALL OF THE NOSE—THE NASAL CONCHAE HAVING BEEN REMOVED.

2. Opening of maxillary sinus.	5. Agger nasi.	8. Cut edge of middle nasal concha.
3. Hiatus semilunaris.	6. Opening of anterior ethmoidal cells.	9. Pharyngeal orifice of auditory tube.

ethmoid. The size of the bulla varies with that of the middle ethmoidal cells which are contained within it and which open on or near its upper surface. Through the hiatus semilunaris the middle meatus opens into the **infundibulum**, a curved channel, limited above by the bullae ethmoidalis, and below by the lateral surface of the **processus uncinatus**. The anterior end of the infundibulum receives

the openings of the anterior ethmoidal cells, and, in rather more than fifty per cent of skulls, is continued upwards as the *fronto-nasal duct* into the frontal air-sinus; in the remainder it is shut off from the lower end of the fronto-nasal duct by the union of the anterior part of the bulla ethmoidalis with the upper end of the *processus uncinatus*, and the fronto-nasal duct then opens into the anterior part of the middle meatus. The *ostium maxillare* or opening of the maxillary sinus is placed below the bulla ethmoidalis, and is hidden by the lower end of the *processus uncinatus*; an accessory ostium is frequently seen in the middle meatus, above the posterior part of the inferior nasal concha.

The *inferior meatus* lies below the inferior nasal concha, under cover of the anterior part of which is the slit-like orifice of the naso-lacrimonal duct (see p. 825).

The *roof* is very narrow, except at its posterior part, and is divisible into three portions, fronto-nasal, ethmoidal, and sphenoidal, in accordance with the bones which enter into its formation.

The *floor* is nearly horizontal from before backwards, and is formed by the palatine process of the maxilla and the horizontal part of the palatine bone. In it, close to the inferior margin of the septum and immediately over the incisive foramen, a slight depression, the *naso-palatine recess*, is sometimes seen; it is directed downwards and forwards for a short distance, and indicates the position of a communication which existed between the nasal and buccal cavities in early foetal life.

Membrana Mucosa Nasi.—The nasal mucous membrane is thick, highly vascular, and firmly bound to the subjacent periosteum and perichondrium. It is continuous, through the choanæ, with the mucous lining of the nasal part of the pharynx; through the naso-lacrimonal and lacrimal ducts, with the conjunctiva; and, through the apertures leading into the air-sinuses, with the delicate lining of these cavities.

Throughout the respiratory region it is covered with columnar, ciliated epithelium, interspersed amongst which are goblet or mucin cells, whilst between the bases of the columnar cells smaller pyramidal cells are interpolated. It contains a freely anastomosing venous plexus, which in some parts, *e.g.* over the inferior nasal conchæ, forms a cavernous plexus. Many acinous glands, secreting a watery fluid, are embedded in it, and are especially large and numerous in the posterior halves of

the nasal cavities, while in children the mucous membrane contains a considerable amount of adenoid tissue.

In the olfactory region the mucous membrane is yellowish in colour, more delicate, and is covered with non-ciliated columnar epithelium (Figs. 675, 676). Embedded in it are numerous tubular and branched

FIG. 675.—SECTION THROUGH THE OLFACTORY MUCOUS MEMBRANE.

glands, the *olfactory glands*, which are lined with polygonal cells and open by fine ducts on its free surface. The epithelium of the olfactory region consists of: (1) supporting cells, (2) olfactory cells, and (3) basal cells.

1. **Supporting Cells.**—The superficial parts of these cells are columnar in shape and contain fine granules of yellow pigment, whilst the deeper portions are continued

for some distance as attenuated or branched processes. These cells contain elliptical or oval nuclei, which are situated at the deep ends of the columnar parts of the cells, and form what is termed the *zone of oval nuclei*. In many animals the free surface of this columnar epithelium is covered by a thin limiting membrane.

2. Olfactory Cells.

—These are bipolar nerve-cells, the central processes of which are continued as the axons of the olfactory nerve-fibres. They are homologous with the cells of the spinal ganglia, but differ from them in that they retain their primitive position in the surface epithelium. The cell bodies are spindle-shaped and are arranged in several rows between the deeper, attenuated parts of the supporting cells. Each consists of a large, spherical nucleus with a small amount of enveloping protoplasm; the nuclei form a layer of some thickness, termed the *zone of round nuclei*. The peripheral process of each cell is rod-like, and extends between the columnar portions of the supporting cells as far as their free surfaces, where it pierces the external limiting membrane and divides into a number of fine hair-like processes, termed **olfactory hairs**. The central process is a delicate, beaded filament, and is continued upwards as the axon of an olfactory nerve-fibre.

FIG. 676.—OLFACTORY AND SUPPORTING CELLS.

A. Frog } M. Schultze. C. Human (v. Brunn).
B. Human }

3. **Basal Cells.**—These cells are branched, and lie on a basement membrane between the deep extremities of the supporting and olfactory cells.

Olfactory Nerves.—The fibres of the olfactory nerves are devoid of medullary sheaths, and arise, as stated, from the olfactory cells. They are collected into fasciculi which form a plexiform network under the mucous membrane and ascend on the medial and lateral walls of the olfactory region of the nasal cavity. They are lodged, near the base of the skull, in grooves or canals in the ethmoid bone and pass into the cranial cavity through the foramina in the lamina cribrosa of the ethmoid. Immediately above this lamina they enter the olfactory bulb, in the glomerular layer of which they subdivide and form synapses with the dendrites of the mitral cells of the bulb.

The trigeminal nerve supplies branches of ordinary sensation to the nasal mucous membrane as follows:—The septum is chiefly supplied by the naso-palatine nerve, but its posterior part receives some filaments from the sphenopalatine ganglion and from the nerve of the pterygoid canal, and its anterior portion from the naso-ciliary branch of the ophthalmic. The lateral wall is supplied—(1) by the upper nasal branches of the nerve of the pterygoid canal and from the sphenopalatine ganglion; (2) by the lower nasal branches derived from the anterior palatine; and in front by (3) the naso-ciliary branch of the ophthalmic. The floor and anterior part of the inferior meatus are supplied by a nasal branch of the anterior superior alveolar nerve.

Blood-vessels.—**Arteries.**—The chief artery of the nose is the sphenopalatine branch of the internal maxillary artery. This reaches the nasal cavity through the sphenopalatine foramen, and divides into—(a) posterior nasal, which ramifies over the meatuses and conchæ and sends branches to the maxillary and frontal sinuses and the ethmoidal cells; and (b) naso-palatine, the artery of the septum. Twigs are given to the upper portion of the cavity by the anterior and posterior ethmoidal arteries, while its posterior part receives some small branches from the descending palatine. The nostrils are supplied by the lateral nasal branch of the external maxillary, and by

the septal artery from the superior labial. The maxillary sinus is partly supplied by the infra-orbital artery, whilst the sphenoidal sinus gets its chief supply from the sphenopalatine artery. The veins form a dense cavernous plexus; this condition is well seen in the respiratory region, and especially so over the middle and inferior nasal conchæ and on the lower part of the septum. The venous blood is carried in three chief directions, viz., *anteriorly* into the anterior facial vein, *posteriorly* into the sphenopalatine vein, and *superiorly* into the ethmoidal veins. The ethmoidal veins communicate with the ophthalmic veins and the veins of the dura mater; further, an ethmoidal vein passes up through the lamina cribrosa of the ethmoid, and opens either into the venous plexus of the olfactory bulb or directly into one of the veins on the orbital surface of the frontal lobe of the brain. The lymph vessels form an irregular network in the superficial part of the mucous membrane, and can be injected from the subdural or subarachnoid cavities. The larger vessels are directed posteriorly towards the choanæ, and are collected into two trunks, of which the larger passes to a lymph gland in front of the epistropheus, and the smaller to one or two lymph glands situated near the greater cornu of the hyoid bone.

The development of the nose is described in the section which deals with "General Embryology" (p. 50).

ORGANON VISUS.

OCULUS.

The bulb of the eye (O.T. eyeball) constitutes the peripheral part of the **organ of sight**; associated with it are certain accessory structures, such as the eyelids and the lacrimal apparatus.

FIG. 677.—DIAGRAM OF A HORIZONTAL SECTION THROUGH LEFT BULBUS OCULI AND OPTIC NERVE ($\times 4$).

Bulbus Oculi.—Situated in the anterior part of the orbital cavity, the bulb of the eye is protected in front by the eyelids, and is pierced behind by the optic nerve, which ramifies in its innermost tunic, the retina. The tendons of the ocular muscles are attached to the outer surface of the bulb, a short distance in front of

its equator, while its posterior two-thirds are enveloped by a loose membrane termed the fascia bulbi (O.T. capsule of Tenon).

The bulb of the eye is not quite spherical, being composed of the segments of two spheres, viz., an anterior, transparent, corneal segment, possessing a radius of 7 or 8 mm., and a posterior, opaque, scleral segment, with a radius of about 12 mm. (Fig. 677). The anterior or corneal segment, in consequence of its shorter radius, projects as a dome in front of the scleral portion, the union of the two parts being indicated externally by a slight groove, the *sulcus scleræ*. The central points of the anterior and posterior curved surfaces of the bulb constitute, respectively, its **anterior** and **posterior poles**, and a straight line joining the two poles is termed the **optic axis**; an imaginary line encircling the bulb, midway between the poles, is named the **equator**. The axes of the two bulbs are almost parallel, diverging only slightly in front; but the axes of the optic nerves converge behind, and, if prolonged backwards, would meet in the region of the dorsum sellæ of the sphenoid. The sagittal and transverse diameters of the bulb are nearly equal—about 24 mm.; its vertical diameter is about 23·5 mm. All three diameters are rather less in the female than in the male, but the size of the bulb is fairly constant in the same sex. What are popularly described as large eyes owe their apparent size to a greater prominence of the bulb and to a wider fissure between the eyelids.

At birth the bulb of the eye is nearly spherical and has a diameter of about 17·5 mm. By the age of puberty this has increased to 20 or 21 mm., after which it rapidly reaches its adult size.

Fascia Bulbi.—The fascia bulbi (O.T. capsule of Tenon) is a fibrous tunic enveloping the posterior two-thirds of the bulb of the eye, and separating the posterior part of the bulb from the surrounding orbital fat. It blends posteriorly with the sheath of the optic nerve and with the sclera around the lamina cribrosa; anteriorly it is continued into the ocular conjunctiva, and is also attached to the ciliary region of the bulb. It is pierced by the tendons of the ocular muscles, and is reflected on each as a tubular sheath. The sheath on the tendon of the obliquus superior surrounds the tendon as far as its pulley, to which it is attached; that on the obliquus inferior is prolonged as far as the floor of the orbit. The sheaths on the recti muscles are continuous posteriorly with the perimysium of these muscles, and each gives off an expansion. The expansion from the sheath of the rectus superior blends with the sheath of the levator palpebræ superioris, and that from the sheath of the rectus inferior is attached to the tarsus of the inferior eyelid. The expansions from the sheaths of the medial and lateral recti are strong, especially that from the latter muscle, and are attached to the lacrimal and zygomatic bones respectively; they are named the *medial* and *lateral check ligaments*, because they probably limit the action of the corresponding muscles. The portion of the fascia bulbi which lies inferior to the bulb of the eye has been named the *suspensory ligament* (Lockwood); it is expanded in the centre, and is slung like a hammock from side to side, its narrow ends being fixed to the lacrimal and zygomatic bones.

The bulb of the eye (Fig. 677) consists of three concentric tunics or coats, and contains three transparent refracting media. The three tunics are: (1) an outer *fibrous tunic*, consisting of an opaque posterior part, the **sclera**, and a transparent anterior portion, the **cornea**; (2) an intermediate vascular, pigmented, and partly muscular tunic, the *tunica vasculosa oculi*, comprising, from behind forwards, the **chorioid**, the **ciliary body**, and the **iris**; (3) an internal *nervous tunic*, the **retina**. The three refracting media are named, from before backwards, the **aqueous humour**, the **crystalline lens**, and the **vitreous body**.

TUNICA FIBROSA OCULI.

Sclera.—The sclera is a firm, opaque membrane, forming approximately the posterior five-sixths of the outer tunic. Thickest posteriorly (about 1 mm.), it thins at the equator to 0·4 or 0·5 mm., and again increases to 0·6 mm. near the sulcus

scleræ. In the child it is thinner than in the adult, and presents a bluish appearance caused by the pigment of the chorioid shining through it; in old age it assumes a yellowish tinge. In front of the equator it gives attachment to the tendons of the ocular muscles, while its anterior part is covered by the conjunctiva. Its deep surface presents a brownish colour, and is loosely attached to the chorioid, except at the entrance of the optic nerve and in the neighbourhood of the sulcus scleræ. It is pierced behind by the optic nerve, the entrance for which is funnel-shaped, wide behind and narrow in front, and is situated 3 mm. to the nasal side and slightly below the level of the posterior pole. The fibrous sheath of the nerve blends with the outer part of the sclera, while the nerve bundles pass through a series of orifices; this perforated portion is named the *lamina cribrosa scleræ*. Around the entrance of the optic nerve are some fifteen to twenty small apertures for the passage of the ciliary nerves and short ciliary arteries. The two long posterior ciliary arteries pierce it, one on each side, some little distance from the entrance of the optic nerve; while a little behind the equator are four openings, two above and two below, for the exit of veins, called *venæ vorticosæ*; near the sulcus scleræ it is perforated by the anterior ciliary arteries. The deep surface of the sclera is lined

with flattened endothelial cells; and between it and the chorioid is an extensive lymph space, the *spatium perichorioideale*, which is traversed by the ciliary nerves and arteries just mentioned, and by an irregular meshwork of fine, pigmented, connective tissue, the *lamina fusca*, which loosely attaches the sclera to the chorioid. At the sclero-corneal junction the fibrous tissue of the sclera passes continuously into that of the cornea, and in the deeper part of this junction there is a circular canal, the *sinus venosus scleræ* (O.T. canal of Schlemm) (Fig. 678).

FIG. 678.—SECTION OF IRIDIAL ANGLE. (Prof. Arthur Thomson.)

When seen in a meridional section of the sclero-corneal junction, the sinus venosus scleræ appears as a narrow cleft; its outer wall is formed by the compact tissue of the sclera, while its inner consists of a triangular mass of trabecular tissue; the apex of the triangle is directed forwards and is continuous with the posterior elastic lamina of the cornea. The sinus is lined with endothelium, and occasionally contains a few red blood corpuscles. It communicates, on the one hand, with the entrance of the optic nerve, and in the region of the spatia anguli iridis in the trabecular tissue, with the anterior chamber of the eye.

Structure.—The sclera consists of bundles of white fibrous tissue, together with some fine elastic fibres, the bundles forming equatorial and meridional layers, which interlace with each other. Numerous spaces containing connective tissue cells and migratory cells exist between the fibres. Pigmented cells are plentiful in the lamina fusca, and a few are found also in the tissue of the sclera, near the entrance of the optic nerve, and in the region of the sclero-corneal junction.

Vascular and Nervous Supply.—The sclera receives its blood-supply from the short posterior ciliary and the anterior ciliary arteries, while its veins open into the *venæ vorticosæ* and anterior ciliary veins. The cell spaces play the part of lymph vessels and communicate with the perichorioid and suprascleral lymph spaces. Its nerves are derived from the ciliary nerves, which, after losing their medullary sheaths, pass between the fibrous bundles; their exact mode of ending is not known.

Cornea.—The cornea is transparent and forms the anterior sixth of the outer tunic; its index of refraction is from 1.33 to 1.35; the thickness of its central part

is about .95 mm., of its peripheral part, about 1.19 mm. Its anterior surface is covered with a stratified epithelium, continuous with that which lines the conjunctiva; its posterior surface is directed towards the anterior chamber of the eye and is in contact with the aqueous humour. Its degree of curvature varies in different individuals; it is greater in youth than in old age, and is, as a rule, slightly greater in the vertical than in the horizontal plane; it diminishes from its centre to its circumference, and is less on the nasal than on the temporal side of the anterior pole. The outline of the anterior surface of the cornea is almost circular, measuring 11 mm. vertically and 11.9 mm. transversely; that of the posterior surface is circular and has a diameter of 13 mm.

The tissue of the cornea is continuous posteriorly with that of the sclera, the line of union being known as the **sclero-corneal junction**. Directly in front of this junction the inner surface of the cornea projects in the form of a rounded rim; behind this rim, in the interval between the sclero-corneal junction and the attachment of the iris, is a groove, the **sulcus circularis corneæ** (Arthur Thomson)¹ (Fig. 679). The outer wall of this sulcus is composed of a thin stratum of trabecular tissue placed on the inner side of the sinus venosus scleræ.

FIG. 679.—SECTION OF A PORTION OF THE BULB OF THE EYE SHOWING THE SULCUS CIRCULARIS CORNEÆ.

FIG. 680.—VERTICAL SECTION OF CORNEA (magnified).

strata of polygonal cells, the majority of which exhibit finger-like processes joining with the corresponding processes of neighbouring cells; the more superficial layers consist of squamous cells. The thickness of this stratified epithelium is about $45\ \mu$ at the centre, and about $80\ \mu$ at the periphery of the cornea.

Between this trabecular tissue and the front of the circumference of the iris is a narrow recess which on section appears as an acute angle; it is named the **filtration angle** or **angle of the iris**.

Structure.—The cornea consists, from before backwards, of the following strata, viz., (Fig. 680):—

1. Epithelium corneæ.
2. Anterior elastic lamina.
3. Substantia propria.
4. Posterior elastic lamina.
5. Endothelium of anterior chamber.

1. The **epithelium corneæ** is continuous with that covering the free surface of the conjunctiva and consists of six or eight strata of nucleated cells. Deepest of all is a single layer of perpendicularly arranged columnar cells, the flattened bases of which rest on the anteriorelastic lamina, while their opposite ends are rounded and contain the nuclei. Superficial to this layer are three or four

¹ The *Ophthalmoscope*, September 1910, and July 1911.

2. The **anterior elastic lamina** is from 19-20 μ thick, and is regarded merely as a differentiation of the anterior part of the substantia propria, from which it is with difficulty separated; it is not stained yellow by picrocarmine, thus differing from true elastic tissue. Its degree of development varies in different animals.

3. The **substantia propria** presents, in a fresh condition, a homogeneous appearance; but, with the assistance of reagents, it is seen to consist of modified connective tissue, with a few elastic fibres. An amorphous interstitial substance binds the fibres into bundles, and, in turn, cements the bundles into lamellæ which are flattened from before backwards. The fibres of any one lamella cross those of adjacent lamellæ almost at right angles, while the superimposed lamellæ are joined by sutural fibres and by amorphous substance. Between the lamellæ are found the cell spaces or lacunæ of the cornea—irregularly stellate in shape, and communicating freely with each other by means of fine canaliculi. The corneal cells or corpuscles are contained in these lacunæ, without, however, completely filling them, the remainder of the cavities being occupied by lymph. The cells are nucleated, flattened, and star-like, and their branched processes join those of neighbouring cells in the canaliculi. Migratory or lymph cells are also found in cell spaces.

After middle age a grayish opaque ring, 1.5 to 2 mm. in breadth, is frequently seen near the periphery of the cornea; it is termed the **arcus senilis**, and results from a deposit of fat granules in the lamellæ and corneal corpuscles.

4. The **posterior elastic lamina** is a clear homogeneous membrane, covering the posterior surface of the substantia propria and possessing a thickness of 6-8 μ at the centre and 10-12 μ at the periphery of the cornea. Less firmly attached than the anterior elastic lamina, it may be stripped off, when it will be found to roll up with its attached surface inwards. Between the ages of twenty and thirty years small wart-like projections appear on its deep surface, near its periphery, and these increase in size and number as years advance, so that in old age the membrane may attain a thickness of 20 μ . At the sclero-corneal junction the posterior elastic lamina splits into bundles of fine fibres which interlace and form the triangular area of trabecular tissue already referred to (p. 808), and which is usually spoken of under the name of the **ligamentum pectinatum iridis**. The meshes or spaces between the trabeculæ are termed the **spatia anguli iridis** (O.T. spaces of Fontana), and are lined with endothelium prolonged from the endothelium of the anterior chamber. They communicate internally with the filtration angle and externally with the sinus venosus scleræ, and form important channels through which fluid may filter from the anterior chamber into the sinus and thence into the anterior ciliary veins. When the trabecular tissue of the ligamentum pectinatum iridis is followed backwards most of its fibres are seen to be attached to the anterior surface of an inwardly directed rim of scleral tissue; in a meridional section this rim appears as a triangular projection, and is named the **scleral spur**. A few fibres of the trabecular tissue are carried past the apex of the scleral spur on to the inner surface of the origin of the meridional fibres of the ciliary muscle, and, passing behind the filtration angle, are prolonged into the iris (Fig. 678), where they are directly continuous with the fibres of the dilator pupillæ muscle (Arthur Thomson).¹

5. The **endothelium of the anterior chamber** consists of a single stratum of nucleated, flattened, polygonal cells, which present a fibrillar structure and are continued as a lining to the spatia anguli iridis; this layer of endothelium is also reflected on to the anterior surface of the iris.

Vascular and Nervous Supply of the Cornea.—In the fœtus the cornea is traversed, almost as far as its centre, by capillaries; but in the adult it is devoid of blood-vessels, except near its margin. The capillaries of the conjunctiva and sclera pass into this marginal area for a distance of about 1 mm., where they terminate in loops. All the remainder of the cornea is nourished by the lymph which circulates in its cell spaces and canaliculi.

The nerves of the cornea are derived from the ciliary nerves. Around its periphery they form an annular plexus, from which fibres pass into the cornea, where, after a distance of 1 or 2 mm., they lose their medullary sheaths and ramify in the substantia propria, forming what is termed the fundamental or stroma plexus. Fibres extend from this plexus through the anterior elastic lamina and form a subepithelial plexus, from which fine filaments ramify between the epithelial cells as far as the superficial layers. From the annular and stroma plexuses fibrils pass to the substantia propria and come into close relation with the corneal corpuscles.

TUNICA VASCULOSA OCULI.

The middle, vascular, and pigmented tunic of the bulb of the eye comprises, from behind forwards, the chorioid, the ciliary body, and the iris (Fig. 681).

Chorioidea.—The chorioid intervenes between the sclera and the retina, reaching as far forwards as the ora serrata of the retina (p. 815). It is dark brown or black in colour, and is thicker behind than in front; posteriorly it is pierced by the optic nerve, and is here firmly attached to the sclera. Its outer surface is flocculent and is connected to the sclera by the loose lamina fusca; its inner surface is smooth and is adherent to the outermost or pigmented layer of the retina.

The chorioid consists of a loose connective tissue, embedded in which are blood-vessels and branched pigment cells; from without inwards it consists of three

¹ *Op. cit.*

layers, viz. : (a) the lamina suprachorioidea ; (b) the proper tissue of the chorioid ; and (c) the lamina basalis (Fig. 681).

FIG. 681.—VERTICAL SECTION OF CHORIOID AND INNER PART OF SCLERA.

The **lamina suprachorioidea** resembles the lamina fusca of the sclera, and consists of a series of fine non-vascular lamellæ, each containing a delicate network of elastic fibres, amongst which are stellate, pigmented cells and amœboid cells. The spaces between the laminae are lined with endothelium, and together form the spatium perichorioideale, already referred to (p. 808).

The proper tissue of the chorioid consists of blood-vessels and numerous pigmented cells, supported by connective tissue, elastic fibres, and some non-stripped muscular fibres. Its outer part contains the larger blood-vessels, and is named the **lamina vasculosa**, while its inner portion is composed of a network of fine capillaries, and is termed the **lamina choriocapillaris** ; these two laminae are joined by a thin **intermediate stratum**. The arteries of the chorioid are derived from the short posterior ciliary vessels which pierce the sclera around the entrance of the optic nerve, and form a wide-meshed plexus in the lamina vasculosa. The circular muscular coats of the arteries are well developed, and longitudinal muscular fibres also are present in the larger branches. The veins,

FIG. 682.—DIAGRAM OF THE CIRCULATION IN THE EYE (Leber).

The circular muscular coats of the arteries are well developed, and longitudinal muscular fibres also are present in the larger branches. The veins,

destitute of muscular tissue, are superficial to the arteries; they are surrounded by perivascular lymph sheaths and converge to form whorls, which open into the *venæ vorticosæ*. In the tissue between the blood-vessels are numerous stellate, flattened, and pigmented cells.

The *lamina choriocapillaris* is composed essentially of small capillaries, which form an exceedingly close network, embedded in a finely granular or almost homogeneous tissue.

The *intermediate stratum* between the *lamina vasculosa* and *lamina choriocapillaris* consists of a network of delicate elastic fibres and contains almost no pigment cells; it is lined, next the *lamina choriocapillaris*, with a layer of endothelium.

The *lamina basalis* is transparent and nearly structureless. Its outer surface exhibits a trellis-like network of fibres which unite it to the *lamina choriocapillaris*, while its inner surface is smooth and is in contact with the pigmented layer of the retina.

Tapetum.—In many animals a brilliant iridescence is seen on the postero-lateral part of the chorioid; to this the name *tapetum* is applied. Absent in man, it may be due, as in the horse, to a markedly fibrous condition of the *stratum intermedium* (*tapetum fibrosum*), or as in the seal, to the presence of some five or six layers of flattened iridescent cells lying immediately outside the *lamina choriocapillaris* (*tapetum cellulosum*).

Corpus Ciliare.—The *ciliary body* connects the chorioid to the circumference of the iris (Fig. 683), and comprises three zones, viz.: (a) the *orbiculus ciliaris*,

(b) the *ciliary processes*, and (c) the *ciliary muscle*.

The *orbiculus ciliaris* is a zone of about 4 mm. in width immediately adjoining the chorioid; it exhibits numerous radially arranged ridges.

Processus Ciliares.

—The *ciliary processes*, about seventy in number, form a circle of radial thickenings, each of a somewhat triangular shape; the base of the triangle is directed forwards, towards the equator of the lens, while the apex is continuous behind with some three or four ridges of the *orbiculus ciliaris*. They vary in size, the largest having a length of 2.5 mm.

The structure of the *orbiculus ciliaris* and *ciliary processes* is similar to that of the chorioid, but the capillaries are larger and more tortuous, and there is no *lamina choriocapillaris*. The deep surface of the *ciliary processes* is covered by

FIG. 683.—SECTION THROUGH CILIARY REGION OF THE BULB OF THE EYE.

two strata of columnar epithelium, the anterior layer of which is pigmented; these two strata form a direct continuation forwards of the retina and constitute the

pars ciliaris retinæ; this epithelium is invaginated to form more or less tubular glands.

M. Ciliaris.—The **ciliary muscle** is triangular on horizontal or vertical section, and consists of two sets of fibres—meridional and circular (Fig. 683). The **meridional fibres** arise from the scleral spur, already described, and radiate backwards, to be attached to the ciliary processes and orbiculus ciliaris. When they contract the chorioid is drawn forwards and the lens becomes more convex, owing to the relaxation of its suspensory ligament (see p. 810). The **circular fibres** form a triangular zone behind the filtration angle, close to the periphery of the iris. Considerable individual differences are found as to the degree of development of these two portions of the ciliary muscle; the meridional fibres are always more numerous than the circular fibres, the latter being absent or rudimentary in myopic eyes, but well developed, as a rule, in hypermetropic eyes.

Iris.—The **iris** forms a contractile diaphragm in front of the lens, and is pierced, a little to the nasal side of its centre, by an almost circular aperture, the **pupil**, which, during life, is continually varying in size in order to regulate the amount of light admitted into the interior of the eye. It partially divides the space between the cornea and lens into two portions, which are filled by the aqueous humour, and named respectively the **anterior** and **posterior chambers** of the eye. It is thinnest at its peripheral or ciliary margin which is directly continuous with the ciliary body, and, through the medium of the ligamentum pectinatum iridis, with the posterior elastic lamina of the cornea. Its pupillary or free margin forms the circumference of the pupil, and rests upon the anterior surface of the capsule of the lens.

The distinctive colour of the eye, in different individuals, depends on the arrangement of the pigment in the iris; in the blue eye the pigment is limited to the posterior surface of the iris, but in the brown or black eye it is also scattered throughout its stroma; in the albino the pigment is absent.

The pupil is closed, during the greater part of foetal life, by a thin transparent vascular membrane, the **membrana pupillaris**, continuous with the pupillary margin of the iris. Its vessels are derived partly from the vessels of the iris and partly from those of the capsule of the lens; they converge towards the middle of the membrane, near which they form loops so as to leave the central part non-vascular. About the seventh month the vessels begin to be obliterated, from the centre towards the circumference; and this is followed by a thinning and absorption of the membrane, which becomes perforated by the aperture of the pupil. This perforation gradually enlarges, and at birth the membrane has entirely disappeared; in exceptional cases it persists.

On the anterior surface of the iris is a layer of flattened endothelium, placed on a basement membrane, and continuous with the endothelium of the anterior chamber. Depressions or crypts are here and there seen in which the endothelium and basement membrane are absent, and are, by some, regarded as stomata, through which the lymph vessels of the iris communicate with the cavity of the anterior chamber. The posterior surface of the iris is covered with a basement membrane, on which are placed two layers of columnar, pigmented epithelium, continuous with the *pars ciliaris retinæ*, and termed the *pars iridica retinæ*. The **stroma iridis**, or proper tissue of the iris, consists of delicate connective tissue and elastic fibres, with pigmented cells, blood-vessels, nerves, and non-striped muscle.

The **blood-vessels of the iris** (Fig. 682) are derived from the long ciliary and the anterior ciliary arteries. The long ciliary arteries, two in number, pierce the sclera on the medial and lateral sides of the optic nerve respectively, and extend forwards, between the sclera and chorioid, towards the ciliary margin of the iris. Here each divides into a superior and an inferior branch, and the resulting four branches anastomose in the form of a circle, termed the **circulus arteriosus major**. This circle is joined by a varying number of anterior ciliary arteries derived from the lacrimonal and muscular branches of the ophthalmic artery, and, after supplying the ciliary muscle, sends converging branches towards the aperture of the pupil, where a second circle, the **circulus arteriosus minor**, is formed. The **veins** proceed

towards the ciliary margin of the iris, and communicate with the veins of the ciliary processes and with the sinus venosus scleræ. The convergence of the blood-

vessels towards the aperture of the pupil gives to the anterior surface of the iris a striated appearance.

The **non-striated muscular fibres** of the iris are arranged in two sets: (*a*) circular, (*b*) radial. The **circular fibres** form a band, the **m. sphincter pupillæ**, around the pupillary aperture; by the contraction of these fibres the size of the pupil is lessened. The **radial fibres** constitute the **m. dilatator pupillæ** and extend outwards from the sphincter to the ciliary margin. Many anatomists regard the radial fibres, in man and most mammals, as being elastic and not muscular. In animals in which the radial fibres are muscular, the

FIG. 684.—BLOOD-VESSELS OF IRIS AND ANTERIOR PART OF CHOROID, viewed from the front (Arnold).

degree of their development varies considerably; they are feebly marked in the rabbit, but are well developed in the bird, and still more so in the otter.

The **nerves of the choroid and iris** (Fig. 685) are derived from the long and short ciliary nerves. The former, two or three in number, are branches of the nasociliary nerve; the latter, varying from eight to fourteen, are derived from the ciliary ganglion. Piercing the sclera around the entrance of the optic nerve, the ciliary nerves traverse the perichorioidal lymph space, where they form a plexus, rich in nerve-cells, from which filaments are supplied to the blood-vessels of the choroid. In front of the ciliary muscle a second plexus, also rich in nerve-cells, is formed; this supplies the ciliary muscle and sends filaments into the iris, as far as its pupillary margin, for the supply of its muscular fibres and blood-vessels. The sphincter pupillæ is supplied by the oculo-motor nerve, the dilatator pupillæ by the sympathetic.

FIG. 685.—DISSECTION OF THE EYEBALL SHOWING THE VASCULAR TUNIC AND THE ARRANGEMENT OF THE CILIARY NERVES AND VESSELS.

RETINA.

The **retina**, or nervous tunic of the eyeball, is a soft, delicate membrane, in which the fibres of the optic nerve are spread out. It consists of two strata, viz.: (*a*) an outer, pigmented layer, attached to the choroid; and (*b*) an inner nervous lamina, the retina proper, in contact with the hyaloid membrane of the vitreous body, but attached to it only around the entrance of the optic nerve and in the region of the ciliary processes. Expanding from the entrance of the optic nerve,

the retina appears to end, a short distance behind the ciliary body, in a wavy border, the *ora serrata* (Fig. 686). Here its nervous elements cease and the membrane becomes suddenly thinned, but a delicate continuation of it is prolonged over the posterior aspect of the ciliary body and iris. This continuation consists of the pigmented layer, together with a layer of columnar epithelium, and constitutes the *pars ciliaris retinæ* and *pars iridica retinæ*, already referred to (p. 813). The portion behind the *ora serrata* is termed the *pars optica retinæ*, and its thickness gradually diminishes from 0.4 mm. near the entrance of the optic nerve, to 0.1 mm. at the *ora serrata*. It presents, at the posterior pole of the eye, and therefore directly in the optic axis, a small, oval yellowish spot, the *macula lutea*. The greatest or transverse diameter of the macula measures from 2.3 mm.; its central part is depressed and is named the *fovea centralis*. About 3 mm. to the nasal side and slightly below the level of the posterior pole is a whitish, circular disc, the *optic disc*, which corresponds with the entrance of the optic nerve, and has a diameter of about 1.5 mm. The circumference of the optic disc is slightly raised and is named the *papilla nervi optici*, while its depressed central portion is termed the *excavatio papillæ nervi optici* (O.T. *optic cup*). The optic disc consists merely of nerve-fibres, the other layers of the retina being absent, and it constitutes the "blind spot."

FIG. 686.—A SEGMENT OF THE BULBUS OCULI SHOWING THE ORA SERRATA.

FIG. 687.—DIAGRAMMATIC SECTION OF THE HUMAN RETINA (modified from Schultze).

The nervous layer of the retina is transparent during life, but becomes opaque and of a grayish colour soon after death. If an animal is kept in the dark before the removal of its eyeball, the retina presents a purple tinge, due to the presence of a colouring matter named *rhodopsin* or *visual purple*, which is rapidly bleached on exposure to sunlight. This colouring matter is absent from the macula lutea, and absent also over a narrow zone, 3-4 mm. in width, near the *ora serrata*.

Structure of the Retina (Figs. 687, 688, 689).—The nervous elements of the retina are supported by non-nervous or *sustentacular fibres*, and are arranged in seven layers, to which must be added the stratum pigmenti.

The layers from within outwards, *i.e.* from vitreous body to chorioid, are:

1. Stratum opticum or layer of nerve-fibres.
2. Ganglionic or nerve-cell layer.
3. Inner molecular or inner plexiform layer.
4. Inner nuclear layer or layer of inner granules.
5. Outer molecular or outer plexiform layer.
6. Outer nuclear layer or layer of outer granules.
7. Layer of rods and cones.
8. Stratum pigmenti.

1. Stratum opticum or layer of nerve-fibres.—Most of the fibres of this stratum are centripetal, and are direct continuations of the axons of the cells in the

ganglionic layer; a few are centrifugal and end in branched clubbed extremities in the inner molecular or inner nuclear layers of the retina.

FIG. 688.—PERPENDICULAR SECTIONS OF MAMMALIAN RETINA (Cajal).

A, Layer of rods and cones; B, Outer nuclear layer; C, Outer molecular layer; D, Inner nuclear layer; E, Inner molecular layer; F, Ganglionic layer; G, Stratum opticum; *r*, rods; *c*, cones, *r.g.*, rod granules; *c.g.*, cone granules; *r.b.*, rod bipolar; *c.b.*, cone bipolar; *c.r.*, contact of rod bipolar with the spherules of the rod fibres; *c.c.*, contact of cone bipolar with the branches of the cone fibres; *ar.*, internal arborisation of cone bipolar; *ar'*, internal arborisation of rod bipolar; *c.n.*, centrifugal nerve fibre; *h.*, horizontal cells; *s.s.*, stratified spongioblasts; *d.s.*, diffuse spongioblasts; *s.g.*, stratified ganglion cell; M, Sustentacular fibre.

2. Ganglionic or nerve-cell layer.—The cells of this stratum vary in size, are oval or piriform in shape, and form a single layer, except at the macula lutea, where several strata are present. Each cell contains a large nucleus, and gives off, from its inner surface, an axon which is continued as a fibre of the stratum opticum. From the outer surface of each cell numerous dendrites arise, which form arborisations in the inner molecular layer. The cells may be divided into uni-stratified, multi-stratified, and diffuse, according as their dendrites ramify in one or in several strata of the inner molecular layer, or extend throughout nearly its whole thickness.

3. Inner molecular or inner plexiform layer.—This is constituted chiefly by the interlacement of the dendritic arborisations of the cells of the ganglionic layer with those of the inner nuclear layer, and has been divided by Ramon y Cajal into five strata. It sometimes contains horizontal cells (spongioblasts), whose branched processes ramify in it.

4. Inner nuclear layer or layer of inner granules.—This is the most complicated of the retinal strata, and consists of numerous cells which may be divided into three groups, viz.: (a) bipolar cells, (b) horizontal cells, and (c) spongioblasts, or amacrine cells.

(a) The **bipolar cells**, by far the most numerous, are fusiform and nucleated, and each gives off an external and an internal process. The internal processes terminate in flattened tufts, at different levels, in the inner molecular layer, while the external produce an abundant ramification in the external zone of the outer molecular layer. These bipolar cells are divided into rod bipolars, cone bipolars, and giant bipolars. The **rod bipolars** end peripherally in vertical arborisations around the button-like ends or spherules of the rod fibres, and, centrally, in branched extremities which mostly become applied to the cells of the ganglionic layer. The **cone bipolars** end peripherally in flattened arborisations in the outer molecular layer, in contact with the ramifications of the foot-plates of the cone fibres, and, centrally, ramify in some one of the five strata of the inner molecular layer. The **giant bipolars** form, peripherally, an extensive horizontally arranged arborisation in the outer molecular layer; centrally, they ramify in one or other of the strata of the inner molecular layer.

FIG. 689.

A, A cone and two rods from the human retina (modified from Max Schultze); B, Outer part of rod separated into discs.

(b) The **horizontal cells** are of two varieties: (1) small, flattened, star-like cells, lying immediately internal to the outer molecular layer, and sending a tuft of dendrites outwards, towards the bases of the cone fibres, while their axons are directed horizontally, for a variable distance; (2) large, irregular cells, lying internal to the above and ending in finger-like ramifications in the outer molecular layer. Their axons run horizontally for some distance, and end, in extensive varicose arborisations, under the spherules of the rod fibres.

(c) The **spongioblasts** are situated in the innermost part of the inner nuclear layer; their processes ramify in the inner molecular layer, it may be in one stratum (stratified spongioblasts) or in several strata (diffuse spongioblasts).

5. **Outer molecular or outer plexiform layer.**—This is constituted by the interlacement of the dendrites of the bipolar and horizontal cells, just described, with the spherules of the rod fibres and the ramifications of the foot-plates of the cone fibres. It is divided into two strata: (a) *external*, indicating the contact of the rod bipolars with the spherules of the rod fibres; (b) *internal*, the line of contact between the cone bipolars and the branches of the cone fibres.

6. **Outer nuclear layer or layer of outer granules.**—This is made up of clear granules which somewhat resemble those of the inner nuclear layer, and are divisible into two kinds: (a) cone granules, (b) rod granules. The **cone granules** are the larger, and each contains an oval nucleus; they lie immediately inside the outer limiting membrane, through which they are continuous with the cones of the next layer. Each is prolonged internally as a straight fibre, which, on reaching the outer molecular layer, expands to form a foot-plate, from which several horizontal fibrils are given off. The **rod granules** are far more numerous than the cone granules, and each contains a small oval nucleus, which is transversely striated. Their outer processes are continuous, through the outer limiting membrane, with the rods of the next layer, while their inner processes pass into the outer molecular layer and end in free, unbranched spherules amongst the arborisations of the rod bipolars.

7. **Layer of rods and cones.**—This consists of two sets of structures, viz., **rods** and **cones**. Except at the macula lutea the rods are far more numerous than the cones, and assume the form of elongated cylinders, while the cones are shorter than the rods, and taper externally to fine points. Each rod and cone consists of two segments—inner and outer. The inner segment of the rod only slightly exceeds in diameter its outer segment, whereas the inner segment of the cone greatly exceeds its outer part. The inner segments of both rods and cones have an affinity for staining reagents, and consist of a basal homogeneous portion and an outer longitudinally striated part, the proportion of the latter to the former being greater in the cones than in the rods. The outer segments have not the same affinity for reagents, but tend to break transversely into numerous discs (Fig. 689, B). The colouring matter, *rhodopsin*, already referred to, is found only in the outer segments of the rods, the terminal parts of which extend into the layer of pigmented epithelium.

8. **Stratum pigmenti.**—This consists of a single stratum of cells which, on surface view, are hexagonal (Fig. 690), their outer flattened surfaces being firmly attached to the chorioid. When seen in profile the outer part of each cell contains a large oval nucleus and is devoid of pigment, while the inner portion is filled with pigment and extends as a series of thread-like processes amongst the outer segments of the rods and cones. When the eye is kept in the dark the pigment accumulates near the outer part of the cell, but when exposed to light it streams in between the rods and cones (Fig. 691).

Sustentacular fibres of the retina.—These form a framework for the support of the nervous structures (Fig. 688, M). They begin at the inner surface of the nerve-fibre layer

FIG. 690. — STRATUM PIGMENTI OF HUMAN RETINA (viewed from the surface).

in single or forked expanded bases, by the apposition of which a delicate membrane, the **membrana limitans interna**, is formed. In the ganglionic layer they give off a few side branches, and, on passing through the inner nuclear layer, supply ramifications amongst the inner granules

FIG. 691.—SECTION THROUGH OUTER LAYERS OF RETINA (semi-diagrammatic).

for their support; in this part of each fibre there is an oval nucleus. In the outer nuclear layer they break up into a network of fibrils which surround the rod and cone granules and fibres, and end externally at the bases of the rods and cones in a delicate membrane, the *membrana limitans externa*.

Structure of the macula lutea and fovea centralis.—The yellow colour of the macula is due to the presence of pigment in the inner layers of the retina. At the circumference of the macula the nerve-fibre layer is greatly thinned and the rods are few in number; the ganglionic layer, on the other hand, is thickened and may contain from seven to nine strata of cells, while the outer granular layer also is thicker and its granules have an oblique direction. At the fovea centralis the retina is much thinned, since here its nerve-fibre and ganglionic layers are absent and its other strata greatly attenuated. The stratum pigmenti, on the other hand, is thicker and its pigmentation more pronounced. The cone nuclei are situated some distance internal to the outer limiting membrane, and thus the thin inner and outer granular layers are in apposition. There are no rods, and the cones, closely crowded together, are narrower and their outer segments more elongated than elsewhere, so that the line of their bases, indicated by the *membrana limitans externa*, presents a convexity directed forwards. The fovea centralis and macula lutea are spoken of by physiologists as the “region of distinct vision.”

Structure of the ora serrata.—Here the nervous layers of the retina suddenly cease; the layer of rods and cones ends a little behind the margin of the ora serrata; the other nervous strata persist as far as its margin. In front of the ora serrata the retina is prolonged over the ciliary processes in the form of two layers of cells: (*a*) an inner layer of columnar epithelium, and (*b*) an outer, consisting of the stratum pigmenti, the two forming the *pars ciliaris retinae*. The same two layers are prolonged over the back of the iris, where both are pigmented and form the *pars iridica retinae*.

Vessels of the retina (Fig. 692).—The retina is supplied by the *arteria centralis retinae*, a branch of the ophthalmic artery, which pierces the sheath of the optic nerve about 2 c.m. behind the bulb of the eye, and makes its appearance in the centre of the optic papilla. Here it divides into an upper and a lower branch, and each of these again bifurcates into a medial or nasal, and a lateral or temporal, branch. The resulting four branches ramify towards the periphery of the retina, and are named the superior and inferior temporal

FIG. 692.—BLOOD-VESSELS OF THE RETINA.

and the superior and inferior nasal arteries. The temporal arteries pass laterally above and below the macula lutea, to which they give small branches; these do not, however, extend as far as the fovea centralis, which is devoid of blood-vessels. The macula also receives two small arteries (superior and inferior macular) directly from the stem of the *arteria centralis*. The larger vessels run in the nerve-fibre layer near the *membrana limitans interna* and form two capillary networks—an inner, in the nerve-fibre layer, and an outer, in the inner nuclear layer. The inner network arises directly from the arteries and sends numerous small branches to form the outer network, from which the veins take origin. The vessels do not penetrate deeper than the inner granular layer, nor do the arteries anastomose, except through the capillary plexuses. The veins follow the course of the arteries; they have no muscular coats, but consist merely of a layer of endothelial cells, outside which is a perivascular lymph sheath, surrounded by delicate retiform tissue.

REFRACTING MEDIA.

Corpus Vitreum.—The vitreous body is a transparent, jelly-like substance situated between the crystalline lens and the retina, and occupying the posterior four-fifths of the bulb of the eye (Fig. 677). In front it presents a deep concavity, the *hyaloid fossa* (O.T. *fossa patellaris*), for the reception of the posterior convexity of the lens. It is enclosed within a thin transparent membrane, the *membrana hyaloidea*, which is in contact with the *membrana limitans interna* of the retina, and is adherent to it at the entrance of the optic nerve. The portion of the *membrana hyaloidea* in front of the *ora serrata* is thickened and strengthened by radial fibres, and is termed the *zonula ciliaris*. Situated behind the ciliary body, the *zonula* is radially folded and presents a series of alternating furrows and elevations. The ciliary processes are received into, and are firmly adherent to, the furrows, with the result that, if removed, some of their pigment remains attached to the *zonula*. The elevations of the *zonula* are not attached to the interciliary depressions, but are separated by a series of lymph spaces named the *recessus camerae posteriores*; these may be regarded as diverticula of the posterior chamber with which they communicate. As the *zonula* approaches the equator of the lens it splits into two chief layers, viz.: (*a*) a thin posterior lamina, which lines the *hyaloid fossa*; and (*b*) a thicker anterior layer, termed the *suspensory ligament* of the lens (Fig. 677), which blends with the front of the lens capsule a short distance from the equator of the lens. Scattered fibres of this ligament are also attached to the equator itself and to the regions immediately anterior and posterior to it. By this suspensory ligament the lens is retained in position, and its convexity varies inversely with the degree of tension of the ligament. The radial fibres of the ciliary muscle, by pulling forward the ciliary processes and the attached *zonula ciliaris*, relax the ligament, and thus allow the lens to become more convex. Behind the suspensory ligament, a sacculated lymph space surrounds the equator of the lens; it is named the *spatia zonularia* (O.T. canal of Petit), and may be easily inflated on introducing a fine blow-pipe through the suspensory ligament (Fig. 677). In the foetus a blood-vessel, termed the *arteria hyaloidea*, is continued from the *arteria centralis retinae* forwards through the vitreous body, for the supply of the capsule of the lens. Its position, in the adult, is represented by a lymph channel, termed the *canalis hyaloideus* of Stilling (Fig. 677), the presence of which may be demonstrated by shaking up the vitreous body in a solution of picrocarmine, when some of the pigment may be seen to extend along the canal (Anderson Stuart).

FIG. 693.—THE SPATIA ZONULARIA DISTENDED AND VIEWED FROM THE FRONT (enlarged).

FIG. 694.—LENS HARDENED IN FORMALIN AND DISSECTED TO SHOW ITS CONCENTRIC LAMINÆ (enlarged).

(Fig. 677). It is enclosed in a thin, transparent, homogeneous capsule, the *capsule of the lens*. The central points of its anterior and posterior surfaces are termed

When the vitreous body is treated by a weak solution of chromic acid it presents a series of concentric, peripherally arranged striae, together with numerous radial striae converging towards its centre. Between these the more fluid part lies, and it frequently contains vacuolated amoeboid cells scattered through it. The vitreous body consists of 98.4 per cent of water, having in solution about 1.4 per cent of sodium chloride and traces of extractives and albumen.

Lens Crystallina.—The crystalline lens lies in front of the vitreous body and behind the iris, and is a biconvex, transparent body

respectively its **anterior** and **posterior poles**, a line joining which is known as its **axis**; its peripheral circumference is named the **equator**. Its axial measurement is 4 mm., and its transverse diameter from 9 to 10 mm. Its anterior surface is less

FIG. 695.—DIAGRAMMATIC REPRESENTATION OF THE RADIAL LINES OF THE FETAL LENS.

A, Seen from the front; B, From behind.

curved than the posterior and on it rests the pupillary margin of the iris; the central part of the surface corresponds with the aperture of the pupil and is directed towards the anterior chamber; the peripheral part is separated from the iris by the aqueous humour of the posterior chamber. Its posterior surface, more convex than the anterior, occupies the hyaloid fossa of the vitreous body. The curvatures of its surfaces, especially that of the anterior, are constantly varying during life for the purpose of focussing near or distant objects on the retina.

The **substantia lentis** consists of a soft outer part, the **substantia corticalis**, easily crushed between the finger and thumb, and of a dense central part, the **nucleus lentis**.

The refractive index of the **substantia corticalis** is about 1.4; that of the **nucleus lentis** about 1.45. Faint radial lines run from the anterior and posterior poles of the lens towards its equator. In the foetus they are three in number, and form angles of 120° with each other (Fig. 696). From the anterior pole one ray ascends vertically and the other two diverge downwards, while from the posterior pole one ray descends vertically and the other two diverge upwards. In the adult the rays may be increased to six or more. They represent the free edges of a corresponding number of septa which dip into the substance of the lens, and along which the extremities of the different groups of lens fibres come into contact, and are attached by a clear, amorphous substance. The lens, when hardened, exhibits a series of concentrically arranged laminae (Fig. 694), superimposed like the scales of an onion and attached to each other by a clear, amorphous substance. Each lamina is split along the radiating lines, and consists of a series of hexagonal, riband-like fibres, the **fibræ lentis**, which are adherent to each other by their margins; those of the deeper laminae are small and serrated, but non-nucleated; while those of the superficial coats are large and nucleated, but non-serrated. The fibres extend in a curved manner from the rays on the anterior surface to the rays on the posterior surface, but no fibre extends from pole to pole. Fibres which start at or near one pole end at or near the equator on the opposite surface, and *vice versa*, while the intervening fibres take up intermediate positions. Between the **substantia lentis** and the anterior part of the capsule there is a layer of nucleated columnar epithelial cells, the **epithelium lentis**. On being traced towards the equator its cells become gradually elongated and transformed into lens fibres, which, when fully formed, lose all trace of their nuclei, except in the more superficial laminae. Each lens fibre represents, therefore, a greatly elongated columnar cell (Fig. 696).

In the foetus the lens is soft, of a pinkish colour, and nearly spherical; while in old age it becomes somewhat flattened, and assumes a yellowish tint.

Camerae Oculi (Fig. 677).—As already stated (p. 813), the space between the cornea and the lens is divided by the iris into two unequal parts, viz., the camera

FIG. 696.

SECTION THROUGH THE EQUATOR OF THE LENS.

Showing the gradual transition of the epithelium into lens fibres (after Babuchin).

oculi anterior in front and the camera oculi posterior behind. These are filled with the **aqueous humour**, and, in the adult, communicate freely through the aperture of the pupil, but in the foetus are separated from each other by the *membrana pupillaris*. The **camera oculi anterior** or **anterior chamber** is bounded in front by the cornea, behind by the iris and lens, whilst peripherally it communicates with the *spatia anguli iridis*. The **camera oculi posterior** or **posterior chamber** is triangular on section, and is bounded in front by the iris, behind by the circumferential part of the lens and its suspensory ligament; the base of the triangle corresponds with the thick, anterior extremities of the ciliary processes. It communicates with the *recessus cameræ posteriores* and *spatia zonularia*. The aqueous humour has a refractive index of about 1.336, and consists of about 98 per cent of water, with 1.4 per cent of sodium chloride, and traces of albumen.

PALPEBRÆ.

The **eyelids** are two movable curtains situated in front of the bulb of the eye, and named, from their positions, **superior** and **inferior**. The superior is the larger and more movable, being provided with a special elevator muscle, the *m. levator palpebræ superioris*. The interval between the eyelids is termed the **palpebral fissure**, and measures transversely about 30 mm., but varies considerably in different individuals and in different races. When the eye is open the fissure is elliptical in shape, but when closed it assumes the form of a transverse slit, which lies on a level with the lower margin of the cornea. The two lids meet at the extremities of the fissure, and form the **lateral** and **medial commissures**. Their free margins are flattened and are sur-

FIG. 697.—EYELID SLIGHTLY EVERTED TO SHOW THE CONJUNCTIVA (enlarged).

mounted by eyelashes, from the lateral commissure to a point about 5 mm. from the medial commissure—a point indicated by a small papilla, the **papilla lacrimalis**. Medial to this papilla the margins are rounded and destitute of eyelashes, and form the upper and lower boundaries of a triangular space, termed the **lacus lacrimalis**, which is occupied by a small pale red body, the **caruncula lacrimalis**. The caruncula consists of a small island of modified skin, and contains sudoriferous and sebaceous glands, and fine hairs. Posteriorly the lids are lined with mucous membrane, the conjunctiva, and are in contact with the bulb of the eye, except near the medial commissure, where, between the bulb of the eye and the caruncula lacrimalis, there intervenes a vertical fold of conjunctiva, the **plica semilunaris conjunctivæ**, which in many animals contains a plate of cartilage.

In each eyelid there exists a framework of condensed fibrous tissue, which gives consistence and shape to the lid, and is termed the **tarsus**. In front of the tarsus are the fibres of the orbicularis oculi muscle and the integument, while embedded in its posterior surface, and covered by the conjunctiva, are numerous modified

sebaceous glands, named the **tarsal glands**. The superior tarsus is larger than the inferior, and of a half oval shape, with its greatest vertical diameter measuring about 10 or 11 mm. Its upper margin is thin and convex, and is continuous with the tendon of the levator palpebræ superioris muscle, while its lower edge is thick and straight. The inferior tarsus is a thin, narrow strip, with a nearly uniform vertical diameter of about 5 mm. The extremities of the two plates are continuous with the **lateral palpebral raphe** and the **medial palpebral ligament**. The lateral palpebral raphe is a narrow band attached to the zygomatic bone; it divides, at the lateral commissure, into superior and inferior pieces which are fixed to the margins of the respective tarsi. The medial palpebral ligament is a strong band attached to the frontal process of the maxilla, directly in front of the lacrimal

FIG. 698.—SAGITTAL SECTION THROUGH SUPERIOR EYELID.

groove; it divides at the medial commissure into two slips, one for each tarsus (Fig. 699).

The eyelids are further strengthened by membranous expansions, termed the **superior and inferior palpebral ligaments**, which extend into them from the margin of the orbit. The superior palpebral ligament is continuous, along the superior margin of the orbit, with the pericranium and with the periosteal lining of the orbit, and blends below with the tendon of the levator palpebræ superioris. The inferior palpebral ligament is prolonged from the lower edge of the inferior tarsus to the inferior margin of the orbit, where it is continuous with the periosteum of the face and orbital floor. Laterally the two palpebral ligaments fuse to form the lateral palpebral raphe, while medially they become thinned, and, separating from the medial palpebral ligament, are attached to the lacrimal bone, behind the lacrimal sac. The superior and inferior palpebral ligaments form the **septum orbitale**, between the superficial and deep structures of the eyelids; this septum is perforated by the vessels and nerves, which extend from the orbital cavity to the face or scalp.

The skin covering the eyelids is thin and delicate, and is continuous, at their margins, with their conjunctival lining. It contains numerous small sudoriferous glands and fine hairs, the latter being provided with sebaceous follicles. Branched pigment cells are present in the cutis, and pigment exists also in the deep layers of the epidermis. The subcutaneous tissue is loose and devoid of fat, and in it are found the fibres of the orbicularis oculi muscle—a small separate bundle of which, termed the **muscle of Riolan**, occupies the margin of the lids behind the eyelashes.

The **glandulæ tarsales** (O.T. **Meibomian glands**) are

elongated sebaceous glands with numerous lateral offshoots; they are embedded in the tarsi and are filled with cubical epithelium. There are from twenty-five to thirty in the superior eyelid, and from twenty to twenty-five in the inferior; they open by small ducts, about 1 mm. in length, along the lid margins, behind the eyelashes; the ducts are lined with stratified epithelium, placed on a basement membrane. Between the eyelashes and the muscle of Riolan are two or three rows of modified sudoriferous glands, termed the **glands of Moll**.

H. Müller described a layer of non-striped muscle in each lid: in the superior extending from the tendon of the levator palpebræ superioris to the upper tarsus, and in the inferior connecting the inferior tarsus with the inferior oblique muscle.

The eyelashes are curved, silky hairs which project from the free margins of the lids; in the upper lid they are longer and more numerous than in the lower, and are curved upwards, while those of the lower lid are bent downwards.

Conjunctiva.—The conjunctiva is the mucous membrane which lines the eyelids, and is continued from them on to the front of the bulb of the eye. The part on the eyelids is termed the **tunica conjunctiva palpebrarum**, that on the bulb of the eye the **tunica conjunctiva bulbi**; the lines of reflection of the membrane from the eyelids to the bulb are known as the **superior and inferior conjunctival fornices**. The conjunctiva palpebrarum is intimately adherent to the tarsi and presents numerous papillæ. It is covered with a layer of columnar epithelial cells, beneath the bases of which are small flattened cells; near the fornices a number of acino-tubular glands, much more plentiful in the upper than in the lower eyelid, open on its free surface. The conjunctiva bulbi is thinner than the conjunctiva palpebrarum, and is loosely attached to the sclera by submucous tissue. The *plica semilunaris conjunctivæ* has already been referred to (p. 821). On the cornea the conjunctiva is represented merely by the epithelium corneæ (p. 809).

Vessels and Nerves.—The chief arteries of the eyelids are the superior and inferior palpebral branches of the ophthalmic, which pierce the septum orbitale above and below the medial palpebral ligament, and run laterally in the corresponding lid near its free margin. On reaching the region of the lateral palpebral commissure they anastomose with each other and with twigs from the lacrimal, superficial temporal, and transverse facial arteries, and in this way an arch is formed in each lid. Secondary smaller arches are found, one above the primary arch in the upper lid, and another below that of the lower lid, while the upper lid receives branches also

FIG. 699.—DISSECTION OF THE RIGHT EYELID. The orbicularis oculi has been completely removed.

from the supra-orbital and frontal arteries. The **veins** are arranged in two sets: (a) subconjunctival or retrotarsal, opening into the muscular tributaries of the ophthalmic veins, and (b) pretarsal, into the angular and superficial temporal veins. The **lymph vessels**, like the veins, form pre- and retrotarsal networks, which communicate with each other through the tarsal plates. The lymph is drained chiefly into the anterior auricular and parotid lymph glands, but partly, by vessels which accompany the anterior facial vein, into the submaxillary lymph glands. The **sensory nerves** of the eyelids are supplied by the trigeminal nerve—the upper lid chiefly by the supra-orbital and supra-trochlear branches of the ophthalmic; the lower, by the infra-orbital branch of the maxillary. The region of the lateral commissure receives some filaments from the lacrimal nerve, that of the medial from the infra-trochlear. These sensory nerves form a marginal plexus behind the orbicularis oculi muscle. The levator palpebræ superioris muscle is supplied by the oculomotor nerve, and the non-stripped fibres of the eyelids by the sympathetic.

APPARATUS LACRIMALIS.

The **lacrimal apparatus** consists of: (1) the lacrimal gland, which secretes the tears; (2) the lacrimal ducts, by which the tears are drained from the front of the eye; and (3) the lacrimal sac and naso-lacrimal duct, which convey them into the nasal cavity.

FIG. 700.—DISSECTION TO SHOW THE LACRIMAL APPARATUS.

Glandula Lacrimalis.—The lacrimal gland is a flattened, oval body situated in the superior and lateral part of the orbital cavity; it consists of two portions—superior and inferior—imperfectly separated from each other by the expansion of the tendon of the levator palpebræ superioris muscle. The **glandula lacrimalis superior** is firm and much larger than the inferior; it measures transversely about 20 mm., and sagittally from 12 to 14 mm. It occupies the fossa lacrimalis on the medial surface of the zygomatic process of the frontal bone, and is fixed by fibrous bands to its periosteum, while its inferior surface is in contact with the levator palpebræ superioris and rectus lateralis muscles, which intervene between it and the bulb of the eye. The **glandula lacrimalis inferior** consists of small, loosely aggregated lobules; it lies below and in front of the orbital portion, and projects into the posterior part of the upper eyelid, where its deep surface is in contact with the conjunctiva. The ducts draining the glandula superior are from three to five in number; they pass between the lobules of the glandula inferior, and open at the upper and lateral part of the fornix conjunctivæ superior. The ducts of the glandula inferior number from three to nine; some of them join those from the glandula superior, while others open separately at the fornix conjunctivæ superior. The lacrimal gland has a structure resembling that of the parotid, and

is supplied by the sympathetic and lacrimal nerves and by the lacrimal artery, while its veins are drained into the ophthalmic vein.

Ductus Lacrimales.—The lacrimal ducts, two in number, commence in minute orifices, termed the *puncta lacrimalia*, at the apices of the papillæ lacrimales (p. 821), and are directed medialwards along the medial parts of the margins of the eyelids, above and below the lacus lacrimalis. The superior duct at first ascends for a short distance and then inclines downwards; the inferior duct descends for a short distance and then runs horizontally; at the angles where they change direction each is dilated into an ampulla. The two ducts open close together into the lateral and front part of the lacrimal sac, a little below its middle; sometimes they open separately into a pouch-like dilatation of the sac, termed the *sinus of Maier*. The ducts are lined with stratified epithelium placed on a tunica propria, outside which is a layer of striped muscular fibres derived from the lacrimal part of the orbicularis oculi. These muscular fibres are arranged somewhat spirally around the ducts, but at the base of each papilla lacrimalis they are circular in direction and form a species of sphincter. On contraction they serve to empty the contents of the lacrimal ducts into the lacrimal sac.

The **saccus lacrimalis** and **ductus nasolacrimalis** together form the passage by which the tears are conveyed from the lacrimal ducts to the nasal cavity.

The **lacrimal sac** is the upper expanded part of the passage, and measures from 12 to 15 mm. in length, about 7 mm. antero-posteriorly, and from 4 to 5 mm. transversely. It lies in the groove formed by the lacrimal bone and frontal process of the maxilla, and ends above in a rounded, blind extremity or fundus, while it narrows below into the naso-lacrimal duct. Here a fold of mucous membrane, named the *valve of Beraud*, together with a laterally directed pouch, the *sinus of Arlt*, are sometimes present. Near its superior extremity it is crossed, in front, by the medial palpebral ligament (O.T. tendo oculi), from the upper and lower edges of which the orbicularis oculi takes origin; the lacrimal part of the orbicularis oculi muscle is behind it.

The **naso-lacrimal duct** averages about 18 mm. in length, and has a diameter of from 3 to 4 mm. Rather narrower in the middle than at its extremities, it is directed downwards and slightly backwards, and opens into the inferior meatus of the nose at the junction of its anterior fourth with its posterior three-fourths, *i.e.* a distance of 30 to 35 mm. from the posterior boundary of the nostril. Its lower orifice is somewhat variable in form and position, and is occasionally duplicated. It is frequently guarded by a fold of mucous membrane, termed the **plica lacrimalis** (Hasneri). Through this orifice the mucous lining of the duct is continuous with that of the nasal cavity. The mucous membrane of the duct is thrown into inconstant folds, several of which have been described as valves. Its epithelium is columnar and in part ciliated; opening into the lower part of the duct are numerous glands, similar to those in the nasal mucous membrane.

The nerves of the lacrimal ducts and sac are derived from the infra-trochlear branch of the naso-ciliary; their arteries from the inferior palpebral and nasal. The veins of the naso-lacrimal duct are large and numerous, forming a sort of erectile tissue similar to that in the nasal cavity.

DEVELOPMENT OF THE EYE.

The retina and optic nerve are developed from a hollow outgrowth of the fore-brain, termed the **optic vesicle** (see pp. 54 and 33). This extends towards the side of the head, and its connexion with the brain is gradually elongated to form the **optic stalk**. The ectoderm overlying the optic vesicle becomes thickened, invaginated, and finally cut off as a hollow island of cells, which is named the **lens vesicle**. This vesicle indents the outer and lower part of the optic vesicle, converting it into a cup (**optic cup**), lined by two layers of cells continuous with each other at the margin of the cup. The inner of these strata, thicker than the outer, is named the **retinal layer**, and becomes differentiated into the nervous and supporting elements of the retina; while the outer, named the **pigmentary layer**, forms the stratum pigmenti. The edge of the optic cup extends in front of the equator of the lens, and bounds the future aperture of the pupil. In front of the lens, and also opposite its equator, the retinal layer is thin, and represented only by a stratum of columnar cells which becomes closely applied to the pigmentary layer, the two forming the

pars ciliaris and pars iridica retinæ. The indentation of the optic cup extends as a groove for some distance along the postero-inferior aspect of the optic stalk, forming what is termed the **chorioidal fissure** (Fig. 701). Through this fissure mesoderm passes inwards between the lens and the retina to form a part of the vitreous body, while the *arteria centralis retinæ* also becomes enclosed in it and so gains its future position in the centre of the optic

FIG. 701.—SECTIONS THROUGH PORTIONS OF THE HEADS OF FŒTAL RABBITS, to illustrate the connexion of the optic cup with the fore-brain, and the invagination of the ectoderm to form the lens.

nerve. The *arteria centralis* is prolonged forwards from the *porus opticus* through the vitreous body, as a cone of branches, as far as the back of the lens. By the fifth or sixth month all these branches have disappeared except one, the *arteria hyaloidea*, which persists until the last month of foetal life, when it also atrophies, leaving only the *canalis hyaloideus* to indicate its position.

The vitreous body is developed between the optic cup and the lens, and is derived partly from ectoderm and partly from mesoderm. It consists primarily of a series of fine protoplasmic fibres which project from the cells of the retinal layer of the cup and form a delicate reticular tissue. At first these fibres are seen in relation to the whole of the optic cup, but later they are limited to the ciliary region, where by a process of condensation they appear to form the *zonula ciliaris*. When the mesoderm reaches the cup through the *chorioidal fissure* it unites with this reticular tissue to form the vitreous body.

FIG. 702.—OPTIC CUP AND LENS VIEWED FROM BEHIND AND BELOW, to show formation of chorioidal fissure and enclosure of the *arteria centralis retinæ* (from model by Ziegler).

The lens, at first in contact with the ectoderm from which it is derived, is soon separated from it by mesoderm, and then consists of a rounded vesicle with epithelial walls. The anterior wall remains as a single layer of cells—the anterior lens epithelium of the adult; the cells of the posterior wall become elongated into lens fibres, and by the forward growth of these the cavity of the vesicle is obliterated. This elongation into lens fibres is greatest at the centre of the lens, while near the equator the fibres are shorter, and here the gradual transition between the anterior epithelium and the lens fibres is seen (Fig. 696). The lens becomes enveloped in a vascular tunic, which receives its vessels from the *arteria centralis retinæ* and from the vessels of the iris. The front part of this tunic forms the *membrana pupillaris*, and this, like the rest of the tunic, disappears before birth.

The hollow optic stalk becomes solid by the thickening of its walls and, acquiring nerve-fibres, is transformed into the optic nerve. These nerve-fibres are mostly centripetal, and are derived from the nerve-cells of the retina; but a few are centrifugal and have their origin in the brain. The further development of the retina resembles, in certain respects, that of the spinal medulla.

Cameron states (*Journ. Anat. and Physiol.*, vol. xxxix.) that in the early stages of the development of the inner or retinal layer of the optic cup all the structures, described by His as being present in the spinal medulla of the human embryo, are to be found, viz., (a) spongioblasts, (b) germinal cells, and (c) neuroblasts.

The spongioblasts undergo ramification and form a network or myelospongium, and also give rise to the inner and outer limiting membranes; the latter is next the original cavity of the optic vesicle, and therefore corresponds to the inner limiting membrane of the spinal medulla. The spongioblasts also form the groundwork of the inner and outer molecular layers into which the processes of the neuroblasts grow and arborise.

The germinal cells are always situated beneath the external limiting membrane, and by their division give rise to the neuroblasts. The first-formed neuroblasts are larger than those of succeeding generations, and are found in the site of the future ganglionic layer. The germinal cells in the middle of the convexity of the retinal cup cease to divide at an early stage of development, and become directly transformed into the rod and cone cells from which the rods and cones develop as processes; hence these structures appear first over the middle of the convexity of the retina, and gradually extend towards the margin of the retinal cup.

The molecular layers make their appearance as plexuses of myelospongium. The internal molecular layer is first developed at the centre of the retinal cup, and gradually extends towards the cup margin, and into it the processes from the nuclei on either side grow and ramify. The rod and cone fibres, and the outer processes of the internal nuclear layer, grow into and arborise within the external molecular layer.

The condensed mesoderm surrounding the optic cup becomes the sclera and chorioid. In the portion of the mesoderm which lies in front of the lens a cleft-like fissure appears, and divides it into a thick anterior and a thin posterior layer. The former becomes the substantia propria of the cornea; the latter, the stroma of the iris and anterior part of the vascular tunic of the lens. The fissure represents the future camera oculi anterior, and its lining cells form the endothelium of this chamber.

The **eyelids** arise as two integumentary folds above and below the cornea, each being covered on both its surfaces by the ectoderm. By the third month the folds meet and unite with each other at their edges, the eyelids being only permanently opened shortly before birth; in many animals they are not opened until after birth. The ectoderm forms the epithelium of the conjunctiva and the epithelium corneæ. It is also invaginated at the lid margins to form the hair follicles and the lining cells of the tarsal glands and glands of Moll, and, at the fornix conjunctivæ superior, to form the lining of the alveoli and ducts of the lacrimal gland.

The **naso-lacrimal duct**, **lacrimal sac**, and **ducts** represent the remains of the furrow between the maxillary and lateral nasal processes (p. 49). It is at first filled with a solid rod of cells, which becomes hollowed out to form the sac and ducts.

ORGANON AUDITUS.

The **ear** or **auditory organ** (Fig. 703) consists of three portions—external, middle, and internal—the last constituting its essential part, since the peripheral terminations of the acoustic nerve are distributed within it.

EXTERNAL EAR.

The **external ear**¹ includes—(a) the auricle, attached to and projecting from the side of the head; and (b) the external acoustic meatus leading inwards from the most depressed part of the auricle to the tympanic membrane.

AURICLE.

The **auricle** (O.T. **pinna**) (Fig. 704) presents two surfaces, lateral and medial, the latter forming an angle (cephalo-auricular angle) of about 30° with the side of the head. The lateral surface is irregularly concave, but presents several well-marked elevations and depressions. The deepest of the depressions is situated near its middle, and is named the **concha auriculæ**. It is divided by an almost transverse ridge, the **crus helicis**, into an upper, smaller, and a lower, larger portion: the former is termed the **cymba conchæ**; the latter, which leads into the meatus, the **cavum conchæ**. Anteriorly, the **crus helicis** is continuous with the margin of the auricle or **helix**, which is incurved in the greater part of its extent, and is directed at first upwards, and then backwards and downwards, to become gradually

¹ Although it is usual to speak of the external, middle, and internal ear, it would be more correct to use the terms external, middle, and internal *portions* of the ear.

lost in the upper part of the lobule. Near the point where the helix begins to descend a small tubercle, the *tuberculum auriculæ* (Darwini), is often seen.

FIG. 703.—DIAGRAMMATIC VIEW OF THE ORGAN OF HEARING.

notch, directed downwards and forwards between these two processes, is named the *incisura intertragica*. The tragus consists really of two tubercles, the upper of which constitutes the *tuberculum supratragicum* of His, and is separated from the helix by a groove, the *sulcus auris anterior*. The lobule is situated below the *incisura intertragica*, and is the most dependent part of the auricle.

The medial or cranial surface also is irregular, and presents elevations corresponding to the depressions on its lateral surface, *e.g.* *eminentia conchæ*, *eminentia triangularis*, etc.

The auricle is usually smaller and more finely modelled in the female than in the male, but presents great variations in size and shape in different individuals. In the newly born child its length is about one-third of that of the adult, while it increases slightly in length and breadth in old age.

The relation of the width to the height is termed the auricular index, and is expressed as follows:—

$$\frac{\text{width of auricula} \times 100}{\text{length of auricula}} = \text{Auricular index.}$$

This index is less in white than in dark races.

The *cephalo-auricular angle* may be practically absent, as in those cases where the skin of the head passes directly on to the lateral surface of the auricle, or it may be increased to nearly a right angle, so that the lateral surface of the auricle looks directly forwards. The *tuberculum auriculæ*, the significance of which was recognised by Darwin, is a somewhat triangular prominence which projects forwards in cases where the helix is well rolled over, but backwards and upwards when the incurving of the helix has been arrested. More frequently present in men than in women, it is of developmental interest since it has been shown to be well marked at the sixth month of foetal life, the entire auricle, at this stage, resembling in appearance that of the adult macaque monkey.

The *lobule* may be small and sessile or considerably elongated; it may adhere to the skin of the cheek (*i.e.* webbed), or may tend to bifurcate at its lower extremity.

FIG. 704.—VIEW OF LATERAL SURFACE OF LEFT AURICLE (half natural size).

Structure of the Auricula.—The greater part of the auricula consists of a lamella of yellow fibro-cartilage, the *cartilago auriculæ*; the cartilage is, however, absent from the lobule, which is composed of fat and connective tissue. When laid bare, the cartilage (Figs. 705, 706) presents, in an exaggerated condition, all the inequalities of the auricula, and is prolonged medially to form a considerable portion of the external acoustic meatus. The cartilage of the helix projects anteriorly as a conical eminence, the *spina helices*, and its inferior extremity extends downwards as a tail-like process, the *cauda helices*, which is separated from the lower part of the antitragus by the *fissura antitrago-helicina*. The cartilage of the auricula is continuous with that of the meatus by a narrow isthmus, the *isthmus cartilaginis auris*, measuring from 8 to 9 mm. in breadth. This isthmus corresponds laterally with the deepest part of the *incisura intertragica*, and medially it forms the outer boundary of a deep fissure, the *incisura terminalis auris*, which separates the cartilage of the meatus from that of the concha. The upper edge of the tragus fits into an angle below the crus helices. Two fissures, in addition to those already described, are usually present, one in the tragus and another immediately behind the spina helices.

FIG. 705.—LATERAL SURFACE OF CARTILAGE OF THE AURICULA (one-half natural size).

On the cranial surface of the cartilage (Fig. 706) the eminences produced by the concha and fossa triangularis are separated by a transverse furrow, the *sulcus antihelices transversus*, corresponding with the crus antihelices inferior; further, the eminentia conchæ is crossed horizontally by a groove, the *sulcus cruris helices*, and almost vertically by a slight ridge, the *ponticulus*: the latter indicates the attachment of the m. auricularis posterior.

FIG. 706.—MEDIAL SURFACE OF THE CARTILAGE OF THE AURICULA (one-half natural size).

Ligaments of the Auricula.—The cartilage of the auricle is attached to the temporal bone by two fibrous bands which form its extrinsic ligaments, viz.: an *anterior*, stretching from the zygomatic process to the spina helices and tragus; and a *posterior*, passing from the eminentia conchæ

and upper wall of the meatus to the mastoid process. Small ligamentous bands pass between individual parts of the auricle, and form what are termed its intrinsic ligaments.

Muscles of the Auricula (Figs. 705, 706).—The muscles of the auricle are divided into two groups, *extrinsic* and *intrinsic*. The extrinsic muscles pass to the auricula from the skull or the scalp, and are described in the section on Myology. The intrinsic muscles, on the other hand, are confined to the auricula and are six in number, four on its lateral and two on its cranial or medial surface.

(a) *On the lateral surface* (Fig. 705).—

1. **M. helix major** passes upwards from the spina helices along the ascending part of the helix. 2. **M. helix minor** covers the crus helices. 3. **M. tragus**, quadrangular in shape, consists of fibres running vertically over the greater part of the tragus. Some of its fibres are prolonged upwards to the spina helices and constitute the m. pyramidalis. 4. **M. antitragicus** covers the antitragus and runs obliquely upwards and backwards as far as the antihelix and cauda helices.

(b) *On the medial surface* (Fig. 706)—

1. **M. transversus auriculæ** consists of scattered fibres, which stretch from the eminentia conchæ to the convexity of the helix. 2. **M. obliquus auriculæ** (Tod) comprises a few fasciculi, which run obliquely or vertically across the furrow corresponding with the crus antihelicis inferior. A small muscle, the **m. stylo-auricularis**, sometimes extends from the root of the styloid process to the cartilage of the meatus.

Skin of the Auricula.—The skin covering the auricle is thin and smooth, and is prolonged, in the form of a tube, as a lining to the external acoustic meatus. On the lateral surface of the auricula, it adheres firmly to the subjacent perichondrium. Strong hairs are present on the tragus and antitragus, and also in the incisura intertragica, forming the **barbula hirci**, which guard the entrance to the concha; soft downy hairs are found over the greater part of the auricula and point towards the tuberculum auriculæ. Sebaceous glands, present on both surfaces of the auricle, are most numerous in the concha and fossa triangularis. Sudoriferous glands are found on the medial surface; few or none on the lateral surface.

Vessels of the Auricula.—The arteries of the auricle are derived—(a) from the superficial temporal, which sends two or three branches to the lateral surface; and (b) from the posterior auricular, which gives three or four branches to the medial surface. From the posterior auricular artery two sets of twigs are prolonged to the lateral surface, one turning round the free margin of the helix, and the other passing through small fissures in the cartilage. The veins from the lateral surface open into the superficial temporal vein; those from the medial surface chiefly join the posterior auricular vein, but some communicate with the mastoid emissary vein. The lymph vessels take three directions, viz.: (a) forwards to the parotid lymph glands, and especially to the anterior auricular gland in front of the tragus; (b) downwards to the lymph glands which accompany the external jugular vein, and to the lymph glands under the sternocleidomastoidens; and (c) backwards to the posterior auricular lymph glands.

Nerves of the Auricula.—The muscles of the auricle are supplied by the facial nerve. The skin receives its sensory nerves from—(a) the great auricular, which supplies nearly the whole of the medial surface, and sends filaments in company with the branches of the posterior auricular artery to the lateral surface; (b) the auriculo-temporal, which supplies the tragus and ascending part of the helix; (c) the lesser occipital, which sends a branch to the upper part of the medial surface.

MEATUS ACUSTICUS EXTERNUS.

The **external acoustic meatus** (Figs. 707, 708) is the passage leading from the concha to the membrana tympani. Its average length, measured from the bottom of the concha, is about 24 mm., but, if measured from the level of the tragus, about 35 mm. On account of the obliquity of the membrana tympani the anterior and inferior walls of the meatus are longer than the posterior and superior. The meatus consists of two parts, viz.: (a) an external portion, the **pars cartilaginea**, about 8 mm. in length; and (b) an internal portion, the **pars ossea**, about 16 mm. in length. The entire meatus forms a somewhat S-shaped bend (Fig. 708), and may be divided into three portions—external, intermediate, and internal; each is directed medialwards, but, in addition, the external part is inclined forwards and slightly upwards; the intermediate, backwards; and the internal, the longest, forwards and slightly downwards. On transverse section the canal is seen to be elliptical, its greatest diameter having an inclination downwards and backwards. Widest at its lateral extremity, it becomes somewhat narrower at the medial end of the pars cartilaginea; once more expanding in the lateral portion of the pars ossea, it is again constricted near the medial end of the latter, where its narrowest part, or **isthmus**, is found at a distance of about 19 mm. from the bottom of the concha. The medial extremity of the meatus is nearly circular and is closed by the membrana tympani.

Bezold gives the diameters of the meatus as follows:—

		Greatest.	Least.
At the commencement of the pars cartilaginea	. . .	9·08 mm.	6·54 mm.
At the end	" " "	7·79 mm.	5·99 mm.
At the commencement of the pars ossea	. . .	8·67 mm.	6·07 mm.
At the end	" " "	8·13 mm.	4·60 mm.

The lumen of the pars cartilaginea is influenced by the movements of the mandible, being increased when that bone is depressed. This can be easily verified by inserting a finger into the meatus, and then alternately opening and shutting the mouth.

The condyle of the mandible lies in front of the pars ossea, while between the condyle and the pars cartilaginea a portion of the parotid gland is sometimes present. Behind the pars ossea, and separated from it by a thin plate of bone, are the mastoid air-cells.

FIG. 707.—FRONTAL SECTION OF RIGHT EAR; ANTERIOR HALF OF SECTION, viewed from behind (natural size).

Structure of the Meatus.—The cartilage of the meatus, directly continuous with that of the auricula, is folded on itself to form a groove, opening upwards and backwards, the margins of which are connected by fibrous tissue. The medial end of the cartilaginous tube is firmly fixed to the lateral margin of the bony meatus, whilst its lateral extremity is continuous with the cartilage of the tragus (p. 829). Two fissures exist in the anterior portion of the pars cartilaginea, and are filled by fibrous tissue. In the lateral part of the meatus the cartilage forms about three-fourths of the circumference of the tube; but, near the medial end of the pars cartilaginea the cartilage forms merely a part of the anterior and lower boundaries of the canal.

FIG. 708.—HORIZONTAL SECTION THROUGH RIGHT EAR; UPPER HALF OF SECTION, seen from below (natural size).

The pars ossea of the meatus is described on p. 127; but it may be well to state here that in the new-born child it is represented only by an incomplete ring of bone, the **annulus tympanicus**, together with a small portion of the squama temporalis, which articulates with, and bridges over the interval between, the extremities of the ring superiorly. In the concavity of the annulus is a groove, the **sulcus tympanicus**, in which the circumference of the membrana tympani is fixed. On the medial surface of the anterior part of the annulus, a little below its free extremity, a groove, the **sulcus malleolaris**, is directed downwards and forwards. It transmits the anterior process and the anterior ligament of the malleus, the tympanic artery, and the chorda tympani nerve. It is limited above by a ridge, the **crista spinarum** (Henle), which ends in front and behind in a spinous process (**spina tympanica major and minor**). Below the sulcus malleolaris there is a second, less prominent ridge, the **crista tympanica** (Gruber), which subsequently unites with a process of the tegmen tympani, and so shuts off the **canalis musculotubarius** from the petrotympanic fissure. A **fibrous tympanic plate** (Symington) intervenes between the annulus tympanicus and the cartilage of the meatus, and into this plate the bony ring extends. The bony outgrowth does not, however, proceed uniformly from the whole of circumference of the annulus, but occurs most rapidly in its anterior and posterior parts. These outgrowths fuse about the end of the second

year of life, so as to surround a foramen (**foramen of Huschke**) in the floor of the meatus; this foramen is usually closed by the fifth year, but persists until adult life in some 19 per cent of skulls (Bürkner).

The lumen of the meatus in the new-born child is extremely small: its outer part is funnel-shaped; its inner a mere slit, bounded below by the fibrous tympanic plate and above by the obliquely placed *membrana tympani*.

The **skin** which envelops the auricula lines the entire meatus, and covers also the outer surface of the *membrana tympani*. It is thick in the *pars cartilaginea*, and contains fine hairs and sebaceous glands, the latter extending for some distance along the postero-superior wall of the *pars ossea*. The sudoriferous glands are enlarged and of a brownish colour; they constitute the *glandulæ ceruminosæ* and secrete the ear wax or cerumen.

Vascular and Nervous Supply of the Meatus.—The external acoustic meatus receives its blood-supply from the posterior auricular and superficial temporal arteries, and also from the deep auricular branch of the internal maxillary artery, the last distributing some minute twigs to the *membrana tympani*. The veins open into the external jugular and internal maxillary veins, and also into the pterygoid plexus, while the lymph vessels have a similar mode of termination to those of the auricle. Sensory nerves are supplied to the meatus by the auriculo-temporal branch of the trigeminal and by the auricular branch of the vagus.

CAVUM TYMPANI OR MIDDLE EAR.

The **tympanic cavity** is a small air chamber in the temporal bone, between the *membrana tympani* and the lateral wall of the internal ear or labyrinth (Figs. 707, 708). Lined with mucous membrane, it contains a chain of ossicles,—malleus, incus, and stapes,—which reaches from its lateral to its medial wall, and transmits the vibrations of the *membrana tympani* across the cavity to the internal ear. Attached to the ossicles are several ligaments and two small muscles.

The tympanic cavity consists of two portions: (1) The **tympanum proper**, or **atrium**, lying medial to the *membrana tympani*; and (2) the **recessus epitympanicus**, or **attic**, lying above the level of the membrane and containing the greater part of the incus and the upper half of the malleus. Including this recess, the vertical and antero-posterior diameters of the tympanic cavity each measure about 15 mm. The distance between its lateral and medial walls is about 6 mm. above and 4 mm. below, while at its central part, owing to the bulging of the two walls towards the cavity, it measures only from 1·5 to 2 mm.

The tympanic cavity is enclosed by six walls, tegmental, jugular, labyrinthic, mastoid, carotid, and membranous.

Paries Tegmentalis.—The tegmental wall or roof (Fig. 709) is formed by a thin plate of bone, the **tegmen tympani**, constituting a portion of the anterior surface of the petrous part of the temporal. It extends backwards so as to cover in the tympanic antrum, and forwards, to roof in the semicanal for the tensor tympani muscle. It separates the tympanic cavity and antrum from the cranial cavity, and may contain a few air-cells, whilst occasionally it is partly deficient. In the child its lateral edge corresponds with the petro-squamous suture, traces of which can generally be seen in the adult bone.

Paries Jugularis.—The jugular wall or floor is narrower than the tegmental wall, and consists of a thin plate of bone which separates the tympanic cavity from the fossa jugularis; anteriorly, it extends upwards and is continuous with the posterior wall of the carotid canal. The inner orifice of the foramen for the transmission of the tympanic nerve is seen near the junction of the jugular and labyrinthic walls.

Paries Labyrinthica.—The labyrinthic or medial wall of the tympanic cavity is formed by the lateral surface of the internal ear (Fig. 709). It presents—(1) a rounded eminence, the **promontory**, which is caused by the first coil of the cochlea, and is grooved for the tympanic plexus of nerves. (2) An oval or somewhat reniform opening, the **fenestra vestibuli**, which is situated above and behind the promontory, with its long axis directed antero-posteriorly. It measures 3 mm. in length and 1·5 mm. in width and, in the macerated bone, leads into the vestibule of the osseous labyrinth, but is closed in the recent state by the base or foot-plate

of the stapes, surrounded by its **ligamentum annulare**. (3) An elevation, the **prominentia canalis facialis**, which is situated above the fenestra vestibuli, in the recessus epitympanicus; this elevation indicates the position of the upper part of the **canalis facialis** (O.T. aqueduct of Fallopius), which contains the facial nerve, and

FIG. 709.—SECTION THROUGH LEFT TEMPORAL BONE, showing labyrinthine wall of tympanic cavity, etc.

is continued backwards and downwards behind the tympanic cavity, to end at the stylo-mastoid foramen. (4) The **septum canalis musculotubarii** (O.T. **processus cochleariformis**), which extends backwards, above the anterior end of the fenestra vestibuli, where it makes a sharp lateral curve, and forms a pulley over which the tendon of the tensor tympani muscle plays. (5) A funnel-shaped recess, situated behind and below the promontory, and almost hidden by its overhanging edge, leads to an irregularly oval opening, termed the **fenestra cochleæ**; in the macerated bone this fenestra communicates with the cochlea, but in the recent state is closed by the **membrana tympani secundaria**; this membrane is bent angularly along a line joining its antero-inferior two-thirds with the postero-superior third; and consists of three layers: (a)

lateral, continuous with the mucous lining of the tympanum, and containing a network of capillaries; (b) *intermediate*, or **membrana propria**, the fibres of which radiate chiefly towards the periphery of the membrane — some branched, dendritic fibres are also present; (c) *medial*, continuous with the epithelial lining of the labyrinth. (6) Be-

FIG. 710.—LEFT MEMBRANA TYMPANI AND RECESSUS EPITYMPANICUS, viewed from within. The head and neck of the malleus have been removed to show the pars flaccida and the malleolar plicæ. $\times 3$.

tween the fenestra vestibuli above and the fenestra cochleæ below is a small circular depression, the **sinus tympani**, which is perforated by one or two minute foramina for blood-vessels, and indicates the position of the ampullated end of the posterior semicircular canal.

Paries Mastoidea.—The mastoid or posterior wall presents, from above downwards: (1) a rounded or triangular opening, extending backwards from the recessus epitympanicus and leading into the **tympenic antrum** (Fig. 709); (2) a depression, the **fossa incudis**, situated in the postero-inferior part of the recessus epitympanicus (Fig. 710), for the reception of the end of the short crus of the incus; (3) a minute conical bony projection, the **eminentia pyramidalis** (Fig. 709), the summit of which is perforated by a round aperture for the passage of the tendon of the stapedius muscle. This aperture is continued downwards and backwards as a canal in front of the facial canal, and frequently opens, by a minute orifice, on the base of the skull in front of the stylo-mastoid foramen; it communicates with the facial canal by one or two small foramina, which transmit the vessels and nerve to the stapedius muscle; a minute spicule of bone often extends from the eminentia pyramidalis to the promontory on the labyrinthine wall of the tympanum; (4) a small aperture, the **apertura tympanica canaliculi chordæ** (Fig. 710), which is situated close to the posterior edge of the membrana tympani, nearly on a level with the upper end of the manubrium mallei; (5) a rounded eminence, the **prominentia styloidea**, is sometimes seen below the last, and is caused by the upward and forward prolongation of the styloid process.

Paries Carotica.—The carotid or anterior wall is narrowed in its transverse diameter by the approximation of the lateral and medial boundaries of the tympanic cavity, and in its vertical diameter by the descent of the roof and the ascent of the carotid canal. It presents (Fig. 709) two parallel semicanals, one above the other, separated by a thin lamella of bone, the **septum canalis musculotubarii** (O.T. **processus cochleariformis**). These run forwards on the lateral wall of the carotid canal and open in the angle between the squama and the petrous part of the temporal bone. The higher and smaller of the two is termed the **semicanalis m. tensoris tympani**, and lies immediately below the tegmen tympani. It has a diameter of about 2 mm., and extends on to the medial wall of the tympanic cavity above the anterior part of the fenestra vestibuli. The lower and larger semicanal gradually increases in size from before backwards, and is named the **semicanalis tubæ auditivæ**. It forms the bony part of the auditory tube and opens on the carotid wall of the tympanic cavity opposite the orifice leading into the tympanic antrum. Below the orifice of the auditory tube the anterior part of the tympanic cavity is separated from the ascending portion of the carotid canal by a thin plate of bone in which there are sometimes gaps or deficiencies. It is perforated by the carotico-tympanic canal, which transmits the carotico-tympanic nerve from the sympathetic plexus of the carotid artery to the tympanic plexus. The auditory tube is described on p. 837.

Paries Membranacea.—The membranous or lateral wall is formed almost entirely by the membrana tympani (Fig. 710), which closes the medial end of the external acoustic meatus, and is fixed throughout the greater part of its circumference in a groove, the **sulcus tympanicus**. The bony ring containing this sulcus is deficient superiorly, where it exhibits a distinct notch, the **notch of Rivinus**. On a level with the upper edge of the membrane, and in front of the ring of bone in which it is fixed, is the medial end of the **petrotympanic fissure**. This transmits the tympanic branch of the internal maxillary artery, and lodges the anterior process and anterior ligament of the malleus. Close to the medial end of the fissure is the **iter chordæ anterius** through which the chorda tympani nerve leaves the tympanic cavity.

Membrana Tympani.—The tympanic membrane is an elliptical disc, its greatest diameter, 9 to 10 mm., being directed from above, downwards and forwards, whilst its least diameter is from 8 to 9 mm. It is placed very obliquely, forming an angle of about 55° with the lower and anterior walls of the external acoustic meatus; it is said to be more oblique in cretins and deaf mutes, and more perpendicular in musicians.

The circumference of that portion of the membrane which is fixed in the sulcus tympanicus is considerably thickened, and is named the **annulus fibrocartilagineus**. It is prolonged from the anterior and posterior extremities of the notch of Rivinus to the processus lateralis of the malleus, in the form of two ligamentous bands, the

anterior and posterior malleolar plicæ. The small triangular portion of the membrane (Fig. 710) situated above these folds is thin and lax, and constitutes the **pars flaccida** (O.T. membrane of Shrapnell); the main portion of the membrane is, on the other hand, tightly stretched and termed the **pars tensa**. A small orifice, sometimes seen in the pars flaccida, is probably either a pathological condition or has been produced artificially during manipulation. The manubrium mallei is firmly fixed to the medial surface of the membrana tympani, the central portion of which is drawn towards the tympanic cavity so that its lateral surface is concave. The deepest part of this concavity corresponds with the lower end of the manubrium of the malleus, and is named the **umbo membranæ tympani**.

The membrana tympani consists of three layers: (1) a lateral, the stratum cutaneum; (2) an intermediate, the membrana propria; (3) a medial, the stratum mucosum.

The **stratum cutaneum** is continuous with the skin of the meatus, and consists of a thin layer of cutis covered with epidermis. The cutis is thickest near the circumference; the epidermis, on the other hand, is thickest near the centre of the membrane.

The **membrana propria** consists of two sets of fibres: (a) a *lateral*, the stratum radiatum, situated immediately under the stratum cutaneum, and radiating from the manubrium of the malleus to the annulus fibrocartilagineus; (b) a *medial*, the stratum circulare, the fibres of which are numerous near the circumference, but scattered and few in number near the centre of the membrane (Fig. 710). Both radial and circular fibres are absent from the pars flaccida, which consists only of the cutaneous and mucous strata. Gruber pointed out that, in addition to the radial and circular fibres, there exists, next the stratum mucosum, a series of *dendritic* or *branched fibres*, which are best developed in the posterior part of the membrane.

The **stratum mucosum** is continuous with the mucous lining of the tympanic cavity. It is thicker over the upper part of the membrane than near its centre, and is covered with pavement epithelium.

Otoscopic Examination of the Membrana Tympani (Fig. 711).—The membrana tympani, in the living, is of a “pearl-gray” colour, but may present a reddish or yellowish tinge, depending upon the condition of its mucous lining and on the condition of the cutaneous lining of the meatus; the posterior segment is usually clearer than the anterior.

At the antero-superior part, close to its periphery, a whitish point appears as if projecting towards the meatus; this is the processus lateralis of the malleus. Passing downwards and backwards from this point to the umbo is a ridge caused by the manubrium mallei, the lower extremity of which appears rounded. Two ridges, corresponding with the malleolar plicæ, extend from the processus lateralis of the malleus, one forwards and upwards, the other backwards and upwards. Behind, and near the lower extremity of the manubrium mallei, is a reddish or yellowish spot, due to the promontory of the medial wall of the tympanic cavity shining through. If the membrane is very transparent, the long crus of the incus may be visible behind the upper part of the manubrium mallei, and reaching downwards as far as its middle. From the lower end of the manubrium mallei, the “cone of light” or “luminous triangle” extends downwards and forwards, its apex being directed towards the handle; this triangle varies in size in different people. A line prolonging the manubrium downwards divides the membrane into two parts, while another, drawn at right angles to this through the umbo, will subdivide it into quadrants, viz., postero-superior, postero-inferior, antero-superior, and antero-inferior; this subdivision is useful in enabling the otologist to localise and describe accurately the seat of lesions in the membrane.

Vascular and Nervous Supply of the Membrana Tympani.—The arteries are arranged in two sets, one on the cutaneous and another on the mucous surface; they anastomose by means of small branches which pierce the membrane, especially near its periphery. The first set is derived chiefly from the deep auricular branch of the internal maxillary, whilst those on the

FIG. 711.—LEFT TYMPANIC MEMBRANE (as viewed from the external acoustic meatus). $\times 3$.

mucous surface are small and proceed from the anterior tympanic branch of the internal maxillary, and from the stylo-mastoid branch of the posterior auricular. The **veins** from the cutaneous surface open into the external jugular; those from the mucous surface partly into the venous plexus on the auditory tube, and partly into the transverse sinus and veins of the dura mater. The **lymph vessels**, like the blood-vessels, are arranged in two sets, cutaneous and mucous, which, however, communicate freely with each other. Kessel has described as lymphatics the spaces between the branches of Gruber's dendritic fibres. The lateral surface of the membrane receives its **nerves** from the auriculo-temporal branch of the trigeminal and from the auricular branch of the vagus; the medial surface, from the tympanic branch of the glossopharyngeal.

ANTRUM TYMPANICUM ET CELLULÆ MASTOIDEÆ.

Antrum Tympanicum.—The tympanic antrum (O.T. mastoid antrum) is an air-space situated above and behind the tympanic cavity. It is nearly as large in the new-born child as in the adult. In the adult its measurements are—length from

FIG. 712.

Preparation to display the position and relations of the tympanic antrum. The greater part of the posterior wall of the external acoustic meatus has been removed, leaving only a bridge of bone at its inner extremity; under this a bristle is displayed, passing from the tympanic antrum through the iter to the cavity of the tympanum.

12 to 15 mm., height from 8 to 10 mm., and width from 6 to 8 mm. It is roofed in by the tegmen tympani, and its floor and medial wall are formed by the pars petrosa and pars mastoidea of the temporal bone, while laterally it is closed by the junction of the thin outer part of the squama with the pars mastoidea. It communicates with the epitympanic recess by a triangular or rounded opening, on the medial wall of which, immediately above and behind the canalis facialis, is a smooth, convex area of bone indicating the position of the ampullated extremities of the superior and lateral semicircular canals. At birth the lateral wall of the antrum has a thickness of only 1-2 mm., but by the ninth year this has increased to about 10 mm. Coincident with the growth of the mastoid process the mastoid air-cells are developed downwards and backwards as diverticula from the antrum, and present the greatest possible variation in different skulls.

Cellulæ Mastoideæ.—The mastoid air-cells may be large, comparatively few in number, and involve the whole mastoid process, in which case the compact bone surrounding them is extremely thin, and the innermost cells are separated

from the transverse sinus by a transparent lamella which, in some instances, is partly deficient. In other cases the cells may be small and numerous, invading only a portion of the process, the remainder consisting of diploëtic tissue; occasionally a solid mastoid is met with. No definite conclusion can be formed as to their condition by external percussion or examination. The air-cells are not limited to the mastoid process, but extend forwards over the roof of the meatus, upwards towards the squama temporalis, and medially towards the temporo-occipital suture; occasionally they invade the pars jugularis of the occipital bone. The tympanic antrum and the mastoid air-cells are lined with thin mucous membrane, continuous with that of the tympanic cavity; the deep surface of the mucous membrane is fixed to the periosteum; its free surface is covered with a layer of flattened, non-ciliated epithelium.

TUBA AUDITIVA.

The **auditory tube** (O.T. **Eustachian tube**) leads from the tympanic cavity to the nasal part of the pharynx, and transmits air to the former, in order that the pressures on the medial and lateral surfaces of the membrana tympani may be equalised; it may also serve to convey mucous secretion from the tympanic cavity. Its **tympanic orifice** (Fig. 709) opens into the anterior part of the tympanic cavity below the semicanal for the tensor tympani muscle. Directed downwards and medially, the tube ends on the upper part of the nasal part of the pharynx by a wide **pharyngeal orifice** (Fig. 674, p. 803). It measures about 35 mm. in length, and forms with the horizontal plane an angle of 30° to 40° , with the sagittal plane an angle of about 45° , and with the bony part of the external acoustic meatus an angle of 135° to 140° . It consists of two portions: (*a*) an antero-medial, the **pars cartilaginea tubæ auditivæ**, having a length of about 25 mm.; and (*b*) a postero-lateral, the **pars ossea tubæ auditivæ**, measuring about 10 mm. in length. The two portions are not in the same plane, the cartilaginous part inclining downwards a little more than the osseous portion, and forming with it a wide angle. The lumen of the tube is widest at the pharyngeal orifice, narrowest at the junction of the bony and cartilaginous portions, forming here the **isthmus**, and again expanding towards the tympanic cavity; hence it presents, on longitudinal section, somewhat the appearance of an hour-glass. The pars ossea occupies the angle between the tympanic part and the petrous part of the temporal bone, and is separated by the septum canalis musculotubarii from the semicanal containing the tensor tympani muscle; medial to it is the carotid canal. The pars cartilaginea consists partly of cartilage and partly of fibrous membrane. The cartilage of the auditory tube is an elongated triangular plate, of which the apex is firmly attached to the medial end of the pars ossea, while the base is free, and forms a projection on the upper and posterior aspects of the pharyngeal orifice. The upper edge of this cartilaginous plate is bent laterally in the form of a hook, and so produces a furrow open below, the furrow being converted into a complete canal by the membranous lamina of the tube. On transverse section (Fig. 713) the cartilage presents two laminae continuous with each other superiorly: (*a*) *lamina medialis*, broad and thick; and (*b*) *lamina lateralis*, thin and hook-shaped. At the pharyngeal orifice the lamina medialis forms the entire medial wall of the tube, but it gradually diminishes in breadth on approaching the isthmus tubæ. Fissures are often seen

FIG. 713.—TRANSVERSE SECTION OF THE CARTILAGINOUS PART OF THE AUDITORY TUBE.

in the cartilage; sometimes it is completely separated into several pieces, or accessory islands may be observed in the roof, floor, or membranous lamina.

The upper and medial surfaces of the medial lamina are firmly fixed to the base of the skull, where it lies in a groove, the *sulcus tubæ auditivæ*, between the great wing of the sphenoid and the petrous part of the temporal. Extending forwards on to the root of the pterygoid process this sulcus ends at a projection, the *processus tubarius*, on the medial pterygoid lamina. The tensor veli palatini muscle lies on the lateral side of the tube and receives some fibres of origin from its lamina lateralis; these fibres constitute the *dilatator tubæ muscle* (Rüdinger). On the medial side of the cartilage are the levator veli palatini and the mucous membrane of the pharynx. The *membranous lamina* consists of a strong fibrous membrane, stretching between the two edges of the cartilage, and so completing the lower and lateral walls of the tube. Thin above, it becomes thickened below and forms the *fascia salpingopharyngea* of Tröltsch, which gives origin to some of the fibres of the tensor veli palatini muscle. Between this fascia and the mucous lining of the tube is a layer of adipose tissue.

The *pharyngeal orifice* of the auditory tube, triangular or oval in shape, is situated on the lateral wall of the nasal part of the pharynx, the centre of the opening being on a level with the posterior end of the inferior nasal concha. It is bounded above and behind by a pad, the *torus tubarius*, produced by the base of the cartilage, which here abuts against the mucous membrane; the posterior part of the torus is very prominent and forms the anterior boundary of the *pharyngeal recess*. Prolonged downwards from it is an elevation of the mucous membrane, termed the *plica salpingopharyngea*, which covers the small salpingopharyngeus muscle. From the upper part of the torus an indistinct fold, the *plica salpingopalatina*, extends to the palate.

The mucous lining of the tube is continuous behind with that of the tympanic cavity, and in front with that of the nasal part of the pharynx. It is thin in the pars ossea, contains few, if any, mucous glands, and is firmly fixed to the bony wall; in the pars cartilaginea it is loose and thrown into longitudinal folds. Numerous mucous glands open into the tube near its pharyngeal orifice, and here also exists a considerable amount of adenoid tissue, which constitutes the "tube-tonsil" of Gerlach. This adenoid tissue is continuous with that of the nasal part of the pharynx, and, like it, is especially well developed in children. The lumen of the tube is lined with ciliated columnar epithelium.

The tube is opened, during deglutition, by the dilatator tubæ and salpingopharyngeus muscles. The former springs superiorly from the cartilaginous hook of the tube, and blends inferiorly with the tensor veli palatini. When the dilatator tubæ contracts, the cartilaginous hook and the membranous lamina of the tube are drawn lateralwards and forwards. Some anatomists believe that the entire tensor veli palatini acts chiefly as a dilator of the tube, and Rüdinger named it the abductor tubæ. The salpingopharyngeus muscle draws downwards and backwards the medial lamina, increasing the angle between it and the lateral lamina. Some difference of opinion exists as to the precise action of the levator veli palatini; probably it assists in opening the tube.

The auditory tube receives its blood-supply from the ascending pharyngeal artery, and from the middle meningeal artery and the artery of the pterygoid canal, both of which are branches of the internal maxillary artery. Its veins form a network which drains into the pterygoid venous plexus. The sensory nerves of the tube are derived from the tympanic plexus and from the pharyngeal branch of the sphenopalatine ganglion.

The auditory tube of the child differs considerably from that of the adult; its lumen is relatively wider, its direction more horizontal, and its pars ossea relatively shorter. Kunkel states that its pharyngeal orifice is below the level of the hard palate in the fœtus; at birth it is on the same level as the palate, whilst at the fourth year it is 3 to 4 mm., and in the adult 10 mm., above it. In the child the pharyngeal orifice forms a narrow fissure, and its cartilage projects less towards the middle line.

OSSICULA AUDITUS.

The *auditory ossicles* form an articulated column connecting the lateral with the medial wall of the tympanic cavity; they are named, from without

inwards, the malleus, incus, and stapes. The first is attached to the medial surface of the membrana tympani; the last is fixed within the circumference of the fenestra vestibuli.

The **malleus** (Fig. 714, B, D), the largest of the three ossicles, has a length of 8 to 9 mm., and consists of a head, a neck, a manubrium, and two processes, viz. :

FIG. 714.—AUDITORY OSSICLES OF LEFT EAR (enlarged about three times).

A, Incus, seen from the front; B, Malleus, viewed from behind; C, Incus, and D, Malleus, seen from medial aspect; E, Stapes.

1. Body of incus, with articular surface for head of malleus.	7. Processus lateralis.	14. Facet for incus.
2. Crus longum.	8. Manubrium.	15. Manubrium.
3. Processus lenticularis.	9. Body of incus.	16. Head of stapes.
4. Articular surface for incus.	10. Crus breve.	17. Neck.
5. Head of Malleus.	11. Crus longum.	18. Crus anterior.
6. Neck of Malleus.	12. Processus anterior.	19. Crus posterior.
	13. Head of malleus.	20. Base.

(a) processus anterior, (b) processus lateralis. The head and neck are situated in the epitympanic recess; the processus lateralis and manubrium are fixed to the medial surface of the membrana tympani; while the processus anterior is directed forwards towards the petro-tympanic fissure, to which, in the adult, it is connected by ligamentous fibres. The head, somewhat rounded, is smooth and convex above and in front, and presents, on its posterior surface, a facet for articulation with the body

FIG. 715.—LEFT MEMBRANA TYMPANI AND CHAIN OF AUDITORY OSSICLES (seen from the medial aspect). $\times 3$.

of the incus. This facet is directed obliquely downwards and medialwards, and is more or less elliptical in form. It is constricted near the middle so as to resemble, somewhat, the figure 8; an oblique ridge, corresponding with the constriction, divides the facet into two parts—an upper and larger, directed backwards, and a lower and lesser, directed medialwards. Opposite the lower part of the constriction the inferior edge of the facet is very prominent, and is continued upwards into the oblique ridge just referred to; it forms a tooth-like process, the **spur** or **cog-tooth** of

the malleus. On the back of the head, below this spur, is an oblique crest, the **crista mallei**, to which is attached the lateral ligament of the malleus. The **neck** is the slightly constricted portion immediately below the head. Flattened from before backwards, its lateral surface is directed towards the *membrana flaccida*, whilst its medial surface is crossed by the *chorda tympani* nerve. The **manubrium** or **handle** is directed downwards, backwards, and medialwards from the neck, forming with the long axis of the head an angle of 126° to 150° . Its upper part is flattened from before backwards, but towards the lower end it is twisted on itself, so that its surfaces look laterally and medially; moreover, the lower end is slightly curved, the concavity being directed forwards and laterally. It is fixed, along its entire length, to the *membrana propria* of the tympanic membrane by its periosteum and by a layer of cartilage (Gruber). The cartilage intervenes between the manubrium and the membrane, and must be regarded as a residue of that stage of development when the entire malleus was cartilaginous. On the medial surface of the manubrium, near its upper extremity, is a slight projection for the attachment of the tendon of the *tensor tympani* muscle. The **processus anterior**, a slender spicule, springs from the front of the neck and is directed forwards towards the petro-tympanic fissure. In the foetus it is the longest process of the malleus, but in the adult it usually assumes the form of a small projection, since its anterior part is replaced by ligamentous tissue. The **processus lateralis** may be looked upon as the upper extremity of the manubrium projected laterally; it is fixed to the upper part of the *membrana tympani* by the cartilaginous layer already referred to, and to the extremities of the notch of Rivinus by the anterior and posterior malleolar plicæ.

The **incus** (Fig. 714, A, C) may be likened to a præmolar tooth with widely divergent roots. It consists of a body, a *crus longum*, and a *crus breve*; the crura form with each other an angle of 90° to 100° . The body and *crus breve* are situated in the *recessus epitympanicus*. The **body** presents a more or less saddle-shaped surface for articulation with the head of the malleus. This surface is directed forwards, and its lower part is hollowed out for the accommodation of the cog-tooth of the malleus; in front of this hollow it is prominent and spur-like. The **crus breve** is thick, triangular in shape, and projects horizontally backwards; its conical extremity, covered with cartilage, is received into the *fossa incudis* in the postero-inferior part of the epitympanic recess. The **crus longum** projects, almost perpendicularly, downwards from the body into the tympanic cavity, where it lies parallel with, but 1.25 mm. behind and medial to, the manubrium mallei. Its lower end is bent medialwards and narrowed to form a short neck, on the end of which is a small knob of bone, the **processus lenticularis**, for articulation with the head of the stapes. Until the sixth month of foetal life this process exists as a separate ossicle, termed the **os orbiculare**.

The **stapes** (Fig. 714, E) consists of a head, a neck, two crura, and a base. The **head**, directed lateralwards, is concave for articulation with the **processus lenticularis** of the incus. The **neck** is slightly constricted, and from it the two crura spring; the tendon of the stapedius is inserted into the posterior aspect of the neck. The **crus anterior** is shorter and less curved than the **crus posterior**. Diverging from each other, the crura are directed medialwards and are attached—one near the anterior, the other near the posterior end of the base. The **base** almost completely fills the *fenestra vestibule*, and, like it, is somewhat oval or reniform, its anterior end being the more pointed. In the recent condition a membrane fills the arch formed by the crura and the base, the crura being grooved for its reception. In the child the crura of the stapes are less curved than in the adult, and the opening bounded by them and the base is nearly triangular.

Articulations of the Auditory Ossicles.—The incudo-malleolar joint between the head of the malleus and the body of the incus is diarthrodial, and may be described as one of reciprocal reception. It is surrounded by an articular capsule, and from the inner surface of the fibrous stratum a wedge-shaped meniscus projects into the joint cavity and incompletely divides it. The incudo-stapedial articulation between the **processus lenticularis** and the head of the stapes is of the nature of an enarthrosis and is surrounded by an articular capsule. An interarticular cartilage has been described as occurring in this joint, while some observers deny

the presence of a synovial cavity and regard the articulation as a syndesmosis, the articular surfaces being held together by fibrous tissue.

Ligamenta Ossiculorum Auditus.—The malleus is attached to the walls of the tympanic cavity by three ligaments (Fig. 715), viz.: anterior, superior, and lateral. The **anterior ligament** consists of two portions: (*a*) the *band of Meckel*, which is attached to the base of the processus anterior, and passes forwards through the petro-tympanic fissure to reach the spine of the sphenoid; it represents the remnant of a portion of Meckel's cartilage, and was formerly described as the *laxator tympani* muscle; (*b*) a firm bundle of fibres, the *anterior ligament of Helmholtz*, which extends from the spina tympanica posterior at the anterior boundary of the notch of Rivinus to the anterior surface of the malleus, above the base of the processus anterior. The **superior ligament** stretches, almost vertically, from the head of the malleus to the roof of the epitympanic recess. The **lateral ligament** is short and fan-shaped; its fibres converge from the posterior half of the notch of Rivinus to the crista mallei. The posterior part of this ligament is strong and constitutes the *posterior ligament of Helmholtz*; it forms, together with the anterior ligament of the malleus, the axis around which the malleus rotates, and the two constitute what Helmholtz termed the "**axis-ligament**" of the malleus.

The posterior extremity of the crus breve of the incus is tipped with cartilage and fixed by means of a ligament to the fossa incudis (Fig. 715). Some observers describe this as a diarthrodial joint. The vestibular surface and the circumference of the base of the stapes are covered with hyaline cartilage, and a similar layer lines the opening of the fenestra vestibuli; that encircling the base of the stapes is joined to that lining the fenestra by a dense ring of elastic fibres, named the *ligamentum annulare baseos stapedis*. The posterior fibres of this ligament are thicker and shorter than the anterior, and thus during the movements of the stapes, the anterior end of its base is free to make greater excursions than the posterior.

Development of the Auditory Ossicles.—It is generally maintained that the malleus and incus are developed from the upper end of Meckel's cartilage, and that the stapes arises from the mesoderm in the region of the fenestra vestibuli, where it is developed around a small artery, the stapedia artery, which atrophies in man, but persists in many mammals. On the other hand, Gadow (*Phil. Trans.*, London, vol. clxxix.) says "the whole system of the one to four elements of the middle ear, which have all the same function, is to be looked upon as *one* organ, of *one* common origin, viz., a modification of the hyomandibular, the proximal paramere of the second visceral arch." Ossification commences in all three bones about the third month of fetal life. The malleus is ossified from two centres, one for the head and manubrium, and one for the processus anterior; the incus from two centres, one for the body including the crura, and a second for the processus lenticularis; the stapes from one centre which appears in the base.

Muscles of the Tympanic Cavity.—These are two in number, viz., *m. tensor tympani* and *m. stapedius*.

The *m. tensor tympani* is the larger, and takes origin from the roof of the cartilaginous part of the auditory tube, from the adjacent part of the great wing of the sphenoid, and from the bony canal in which the muscle lies. The muscle ends in a tendon which bends laterally, nearly at a right angle to the belly of the muscle, round the pulley-like posterior extremity of the septum canalis musculotubarii. Passing across the tympanic cavity this tendon is inserted into the medial edge and anterior surface of the manubrium mallei, near its upper end. When the muscle contracts it draws the manubrium of the malleus towards the tympanic cavity, and so renders tense the membrana tympani; it probably also slightly rotates the malleus around its long axis. It receives its nerve from the motor division of the trigeminal nerve, through the otic ganglion.

The *m. stapedius* arises within the eminentia pyramidalis, and from the canal which prolongs the hollow of the pyramidal eminence downwards. Its tendon emerges from the apex of the eminence and is inserted into the posterior surface of the neck of the stapes. On contraction it draws back the head of the stapes, and so tilts the anterior end of the base towards the tympanic cavity and the

posterior end towards the labyrinth, thus rendering tense the ligamentum annulare—the lateral movement of the anterior end of the base being greater than the medial movement of its posterior end. The muscle is supplied by the facial nerve.

Movements of the Auditory Ossicles.—The manubrium mallei follows all the movements of the membrana tympani, while the malleus and incus move together around an axis extending forwards through the crus breve of the incus and the anterior ligament of the malleus. When the membrana tympani moves medialwards it carries with it the manubrium mallei, while the incus, moving medialwards at the same time, forces the base of the stapes towards the labyrinth. This movement is communicated to the fluid (perilymph) in the labyrinth, and causes a lateral bulging of the secondary tympanic membrane, which closes the fenestra cochleæ. These movements are reversed when the membrana tympani is relaxed, unless the lateral movement of the membrane is excessive. In such a condition the incus does not follow the full movement of the malleus, but merely glides on this bone at the incudo-malleolar joint, and thus the forcible dragging of the base of the stapes out of the fenestra vestibuli is prevented. The cog-tooth arrangement, already described, on the head of the malleus and body of the incus, causes the incudo-malleolar joint to become locked during the medial movement of manubrium mallei, the joint becoming unlocked during its lateral movement.

Tunica Mucosa Tympanica.—The mucous lining of the tympanic cavity is continuous, through the auditory tube, with that of the nasal part of the pharynx; it extends backwards also and lines the tympanic antrum and the mastoid air-cells. Thin, transparent, and closely united with the subjacent periosteum, it covers the medial surface of the membrana tympani and is reflected over the auditory ossicles and their ligaments. It also supplies sheaths for the tendons of the tensor tympani and stapedius muscles, and forms the following folds, viz.: (a) one from the roof of the recessus epitympanicus to the head of the malleus and body of the incus; (b) one enveloping the chorda tympani nerve and crus longum of the incus; (c) two extending from the processus lateralis mallei—one to the anterior, the other to the posterior margin of the notch of Rivinus. A recess, the **pouch of Prussak**, is situated between the membrana flaccida and the neck of the malleus. Communicating behind with the tympanic cavity, this pouch may serve as a reservoir to confine pus or other fluid, since its opening into the tympanic cavity is above the level of its floor, a condition analogous to the opening from the maxillary sinus into the nasal cavity. The fold of mucous membrane which extends downwards to envelop the chorda tympani nerve gives rise to two pouches, one in front of, and the other behind, the manubrium mallei; these are named the **anterior** and **posterior recesses of Tröltsch**. The epithelium which lines the mucous membrane is flattened over the membrana tympani, promontory, and auditory ossicles, but ciliated and columnar over the greater portion of the rest of the cavity.

Vessels and Nerves of the Tympanic Cavity.—The arteries supplying the tympanic cavity are: (1) The anterior tympanic artery, a branch of internal maxillary, which reaches the cavity by way of the petro-tympanic fissure. (2) The stylo-mastoid branch of posterior auricular, which passes through the stylo-mastoid foramen and the facial canal; it supplies branches to the tympanic antrum and mastoid air-cells, to the stapedius muscle, to the floor and medial wall of the tympanic cavity, and forms an anastomotic circle, around the membrana tympani, with the anterior tympanic artery. (3) The middle meningeal artery sends a branch to the tensor tympani muscle, and, after entering the skull, gives off its petrosal artery, which is conducted to the tympanic cavity along the hiatus canalis facialis; some twigs from the posterior division of the middle meningeal reach the tympanic antrum and epitympanic recess through the petro-squamous fissure. (4) The internal carotid artery, in its passage through the canal in the temporal bone, gives off one or two tympanic twigs, while (5) a branch from the ascending pharyngeal accompanies the tympanic nerve. The **veins** drain into the pterygoid plexus, and the superior petrosal sinus. The **lymph vessels** form a network in the mucous membrane and end mainly in the retro-pharyngeal and parotid lymph glands. The **nerves** supplying the muscles of the tympanic cavity have already been referred to (pp. 832, 834). The mucous membrane receives its nerves from the tympanic plexus, which is described on p. 786. The chorda tympani branch of the facial nerve passes from behind, upwards, and forwards through the tympanic cavity. Its course is described on p. 782.

Early Condition of Tympanic Cavity.—During the greater part of intra-uterine existence the tympanic cavity is almost completely filled by a soft, reddish, jelly-like embryonic tissue in which there is a slit-like space lined with epithelium. Towards the end of foetal life this tissue disappears and at birth the cavity is filled with fluid which becomes absorbed, after the entrance of air from the nasal part of the pharynx through the auditory tube.

AURIS INTERNA.

The **internal ear** or essential part of the organ of hearing is situated in the substance of the petrous part of the temporal bone, and consists of two sets of structures, viz.: (1) a series of passages hollowed out of the bone and constituting the **osseous labyrinth**; these are continuous with each other, and are named

FIG. 716.—LEFT BONY LABYRINTH (viewed from the lateral aspect).

FIG. 717.—INTERIOR OF LEFT BONY LABYRINTH (viewed from lateral aspect).

from before backwards the **cochlea**, **vestibule**, and **semicircular canals** (Figs. 716, 717); (2) a complex arrangement of membranous channels (Fig. 720), situated within, but not nearly filling, the bony labyrinth and forming the **membranous labyrinth**. These channels are named the **ductus cochlearis**, the **utricle**, the **saccul**, and the **semicircular ducts**; the utricle and saccul are lodged within the vestibule.

LABYRINTHUS OSSEUS.

Vestibulum.—The **vestibule** is the central portion of the osseous labyrinth, and communicates behind with the semicircular canals and in front with the cochlea. It is somewhat ovoid in shape, its long axis being directed forwards and lateralwards; it measures about 6 mm. antero-posteriorly, 4.5 mm. vertically, and about 3 mm. transversely. Its lateral wall is directed towards the tympanic cavity, and in it is the **fenestra vestibuli**, which is closed by the base of the stapes. Its medial wall corresponds with the bottom of the internal acoustic meatus, and presents, at its antero-inferior part, a rounded depression, the **recessus sphaericus**, which lodges the saccul. This recess is perforated by twelve or fifteen small foramina (**macula cribrosa media**), which transmit the filaments of the acoustic nerve to the saccul. The recessus sphaericus is limited above and behind by an oblique ridge, the **crista vestibuli**, the anterior extremity of which is triangular in shape and named the **pyramis vestibuli**. Posteriorly this crista divides into two limbs, between which is a small depression, the **recessus cochlearis**, perforated by about eight small foramina, which give passage to the nervous filaments supplying the vestibular end of the ductus cochlearis. Above and behind the crista vestibuli, in the roof and medial wall of the vestibule, is an oval depression, the **recessus ellipticus**, which lodges the utricle. The pyramis vestibuli and adjacent part of the recessus ellipticus are perforated by twenty-five or thirty small apertures (**macula cribrosa superior**). The foramina in the pyramis vestibuli transmit the nerves to the utricle; those in the recessus ellipticus, the nerves to the ampullae of the superior and lateral semicircular ducts. Behind and below the recessus ellipticus is a furrow, gradually deepening to form a canal, the **aqueductus vestibuli**, which passes backwards through the petrous part of the temporal bone, and opens, as a slit-like fissure, about midway between the internal acoustic meatus and the groove for the transverse sinus. This aqueduct measures 8-10 mm. in length, and gives passage to the

ductus endolymphaticus and a small vein. The posterior part of the vestibule receives the five rounded apertures of the semicircular canals; its anterior part leads, by an elliptical opening, into the scala vestibuli of the cochlea. This opening is bounded inferiorly by a thin osseous plate, the *lamina spiralis ossea*, which springs from the floor of the vestibule immediately lateral to the recessus sphaericus, and forms, in the cochlea, the bony part of the septum between the scala tympani below and the scala vestibuli above. From the anterior part of the floor of the vestibule a narrow cleft, the *fissura vestibuli*, extends forwards into the bony canal of the cochlea. It is bounded internally by the lamina spiralis ossea, and externally by a second, smaller lamina, the *lamina spiralis secundaria*, which projects from the outer wall of the cochlea. These two lamina are continuous with each other round the posterior extremity of the fissura vestibuli.

Canales Semicirculares Ossei.—The osseous semicircular canals (Figs. 716, 717), three in number, are situated above and behind the vestibule. They are distinguished from each other by their position, and are named superior, posterior, and lateral. They open into the vestibule by five apertures, since the medial end of the superior and the upper end of the posterior join to form a common canal or *crus commune*. Differing slightly in length, each forms about two-thirds of a circle, one extremity of which is dilated and termed the osseous ampulla. They are somewhat compressed from side to side, and their diameter is from 1 to 1.5 mm., whilst that of the ampullæ is about 2 mm.

The **superior semicircular canal**, 15 to 20 mm. in length, is vertical and placed transversely to the long axis of the petrous part of the temporal bone. Its convexity is directed upwards, and its position is indicated on the anterior surface of the petrous part of the temporal bone by the arcuate eminence. Its ampulla is anterior and lateral, and opens into the vestibule immediately above that of the lateral canal. Its opposite extremity joins the non-ampullated end of the posterior canal to form the *crus commune*, which is about 4 mm. in length, and opens into the upper and medial part of the vestibule. The **posterior semicircular canal** is the longest and measures from 18 to 22 mm. Its ampulla is placed inferiorly, and opens into the lower and back part of the vestibule, where may be seen about six or eight small apertures (*macula cribrosa inferior*), for the transmission of the nerves to this ampulla. Its upper extremity ends in the *crus commune*. The **lateral canal** is the shortest; it measures from 12 to 15 mm., and arches nearly horizontally. Of its two extremities the lateral is ampullated, and opens into the vestibule immediately above the fenestra vestibuli and in close relationship to the ampullary end of the superior canal.

Crum Brown (*Journ. Anat. and Physiol.*, London, vol. viii.) pointed out that the lateral canal of one ear is very nearly in the same plane as that of the other; while the superior canal of one ear is nearly parallel to the posterior canal of the other.

Cochlea.¹—When freed from its surroundings the cochlea assumes the form of a short cone (Fig. 720); the central part of its base corresponds with the bottom of the internal acoustic meatus, whilst its apex or *cupula* is directed forwards and laterally, and comes into close relation with the semicanal for the tensor tympani muscle. It measures about 9 mm. across the base and about 5 mm. from base to apex, and consists of a spirally arranged tube, which forms from $2\frac{1}{2}$ to $2\frac{3}{4}$ coils around a central pillar, termed the *modiolus*. The length of the tube is from 28 to 30 mm., and its diameter, near the base of the cochlea, 2 mm. Its coils are distinguished by the terms basal, central, and apical; the first, or basal coil, gives rise to the promontory on the labyrinthine wall of the tympanic cavity.

The *modiolus* is about 3 mm. in height, and diminishes rapidly in diameter from base to apex, while its tapered extremity fails to reach the cupula by a distance of 1 mm. Its base corresponds with the *area cochleæ* on the fundus of the internal acoustic meatus, and exhibits the *tractus spiralis foraminosus*, which transmits the nerves for the basal and central coils of the cochlea and the *foramen centrale*, which gives passage to the nerves for the apical coil. The foramina of the *tractus spiralis foraminosus* traverse the *modiolus*, at first parallel to its long axis, but, after a

¹ In the following description the cochlea is supposed to be placed on its base.

varying distance, they bend outwards to reach the attached edge of the lamina spiralis ossea, where they expand and form by their apposition a spiral canal, the *canalis spiralis cochleæ*, which lodges the *ganglion spirale cochleæ*. From this spiral canal numerous small foramina, for the transmission of vessels and nerves, pass outwards to the free edge of the lamina spiralis ossea. The *lamina spiralis ossea*, a thin, flat shelf of bone, winds round the modiolus like the thread of a screw, and, projecting about half-way into the cochlear tube, incompletely divides it into two passages—an upper is named the *scala vestibuli*; a lower, the *scala tympani*. The lamina spiralis ossea begins at the floor of the vestibule, near the fenestra cochleæ, and ends close to the apex of the cochlea in a sickle-shaped process, the *hamulus laminæ spiralis*, which assists to bound an aperture named the *helicotrema*. In the

FIG. 718.—SECTION OF BONY COCHLEA.

basal coil the upper surface of the lamina spiralis ossea forms almost a right angle with the modiolus, but the angle becomes more and more acute on ascending the tube. In the lower half of the basal coil a second smaller bony plate, the *lamina spiralis secundaria*, projects from the outer wall of the cochlea towards the lamina spiralis ossea, without, however, reaching it. If viewed from the vestibule the slit-like fissura vestibuli, already referred to (p. 844), is seen between the two laminae. A membrane, the *membrana basilaris*, stretches from the free edge of the lamina spiralis ossea to the outer wall of the cochlea, and completes the septum between the scala vestibuli and scala tympani, but the two scalæ communicate with each other through the opening of the helicotrema at the apex of the cochlea. The scala tympani begins at the fenestra cochleæ, which is closed by the secondary tympanic membrane (*vide* p. 833). At the commencement of the scala tympani a crest, termed the *crista semilunaris*, stretches from the attached margin of the lamina spiralis ossea towards the orifice of the fenestra cochleæ. Close to this crest is seen the inner orifice of the *aquæductus cochleæ*, a canal measuring from 10 to 12 mm. in length, and opening on the under surface of the petrous part of the temporal bone medial to the fossa jugularis. Through it a communication is established between the scala tympani and the subarachnoid cavity, and through it, also, a small vein passes to join the inferior petrosal sinus. The scala vestibuli, the higher of the two passages, begins in the vestibule; its diameter in the basal coil is less than that of the scala tympani, but in the upper coils it exceeds that of the scala tympani.

Meatus Acusticus Internus.—It is convenient, at this stage, to study the fundus of the internal acoustic meatus, which has been referred to as forming the medial wall of the vestibule and the

FIG. 719.—BOTTOM OF INTERNAL ACOUSTIC MEATUS DIVIDED INTO UPPER AND LOWER AREAS BY THE CRISTA TRANSVERSA.

base of the modiolus. It is divided by a transverse ridge, the *crista transversa*, into two parts—an upper or *fossula superior* and a lower or *fossula inferior*. The anterior part of the *fossula superior* is termed the *area n. facialis* and exhibits a single large opening, the commencement of the facial canal, for the transmission of the facial nerve. Its posterior part is named the *area vestibularis superior*, and is perforated by the nerves for the utricle and the ampullæ of the superior and lateral semicircular ducts. The anterior part of the *fossula inferior* is termed the *area cochleæ*, and consists of the *canalis centralis* and the surrounding *tractus spiralis foraminosus*, for the passage of the nerves to the cochlea. Behind the *area cochleæ*, and separated from it by a ridge, is the *area vestibularis inferior*, which is pierced by the nerves to the sacculæ; at the posterior part of the *fossula inferior* is the *foramen singulare*, which gives passage to the nerves for the ampulla of the posterior semicircular duct.

LABYRINTHUS MEMBRANACEUS.

The **membranous labyrinth** (Fig. 720) is contained within the bony labyrinth, but does not nearly fill it. It contains a fluid termed **endolymph**, while the interval between it and the bony labyrinth is named the **perilymphatic space**, and is occupied by a fluid termed **perilymph**. The perilymphatic space in the vestibule is continuous behind with the perilymphatic space of the semicircular canals, and opens in front into the *scala vestibuli*. At the apex of the cochlea it is continuous, through the

helicotrema, with the *scala tympani*, which is shut off from the tympanic cavity by the secondary tympanic membrane. The perilymphatic space is prolonged into the aquæductus cochleæ, at the extremity of which it communicates with the subarachnoid cavity. The ductus semicirculares and the ductus cochlearis follow the course

FIG. 720.—DIAGRAMMATIC REPRESENTATION OF THE DIFFERENT PARTS OF THE MEMBRANOUS LABYRINTH.

and lie along the inner surface of the outer walls of the corresponding bony tubes. The bony vestibule, on the other hand, contains two chief membranous structures, the **utricle** and **sacculæ**. The former receives the extremities of the ductus semicirculares, whilst the latter communicates with the ductus cochlearis. Moreover, the cavities of the utricle and sacculæ are indirectly connected, and thus all parts of the membranous labyrinth communicate with each other, and the endolymph is free to move from one portion to another. The vestibule contains also the ductus endolymphaticus and the commencement of the ductus cochlearis.

Utriculus.—The **utricle**, the larger of the two sacs (Fig. 720), occupies the postero-superior portion of the vestibule. Its highest part, or **recessus utriculi**, lies in the recessus ellipticus and receives the ampullæ of the superior and lateral semicircular ducts. Its central part receives on its lateral aspect the non-ampullated end of the lateral semicircular duct, and is prolonged upwards and backwards as the **sinus superior**, into which the crus commune of the superior and posterior semicircular ducts open. The ampulla of the posterior semicircular duct opens into the lower and medial part, or **sinus inferior**. The floor and anterior wall of the recessus utriculi are thickened to form the **macula acustica utriculi**, to which the utricular fibres of the acoustic nerve are distributed. Whitish in colour, and of an oval or nearly rhombic shape, this macula measures 3 mm. in length and 2·3 mm. in its greatest breadth.

Sacculus.—The **sacculæ** occupies the recessus sphaericus, in the lower and anterior part of the vestibule (Fig. 717). Smaller than the utricle, it is of an oval shape and measures 3 mm. in its longest, and about 2 mm. in its shortest diameter. It presents

anteriorly an oval, whitish thickening, the *macula acustica sacculi*. This has a breadth of about 1·5 mm., and to it the saccular fibres of the acoustic nerve are distributed. The superior extremity of the sacculi is directed upwards and backwards, and forms the *sinus utricularis sacculi*, which abuts against, but does not fuse with, the wall of the utricle. From the lower part of the sacculi a short canal, the *ductus reuniens* (*Henseni*), opens into the ductus cochlearis, a short distance in front of its vestibular extremity. A second small channel, the *ductus endolymphaticus*, is continued from the posterior part of the sacculi, and, passing between the utricle and the medial wall of the vestibule, is joined by a small canal, the *ductus utriculosaccularis*, which arises from the medial side of the utricle. It then enters and traverses the aquæductus vestibuli and ends, under the dura mater on the posterior surface of the petrous part of the temporal bone, in a dilated blind extremity, termed the *sacculus endolymphaticus*; this, according to Rüdinger, is perforated by minute foramina, through which the endolymph may pass into the meningeal lymphatics.

The vestibule also contains the vestibular extremity of the ductus cochlearis, which lies immediately below the sacculi in the recessus cochlearis.

The walls of the utricle and sacculi are composed of connective tissue which blends with the periosteal lining of the vestibule. It is modified medially to form a homogeneous membrana propria, which is covered with a layer of pavement epithelium and is thickened at the maculæ acusticæ. Towards the periphery of the maculæ the epithelium is cubical, while on them it is columnar.

The **structure of the maculæ** in the utricle and sacculi is practically the same; two kinds of cells are found, viz., (*a*) supporting cells, and (*b*) hair cells. The **supporting cells** are some-

what fusiform, each containing, near its middle, a nucleus. Their branched, deep extremities are attached to the membrana propria; their free ends lie between the hair cells and form a thin inner limiting cuticle. The **hair cells** are flask-shaped and do not reach the membrana propria, but end in rounded extremities which lie between the supporting cells. Each contains, at its deepest part, a large nucleus, the rest of the cell being granular and pigmented. From the free end of each there projects a stiff, hair-like process, which, on the application of reagents, splits into several finer filaments. The nerve-fibres pierce the membrana propria, and ramify around the deep extremities of the hair cells (Fig. 722). A collection of small, rhombic crystals of carbonate of lime, termed **otoconia**, adheres to each of the maculæ.

Ductus Semicirculares.—The semicircular ducts are elliptical on transverse section (Fig. 721), and are attached to the walls of the bony canals. The convex wall of each duct is fixed to the periosteal lining of the canal, whilst the opposite part is free, except that it is connected by irregular ligamentous bands, which pass through the perilymphatic space to the bony wall. Like the bony canals, each of the semicircular ducts is dilated at one extremity into a membranous ampulla,

FIG. 721.—TRANSVERSE SECTION OF HUMAN SEMICIRCULAR CANAL AND SEMICIRCULAR DUCT (Rüdinger).

which is especially developed towards the concavity of the tube. The membranous ampullæ nearly fill the corresponding portions of the bony tubes, but the diameter of the semicircular ducts is only about one-fourth of that of the osseous canals.

Each semicircular duct consists of three layers, viz.: (*a*) an outer vascular and partly pigmented **fibrous stratum** which fixes the duct to the bony wall;

FIG. 722.—VERTICAL SECTION OF THE WALL OF THE RECESSUS UTRICULI WITH THE MACULA ACUSTICA AND THE BUNDLES OF NERVE FIBRES.

(*b*) an intermediate, transparent **tunica propria**, presenting a number of papilliform elevations which project towards the lumen. The fibrous layer and tunica propria are thinnest along the attached surface of the duct, and in this region also the papilliform elevations are absent; (*c*) an internal **epithelial layer**, composed of pavement cells. In the ampullæ the tunica propria is much thickened, and projects into the cavity as a transverse elevation, termed the **septum transversum**, which, when seen from above, is somewhat fiddle-shaped; its most prominent part is covered by acoustic epithelium forming the **crista ampullaris**, at each end of which is a half-moon-shaped border of small columnar cells, the **planum semilunatum**. The cells covering the crista ampullaris consist of **supporting cells** and **hair cells**, and are similar in their arrangement to those in the maculæ of the utricle and saccule; the hairs of the hair cells are, however, considerably longer, and project as far as the middle of the ampullary lumen. In fresh specimens they appear to end free, but in hardened preparations are seen to terminate in a soft, clear, dome-like structure, the **cupula terminalis**, which is striated, the striæ converging towards its concavity. The nerves form arborisations around the bases of the hair cells.

FIG. 723.—SECTION ACROSS THE DUCTUS COCHLEARIS (Retzius).

Ductus Cochlearis.—The ductus cochlearis (O.T. **membranous cochlea** or **scala media**) is closed at both of its extremities; the lower extremity occupies the recessus cochlearis of the vestibule and communicates with the saccule through the ductus reunions. It forms a spirally arranged canal inside the cochlea, and at

the apex of the latter its upper extremity, the *lagena*, or *cæcum capulare*, is fixed to the cupula and partly bounds the *helicotrema*. As already stated, the *membrana basilaris* extends from the free edge of the *lamina spiralis ossea* to the outer wall of the cochlea. A second, more delicate membrane, the *membrana vestibularis* (O.T. *membrane of Reissner*), stretches from the thickened periosteum covering the upper surface of the *lamina spiralis ossea* to the outer cochlear wall, some little distance above the external attachment of the *membrana basilaris*. A canal is thus enclosed between the underlying *scala tympani* and the overlying *scala vestibuli*, and constitutes the *ductus cochlearis*. Triangular on transverse section, the duct possesses a roof, an outer wall, and a floor, and is lined throughout with epithelium and filled with endolymph. On its floor the epithelium is greatly modified, and here are found the endings of the cochlear nerve.

The roof or vestibular wall of the ductus cochlearis is formed by the *membrana vestibularis*, a delicate, nearly homogeneous membrane, covered on each surface by a layer of epithelium. Its entire thickness is about 3 μ .

The outer wall of the ductus cochlearis (Fig. 724) consists of the periosteal lining of the bony cochlea, which, however, is thickened and greatly modified to form the *ligamentum spirale cochleæ*. Occupying the whole outer wall, this ligament projects inwards inferiorly as a triangular prominence, the *crista basilaris*, to which the outer edge of the *membrana basilaris* is attached. In the upper part of the *ligamentum spirale* the periosteum is of a reddish-yellow colour, and contains, immediately under its epithelial lining, numerous small blood-vessels and capillary loops, forming the *stria vascularis*. The lower limit of this stria is bounded by a prominence, the *prominentia spiralis*, in which is seen a vessel, the *vas prominens*, and between this prominence and the *crista basilaris* is a concavity, the *sulcus spiralis externus*. The height of the outer wall diminishes towards the apex of the cochlea.

The floor or tympanal wall of the ductus cochlearis is formed by the periosteum covering that portion of the *lamina spiralis ossea* which is situated to the outer side of the *membrana vestibularis*, and by the *membrana basilaris*, which stretches from the free edge of the *lamina spiralis ossea* to the *crista basilaris*. On the inner part of the *membrana basilaris* the complicated structure termed the *organon spirale* (O.T. *organ of Corti*) is situated. The *lamina spiralis ossea* consists of two plates of bone, between which are placed the canals for the branches of the cochlear nerve. On the upper plate the periosteum is thickened and modified to form the *limbus laminae spiralis*, the outer extremity of which forms a C-shaped concavity, the *sulcus spiralis internus*. The portions of the *limbus* which project above and below this concavity are termed respectively the *labium vestibulare* and *labium tympanicum*. The latter is perforated by about 4000 small apertures, the *foramina nervosa*, for the transmission

FIG. 724.—TRANSVERSE SECTION THROUGH OUTER WALL OF DUCTUS COCHLEARIS (Schwalbe).

of the cochlear nerves, and is continuous with the membrana basilaris. The upper surface of the labium vestibulare presents a number of furrows crossing each other nearly at right angles, and intersecting a series of elevations which, at the free margin of the labium, form a row of tooth-like structures, about 7000 in number, the **auditory teeth of Huschke**. Covering the limbus is a layer of apparently squamous epithelium; the deeper protoplasmic portions of the cells, however, with their contained nuclei, lie in the intervals between the elevations and auditory teeth. This layer of epithelium is continuous above with that covering the under surface of the membrana vestibularis and below with that which lines the sulcus spiralis internus.

Membrana Basilaris.—The inner part of this membrane is thin, and supports the organon spirale; it is named the **zona arcuata**, and reaches as far as the foot-plate of the outer rod of Corti. Its outer part, extending from the foot-plate of the outer rod of Corti to the crista basilaris, is thicker and distinctly striated, and is termed the **zona pectinata**. The substantia propria of the membrane is almost homogeneous, but exhibits, in its deeper part, numerous fibres. These fibres are most distinct in the zona pectinata, and number, according to Retzius, about 24,000. Covering the under surface of the membrana basilaris is a layer of connective tissue, containing, in its inner part, small blood-vessels; one of these is larger than the others and lies below the tunnel of Corti, and is named the **vas spirale**. The width of the membrana basilaris increases from $210\ \mu$ in the basal coil to $360\ \mu$ in the apical coil.

Organon Spirale (O.T. Organ of Corti) (Fig. 725).—Placed upon the inner portion of the membrana basilaris, the organon spirale consists of an epithelial eminence which extends along the entire length of the ductus cochlearis, and comprises the following structures, viz.: (1) Corti's rods or pillars, (2) hair cells (inner and outer), (3) supporting cells of Deiters, (4) the cells of Hensen and Claudius, (5) the lamina reticularis, and (6) the membrana tectoria.

The **rods of Corti** form two rows, **inner and outer**, of stiff, pillar-like structures, and each rod presents a base or foot-plate, an intermediate elongated portion, and an upper

FIG. 725.—TRANSVERSE SECTION OF THE ORGANON SPIRALE FROM THE CENTRAL COIL OF THE DUCTUS COCHLEARIS (Retzius).

end or head. The bases of the two rows are planted on the membrana basilaris some little distance apart. The intermediate portions of the rods incline towards each other and the heads come into contact, so that, between the two rows above and the membrana basilaris below, a triangular tunnel, the **tunnel of Corti**, is enclosed; this tunnel increases both in height and width on passing towards the apex of the cochlea. The **inner rods** number nearly 6000, and the head of each resembles somewhat the proximal end of the ulna, presenting externally a deep concavity for the reception of a corresponding convexity on the head of the outer rod. The part of the head which overhangs this concavity is prolonged outwards, under the name of the **head-plate**, and overlaps the head of the

outer rod. The expanded bases of the inner rods are situated on the innermost portion of the *membrana basilaris*, immediately to the outer side of the *foramina nervosa* of the *labium tympanicum*. The intermediate parts of the inner rods are sinuously curved, and form with the *membrana basilaris*, an angle of about 60° . The **outer rods** number about 4000, and are longer than the inner, especially in the upper part of the cochlea. They are more inclined towards the *membrana basilaris*, and form with it an angle of about 40° . The head of each is convex internally, to fit the concavity on the head of the inner rod, and is prolonged outwards as a plate, the **phalangeal process**, which becomes connected with the *lamina reticularis*; in the head is an oval body which has an affinity for certain reagents. The main part of each rod consists of a nearly homogeneous material, which is finely striated. At the bases of the rods, on the side next Corti's tunnel, is a nucleated mass of protoplasm which reaches as far as the heads of the rods, and covers also the greater part of the tunnel floor; this protoplasm may be regarded as the undifferentiated part of the cell from which the rod was developed. Slit-like intervals, for the transmission of nerves, exist between the intermediate portions of adjacent rods.

Hair Cells.—These, like Corti's rods, form two sets, **inner** and **outer**. The former consists of a single row lying immediately internal to the inner rods—the latter of three, or, it may be, four rows placed to the outer side of the external rods. The **inner hair cells** are about 3500 in number; the diameter of each is greater than that of an inner rod, and so each inner hair cell is supported by more than one rod. Somewhat oval in shape, their free extremities are surmounted by about twenty fine hair-like processes, arranged in the form of a crescent, with its concavity directed inwards. The deep end of the cell contains a large nucleus and is rounded; it reaches only about half-way down the rod, and is in contact with the arborisations of the nerve terminations. To the inner side of this row of hair cells are two or three rows of elongated columnar cells, which act as supporting cells, and are continuous with the low columnar cells lining the *sulcus spiralis internus*. The **outer hair cells** number about 12,000, and form three rows in the basal coil and four rows in the upper two coils, although in the higher coils the rows are not so regularly arranged. The rounded free ends of the hair cells support some twenty hairlets arranged in the form of a crescent, opening inwards. Their deep extremities reach about half-way to the *membrana basilaris*, and are in contact with the nerve arborisations.

Alternating with the rows of the outer hair cells are the rows of **Deiters' supporting cells**, the lower extremities of which are expanded on the *membrana basilaris*, whilst their upper ends are tapered; the nucleus is placed near the middle of each cell, and, in addition, each cell contains a bright, thread-like structure called the **supporting fibre**. This fibre is attached by a club-shaped base to the *membrana basilaris*, and expands, at the free end of the cell, to form a **phalangeal process** of the *membrana reticularis*.

The **cells of Hensen**, or outer supporting cells, consist of about half a dozen rows, immediately outside Deiters' cells, and form a well-marked elevation on the floor of the *ductus cochlearis*. Their deep extremities are narrow and attached to the *membrana basilaris*, while their free ends are expanded; each cell contains a distinct nucleus and some pigment granules. The columnar cells, situated externally to the cells of Hensen, cover the outer part of the *zona pectinata*, and are named the **cells of Claudius**. A space, the **space of Nuel**, exists between the outer rods of Corti and the neighbouring row of hair cells; it communicates internally with Corti's tunnel, and extends outwards between the outer hair cells as far as Hensen's cells.

The **lamina reticularis** is a thin cuticular structure which lies over the organon spirale, and extends from the heads of the outer rods as far as Hensen's cells, where it ends in a row of quadrilateral areas which form its outer border. It consists of two or three rows of structures, named **phalanges**, which are elongated cuticular plates resembling in shape the digital phalanges. The innermost row is formed by the phalangeal processes of the heads of the outer row of Corti's rods; the succeeding row, or rows, represent the expanded upper ends of Deiters' supporting cells. The number of rows of phalanges, therefore, varies with the number of rows of outer hair cells and the alternating cells of Deiters. The free ends of the hair cells occupy the somewhat circular apertures between the constricted middle portions of the phalanges.

The **membrana tectoria** (Fig. 725) is an elastic membrane overlying the *sulcus spiralis internus* and the organon spirale. Attached, by its inner end, to the *limbus laminae spiralis*, near the lower edge of the *membrana vestibularis*, it reaches outwards as far as the outer row of hair cells. Its inner portion is thin and overlies the auditory teeth of Huschke. Its outer part is thickened, but becomes attenuated near its external border, which, according to Retzius, is attached to the outer row of Deiters' cells. Its lower edge

presents a firm, homogeneous border, and opposite the inner row of hair cells contains a clear, spirally arranged band, named **Hensen's stripe**.

Nervus Acusticus (Fig. 726).—The acoustic nerve divides within the internal acoustic meatus into an anterior or cochlear and a posterior or vestibular nerve.

FIG. 726.—MEMBRANOUS LABYRINTH OF A FIVE MONTHS' FETUS, viewed from its postero-medial aspect (Retzius).

N. Cochleæ.—The cochlear nerve is distributed to the hair cells of the organon spirale, the branches for the basal and middle coils entering the foramina in the tractus spiralis foraminosus, those for the apical coil running in the canalis centralis of the modiolus. Extending upwards, in the bony canals of the modiolus, the nerve-fibres radiate outwards between the lamellæ of the lamina spiralis ossea. Contained

FIG. 727.—PART OF COCHLEAR NERVE, highly magnified (Henle).

in the spiral canal of the modiolus, near the attached margin of the lamina, is a ganglion of bipolar nerve-cells which winds spirally round the modiolus, and is named the **ganglion spirale** (O.T. **ganglion of Corti**) (Fig. 727); the fibres of the nerve arise from the cells of this ganglion. Beyond the ganglion spirale the nerve-fibres extend outwards, at first in bundles, and then in a more or less continuous sheet, from the outer edge of which they are again collected into bundles, which pass through the foramina nervosa of the labium tympanicum. Beyond this they appear

as naked axis-cylinders, and, turning in a spiral manner (**inner or first spiral fasciculus**), send fibrillæ towards the inner row of hair cells. Other fibrils run between the inner rods and form a **second spiral fasciculus** in Corti's tunnel, from which fibrils extend outwards across the tunnel, and, passing between the outer rods, enter Nuel's space. They form a spiral fasciculus on the inner aspect of each row of Deiters' cells, and fibrillæ pass from these fasciculi towards the bases of the outer hair cells.

The cochlear nerve gives off a vestibular branch, the terminal filaments of

which go through the foramina in the recessus cochlearis and are distributed to the hair cells of the vestibular part of the ductus cochlearis. On this vestibular branch, close to its origin from the cochlear nerve, is a minute ganglion (Boettcher).

N. Vestibuli.—The vestibular nerve is distributed to the utricle, the saccule, and the ampullæ of the semicircular ducts. It divides into three branches, superior, inferior, and posterior, and each of these splits into filaments which pass through foramina in the fundus of the internal acoustic meatus. The filaments from the superior branch go through the foramina in the area vestibularis superior and supply the macula of the utricle and the cristæ ampullares of the superior and lateral semicircular ducts; those from the inferior branch run through the foramina in the area vestibularis inferior to the macula of the saccule. The posterior branch passes through the foramen singulare, and its filaments, six to eight in number, are distributed to the crista ampullaris of the posterior semicircular duct.

Ganglion Vestibulare.—On the trunk of the vestibular nerve, within the internal acoustic meatus, is a ganglion, the vestibular ganglion, of bipolar nerve cells; the fibres of the nerve arise from the cells of this ganglion. Sometimes the vestibular nerve divides on the proximal side of the ganglion and the latter is then split into three parts, one on each of the three branches of the nerve.

Vessels of the Internal Ear.—The internal auditory artery, a branch of the basilar, enters the internal acoustic meatus and divides into vestibular and cochlear branches. The vestibular branch supplies the soft tissues in the vestibule and semicircular canals, each canal receiving two arteries, which, starting from opposite extremities of the canal, anastomose on the summit of the arch. The cochlear branch divides into numerous twigs, which enter the foramina in the tractus spiralis foraminosus, and run outwards in the lamina spiralis ossea to reach the soft structures; the largest of these arteries runs in the canalis centralis. The stylo-mastoid artery also supplies some minute branches to the cochlea. Siebenmann describes the internal auditory artery as dividing into three branches, viz.: (1) anterior vestibular, (2) cochlear proper, and (3) vestibulo-cochlear. The veins from the cochlea and vestibule unite, at the bottom of the meatus, with the veins from the semicircular canals to form the internal auditory vein, which may open either into the posterior part of the inferior petrosal sinus or into the transverse sinus. Small veins also pass through the aquæductus cochleæ and aquæductus vestibuli, the former opening into the inferior petrosal sinus or into the internal jugular vein, the latter into the superior petrosal sinus.

DEVELOPMENT OF LABYRINTH.

The epithelial lining of the labyrinth is derived from an invagination of the cephalic ectoderm, termed the **auditory pit**, which appears opposite the hind brain immediately above the first visceral cleft. The mouth of the pit is closed by the growing together of its margins, and it then assumes the form of a hollow vesicle, the **otic vesicle**, which severs its connexion with the ectoderm and sinks into the subjacent mesoderm. The vesicle soon becomes pear-shaped; and its dorsal tapering part rapidly lengthens into a recess, the **recessus labyrinthi**, which later forms the ductus and saccus

FIG. 728.—SECTIONS THROUGH THE REGION OF THE HIND BRAIN OF FETAL RABBITS (to illustrate the development of the labyrinthine epithelium).

In A the ectoderm is invaginated to form the auditory pit; in B the auditory pit is closed and detached from the ectoderm, forming the otic vesicle; while C shows a further stage in the development of the vesicle.

endolymphaticus. About the fifth week, the lower part of the vesicle is prolonged forwards as a diverticulum, the future ductus cochlearis. This is at first straight, but

FIG. 729.

A, Left labyrinth of a human embryo of about four weeks; B, Left labyrinth of a human embryo of about five weeks (from W. His, jun.).

as it elongates it curves on itself, so that at the twelfth week all three coils are differentiated. From the upper part of the vesicle the semicircular ducts are developed, and appear as three hollow, disc-like evaginations; the central parts of the walls of each disc coalesce and disappear, leaving only the peripheral ring or canal. The three ducts are free about the beginning of the second month, and are developed in the following order, viz.: superior, posterior, and lateral. The intermediate part of the otic vesicle represents the vestibule, and is divided by a constriction into an anterior part, the sacculæ, communicating with the ductus cochlearis, and a posterior portion, the utricle, receiving the extremities of the semicircular ducts. The constriction extends for some distance into the ductus endolymphaticus, and thus the utricle and sacculæ are connected by a Y-shaped tube. Another constriction makes its appearance between the sacculæ and the vestibular end of the ductus cochlearis and forms the *canalis reuniens*. The epithelial lining is at first columnar, but becomes cubical throughout the whole labyrinth, except opposite the terminations of the acoustic nerve, where it forms the columnar epithelium of the maculæ of the utricle and sacculæ, of the *cristæ ampullæ*, and of the *organon spirale*. On the floor of the ductus cochlearis two ridges appear, of which the inner forms the *limbus laminae spiralis*, whilst the cells of the outer become modified to form the rods of Corti, the hair cells, and the supporting cells of Deiters and Hensen.

The mesoderm surrounding the otic vesicle is differentiated into: (1) a fibrous layer, the wall of the membranous labyrinth; (2) a cartilaginous capsule, the future petrous bone; and (3) an intervening layer of gelatinous tissue, which is ultimately absorbed, leaving the perilymphatic space between the bony and membranous labyrinths.

The development of the external and middle parts of the ear are described on pp. 50-53.

ORGANON GUSTUS.

The peripheral **gustatory organ** consists of groups of modified epithelial cells, termed *calyculi gustatorii* or **taste buds**, found on the tongue and in its immediate neighbourhood.

Taste buds are present in large numbers around the circumference of the *papillæ vallatæ*, while some are found also on their opposing walls (Fig. 730). They are very numerous over the *foliate papillæ*, which correspond with the *papillæ foliatæ* of the tongue of the rabbit, and are found also over the posterior part and sides of the tongue, either on the *papillæ fungiformes* or throughout the stratified epithelium. They exist, also, on the oral surface of the *velum palatinum* and on the posterior surface of the *epiglottis*.

Structure of Taste Buds (Fig. 731).—The taste buds are oval or flask-shaped, and occupy nests in the stratified epithelium of the regions mentioned. The deep extremity of each is expanded and rests upon the corium; the free end is perforated by a minute pore, termed the **gustatory pore**. They consist of two kinds of epithelial cells—(a) supporting cells, and (b) gustatory cells (Fig. 732). The **supporting cells** are elongated, nucleated spindles, and are mostly arranged like the staves of a cask to form the outer envelope of the bud; but some are found in the

interior of the bud, amongst the gustatory cells. The **gustatory cells** occupy the centre

of the bud, and each consists of a nucleated cell-body, prolonged into a peripheral

and a central process. The peripheral process is rod-like and almost hyaline, and terminates at the gustatory pore in a slender filament, the **gustatory hair**. The central process passes towards the deep extremity of the bud, where it ends free, as a single or branched varicose filament.

Nerves of Taste.—The nerve supplying the taste buds over the anterior part of the tongue is the chorda tympani, which is derived from the sensory root of the facial nerve; that for the posterior part is the glosso-pharyngeal. The nerve fibrils, having lost their medullary sheaths, ramify partly between the gustatory cells and partly amongst the supporting cells of the taste buds.

The ducts of Ebner's glands open into the bottom of the valleys surrounding the papillae vallatæ, and the serous-like secretion of these glands probably washes the free

- a, Supporting cells. b, Gustatory cells.

hair-like extremities of the gustatory cells, and so renders them ready to be stimulated by successive substances. It should be added that there is a close association between the senses of smell and taste. This can be best appreciated by considering the defective taste perceptions resulting from inflammatory conditions of the nasal mucous membrane, or the common practice of holding the nose in order to minimise the taste of nauseous drugs.

The development of the tongue is described on pp. 45-46.

INTEGUMENTUM COMMUNE.

The **integument** or **skin** covers the body, and is continuous, at the orifices on its surface, with the mucous lining of its alimentary and other canals. It contains the peripheral terminations of many of the sensory nerves, and serves as an organ of protection to the deeper tissues. It is the chief factor in the regulation of the body temperature, and by means of the sudoriferous and sebaceous glands, which

open on its free surface, constitutes an important excretory structure. Its superficial layers are modified to form appendages in the shape of hairs and nails.

The skin is very elastic and resistant, and its colour, determined partly by its own pigment and partly by that of the blood, is deeper on exposed parts and in the regions of the genitals, axillæ, and mammary areolæ, than elsewhere. The colour varies also with race and age, the different races of the world being roughly classified, according to the colour of their skin, into the

FIG. 733.—VERTICAL SECTION OF THE SKIN (schematic).

three groups of white, yellow, and black. Pinkish in colour in childhood, the skin assumes a yellowish tinge in old age, while in certain diseases (*e.g.* icterus and *melasma Addisonii*) the colour undergoes marked alteration.

The surface of the skin is perforated by the hair follicles and by the ducts of the sudoriferous and sebaceous glands, and on the palms, soles, and flexor aspect of the digits it presents numerous permanent ridges, the *cristæ cutis*, which correspond with rows of underlying papillæ. Over the terminal phalanges these ridges form distinctive patterns, which are retained from youth to old age, and are utilised for purposes of identification. Retinacula of the skin are seen in the neighbourhood

of the joints, and it can be thrown into wrinkles by the contraction of the subcutaneous muscles, where these exist. Over the greater part of the body it is freely movable; but on the scalp and lateral surfaces of the auriculæ, as well as on the palms and soles, it is bound down to the subjacent tissues.

The skin consists of two strata, viz. : a deep, termed the corium, and a superficial, the epidermis (Fig. 734).

The **corium** or **cutis vera** is derived from the embryonic mesoderm, and consists essentially of a felted interlacement of connective tissue and elastic fibres. In its deeper part, or **stratum reticulare**, the fibrous bundles are coarse and form an open network, in the meshes of which are vessels, nerves, pellets of fat, hair follicles, and glands. This reticular stratum passes, as a rule, without any line of demarcation, into the panniculus adiposus or subcutaneous fatty tissue, but in some parts it rests upon a layer of striped or unstriped muscular fibres—the latter in the case of the scrotum. In the superficial layer, or **stratum papillare**, of the corium, the connective tissue-bundles are finer and form a close network. Projecting from its superficial surface are numerous finger-like, single, or branched elevations, termed **papillæ** (Fig. 734), which are received into corresponding depressions on the under surface of the epidermis. These papillæ vary in size, being small on the eyelids, but large on the palms and soles, where they may attain a length of $225\ \mu$, and where they produce the permanent curved ridges already referred to. Each ridge usually contains two rows of papillæ, between which the ducts of the sudoriferous glands pass to reach the surface. The papillæ consist of fine connective tissue and elastic fibres, mostly arranged parallel to the long axis of the papillæ; the majority contain capillary loops, but some contain the terminations of nerves. The superficial surface of the corium is covered with a thin, homogeneous basement membrane.

The **epidermis** or **cuticle** is derived from the embryonic ectoderm and covers the corium. Its thickness varies in different parts of the body and ranges from 0.3 mm. to 1 mm. or more; it is thickest on the palms of the hands and soles of the feet, and thinnest on the eyelids and penis. It is non-vascular and consists of stratified epithelium; its superficial layers are modified to form the **stratum corneum**, which may be separated by maceration or blistering from the deeper, softer portion, or **stratum mucosum** (Malpighi). The epidermis consists from within outwards of the following five strata (Fig. 734):—

1. The **stratum germinativum** is a single stratum of nucleated columnar cells planted by denticulated extremities on the basement membrane of the corium.

2. The **stratum mucosum** consists of six or eight layers of polygonal, nucleated "prickle" or "finger" cells, the processes of which join those of adjacent cells. Between the cells of this layer are minute channels, in which leucocytes or pigment

FIG. 734.—VERTICAL SECTION OF EPIDERMIS AND PAPILLÆ OF CORIUM (highly magnified).

granules may be seen. The cells of the stratum mucosum are characterised by the presence of numerous epidermic fibrils, which are coloured violet by hæmatoxylin and red by carmine. These fibrils are unaffected by boiling, but swell up under the action of acids and alkalies, and form the filaments of union between adjacent cells. On account of their presence, L. Ranvier has named this layer the **stratum filamentosum**. The dark colour of the negro's skin is caused by the presence of numerous pigment granules in the deeper layers of the stratum mucosum; the pigment—of which *melanin* forms an important constituent—is absent from the more superficial layers of the epidermis.

3. The **stratum granulosum** comprises two or three layers of horizontally arranged, flattened cells, scattered around the nuclei of which are elliptical or spherical granules of *eleidin*, a substance staining deeply with carmine and hæmatoxylin, and probably representing an intermediate stage between the protoplasm of the deeper cells and the keratin of the superficial layers.

4. The **stratum lucidum**, an apparently homogeneous layer, is in reality made up of several strata of flattened or irregular squames, which contain granules or droplets of *keratohyalin*, a hyaline substance, staining less deeply than eleidin.

5. The **stratum corneum** comprises several layers of flattened non-nucleated squames, the more superficial of which assume the form of horny scales and are from time to time removed by friction. The deeper cells contain granules of a fatty material having the consistency and plasticity of beeswax, and staining with osmic acid. The peripheral parts of the cells consist of **keratin**, a highly resistant substance which is unaffected by mineral acids, and is indigestible in pepsin-hydrochloric acid.

L. Ranvier has pointed out that the **stratum lucidum** is really double, and has named the deeper of its two layers the **stratum intermedium**; this he describes as consisting of two or three layers of clear cells with atrophied nuclei, while in the cell-walls the epidermic fibrils "are rolled up like the threads of a cocoon."

Regeneration of the epidermis is generally regarded as taking place by cell proliferation in the stratum germinativum, the young cells gradually passing through the polyhedral and granular stages, and ultimately becoming the flattened squames of the stratum corneum, while the eleidin granules of the stratum granulosum are converted into the keratin of the stratum corneum.

Vessels and Nerves of the Skin.—In the subcutaneous tissue the arteries form a plexus from which branches extend into the corium, where they supply the hair follicles and glands, and form a second plexus under the papillæ, to which small loops are given. The veins and the lymphatic vessels commence in the papillæ, and, after forming subpapillary plexuses, open into their respective subcutaneous vessels.

The **nerves** of the skin vary in number in different parts of the body; they are extremely numerous where the sense of touch is acute, *e.g.* on the palmar surfaces of the terminal phalanges, while in the skin of the back, where the sensibility is less, they are fewer in number. Their different modes of ending are described on pp. 863-866.

FIG. 735.—TACTILE CORPUSCLES.

APPENDAGES OF THE SKIN.

The appendages of the skin are the nails, the hairs, the sebaceous glands, and the sudoriferous or sweat glands.

Ungues.—The nails (Figs. 736, 737) are epidermal structures, and represent the hoofs and claws of the lower animals. The **root** of the nail is hidden

from view and embedded in a fold of skin; the **body**, or uncovered part, rests on the corium and ends in a **free margin**. The greater part of the lateral margin is overlapped by a duplicature of skin, termed the **vallum unguis** or **nail-wall**. The nails are pink in colour, with the exception of a small semilunar area near the root, which is more opaque than the rest, and is named the **lunula**. The lunulae diminish in size from the thumb towards the little finger, while the thickness of the nail diminishes towards its root and lateral margins. The corium under the nail is highly vascular and sensitive, and presents, especially under

FIG. 736.—TRANSVERSE SECTION OF A NAIL.

the anterior part of the body, numerous longitudinally arranged ridges. The part of the corium under the body is termed the **nail bed**; that under the root, the **nail matrix**. The deep part of the nail consists of the stratum germinativum and stratum mucosum, while its superficial horny portion is constituted by a greatly thickened stratum lucidum, and consists of nucleated, keratinised squames. The stratum corneum is represented by the thin cuticular fold overlapping the lunula, and termed the **eponychium**, while the stratum granulosum can be traced only as far forwards as the nail root.

FIG. 737.—LONGITUDINAL SECTION THROUGH ROOT OF NAIL.

Pili.—**Hairs** are well developed on the external genitals, scalp, and margins of the eyelids, in the axilla, the vestibule of the nose, and at the entrance to the concha, and also on the face of the male. Those on the genitals and face appear about puberty. Rudimentary over the greater part of the body, they are entirely absent from the flexor surfaces of the hands and feet, the dorsal surfaces of the terminal phalanges, the glans penis, the inner surface of the prepuce, and medial surfaces of the labia. Marked variations, individual and racial, exist as to the colour of the hair, and also as to the manner of its growth; hence the terms straight, curly, woolly, etc. are used to designate it. Straight hairs are coarser than curly ones, and have, moreover, a circular or oval outline on transverse section, curly hairs being flat and riband-like.

The **root of the hair** is embedded in a depression of the skin, termed the **hair follicle** (Fig. 738); the free portion is named the **scapus** or **shaft**, and consists

from without inwards of three parts, viz., cuticle, cortex, and medulla. The *cuticle* is formed by a layer of imbricated scales which overlap one another from below upwards. The *cortex* consists of longitudinally arranged fibres made up of elongated, closely applied, fusiform cells, which contain pigment and sometimes air spaces, the latter especially in white hairs. The *medulla*, absent from the fine hairs of the body generally and from the hairs of young children, forms a central core, which appears black by transmitted, and white by reflected light, and is composed of polyhedral nucleated cells containing pigment, fat granules, and air spaces.

The *hair follicle* consists of an oblique or curved—the latter in curly hairs—invagination of the epidermis and corium, and in the case of large hairs extends into the subcutaneous tissue (Fig. 733); some little distance below its orifice the ducts of the sebaceous glands open into it. The dermic coat or portion of the follicle derived from the corium consists of a fibrous sheath of external longitudinal and internal circular connective tissue fibres, the latter being lined by a hyaline layer directly

FIG. 738.—TRANSVERSE SECTION OF HAIR FOLLICLE WITH CONTAINED HAIR (highly magnified).

continuous with the basement membrane of the corium. The parts of the follicle derived from the epidermis are named the *inner* and *outer root sheaths*. Below the orifices of the sebaceous gland ducts the outer root sheath is formed by the stratum germinativum and stratum mucosum, while above them all the epidermal strata contribute to it. The inner root sheath surrounds the cuticle of the hair, and comprises from without inwards—(a) *Henle's layer*, a single stratum of nucleated cubical cells; (b) *Huxley's layer*, a single or double layer of polyhedral nucleated cells; and (c) a *delicate cuticle*, composed of a single layer of flattened imbricated cells, with atrophied nuclei. The bottom of the hair follicle is moulded on a vascular *papilla*, derived from the corium and capped by the *bulb of the hair* or expanded part of the hair root. The cells of the bulb are continuous with those of the outer root sheath, and form the different parts of the hair, as well as its inner root sheath. The vessels form capillary loops in the papilla of the hair, and send twigs into the outer layer of its fibrous sheath; the inner and outer root sheaths and the different parts of the hair are non-vascular. The nerves end in longitudinal and annular fibrils below the level of the sebaceous glands and outside the hyaline layer of the follicle.

Glandulæ Sebaceæ.—Sebaceous glands exist wherever there are hairs, and their

ducts open into the superficial parts of the hair follicles (Fig. 733); the number of glands associated with each follicle varies from one to four. On the labia minora and mammary areolæ they open on the surface of the skin independently of hair follicles, and in the latter situations undergo great enlargement during pregnancy. The deep extremity of each gland expands into a cluster of oval or flask-shaped *alveoli*, which are surrounded by a basement membrane, and filled with polyhedral cells containing oil droplets. By the breaking down of the superficial cells, their oily contents are liberated as the *sebum cutaneum* and discharged into the hair follicle, whilst the deeper cells undergo proliferation. The size of the gland bears no proportion to that of the hairs, since they are very large in the minute hair follicles of the fœtus and newly born child, and also in the follicles of the rudimentary hairs of the nose and certain parts of the face.

Bundles of non-stripped muscular fibre are associated with the hair follicles, and are named the *mm. arrectores pilorum*. Attached to the deep part of the hair follicle, and forming with it an acute angle, they pass outwards close to the sebaceous glands, and end in the papillary layer of the corium. They are situated on the side towards which the hair slopes, so that, on contraction, they diminish the obliquity of the hair follicle and render the hair more erect, and, at the same time, compress the sebaceous glands and expel their contents. The condition of "goose-skin" is caused by the contraction of these slender muscles.

Arthur Thomson suggests that the condition of curly hair is produced by the contraction of the *mm. arrectores pilorum*. Straight hair is thick and cylindrical; curly hair is flat and ribbon-like. When the arrector muscle contracts, the thick rounded hair resists the tendency of the muscle to bend it, while the flat hair, not sufficiently strong to resist the strain of the muscle, becomes bent, and this is probably the explanation why the follicle assumes the curved form characteristic of the scalp of a bushman. The sebaceous gland lies in the concavity of the bend between the follicle and the muscle, and forms a mass of greater resistance, around which the follicle may be curved by the contraction of the muscle. The cells at the root of the hair accommodate themselves to the curved follicle, and, becoming more horny as they advance to the surface, retain the form of the follicle in which they are moulded.

Glandulæ Sudoriferæ.—Sudoriferous or sweat glands are found in the skin of nearly every part of the body; they are relatively few in number on the back of the trunk, but are very plentiful on the palms and soles, where they open on the summits of the curved ridges. Each consists of an elongated tube, the deeper portion of which forms its secretory part, and is coiled in the subcutaneous tissue or deep part of the corium in the form of an ovoid or spherical ball, termed the *corpus glandulæ sudoriferæ* (O.T. *glomerulus*) (Fig. 733). The superficial part of the tube, or *ductus sudoriferus*, extends through the corium and epidermis, and opens on the surface by a funnel-shaped orifice, the *porus sudoriferus*; where the epidermis is thick the duct is spirally coiled. The *bodies of the glands*, as a rule, vary in diameter from 0.1 to 0.5 mm., but in the axillæ they are much larger, and may measure from 1 to 4 mm. Each is surrounded by a capillary network and by a capsule of connective tissue, inside which is a homogeneous basement membrane. The lumen of the tube is lined with a layer of nucleated, granular, and striated, columnar, or prismatic epithelial cells, between the deep extremities of which and the basement membrane is a layer of non-stripped muscular fibres, the long axis of which is more or less parallel with that of the tube. The excretory ducts are devoid of muscular fibres, and consist of a basement membrane lined by two or three layers of polyhedral cells, which are covered, next the lumen of the duct, with a thin cuticle.

The *glandulæ ciliares*, at the margins of the eyelids, and the *glandulæ ceruminosæ* of the external acoustic meatus, are modified sudoriferous glands; the former are, however, not coiled, while the cell protoplasm of the latter contains yellowish pigment, and their gland ducts, in the fœtus, open into hair follicles.

DEVELOPMENT OF THE SKIN AND ITS APPENDAGES.

Skin.—The vascular and sensitive corium is developed from the mesoderm, the cells of which, immediately underlying the ectoderm, have, by the second month of fœtal life, become aggregated together and flattened parallel to the surface of the embryo. By the third month they are seen to form two layers, the superficial of which becomes the

corium, and the deeper the subcutaneous tissue; the papillæ of the corium make their appearance in the fourth month. The epidermis, nails, hairs, sudoriferous and sebaceous glands are of ectodermal origin.

The epidermis at first consists of a single layer of cells, but by the end of the second month it is duplicated, and then exhibits a superficial layer of irregular cells and a deeper layer of more or less cubical cells. By the third month three strata are seen: (a) a deep layer, consisting of a single layer of cubical cells—the future stratum germinativum; (b) a middle layer, comprising two or three strata of irregular cells—the future stratum mucosum; and (c) an outer layer, a double stratum of large cells. This outer layer appears to be homologous with a thin membrane, termed the *epitrichium*, first described as covering the embryo of the sloth and overlying its hairs, but since shown to be present also in birds and mammals. Over the hairy parts of the body it disappears about the sixth month; but over the free edge and root of the nails, and on the palms and soles, it develops into several layers of cells, which, in these parts, probably persist to form the thick stratum corneum. The part which persists over the root of the nail is termed the *eponychium*, and covers the proximal part of the lunula (*vide* p. 859, Fig. 737).

Nails.—The first rudiment of the nails is seen about the beginning of the third month of embryonic life, and consists of a thickening of the epitrichium over the ends of the digits. Owing to the greater growth of the volar surfaces of the digits, the nail rudiment comes to be placed dorsally, and, at its proximal edge, an ingrowth of the stratum mucosum occurs to form its root, while the future nail is limited behind and at the sides by a groove. The superficial cells of the stratum mucosum become keratinised to form a thick stratum lucidum, the future nail proper, over the greater part of which the epitrichium disappears. The latter persists in the adult as the eponychium across the root of the nail, and, until fifth month, also forms a thick mass over the extremity of the nail, and is continued into the stratum corneum over the end of the digit. The future distal edge of the nail, at this stage, is continuous with the stratum lucidum in front of it; but this continuity is lost, and by the seventh month the nail presents a free border. The nails grow in length, and are renewed, in case of removal, by a proliferation of the cells of the stratum mucosum at the root of the nail, while an increase in their thickness takes place from the part of the same stratum which underlies the lunula.

Hairs.—The hair rudiments appear about the third month of embryonic life as solid downgrowths of the stratum mucosum, which pass obliquely into the subjacent corium. The deep end of this column of cells expands to form the hair bulb, and is moulded on a papilla derived from the corium; the epidermis immediately overlying the papilla becomes differentiated into the hair and its inner root sheath, while the peripheral cells form its outer root sheath. The surrounding corium is condensed to form the fibrous sheath of the hair follicle, the hyaline layer of which is continuous with the basement membrane covering the corium. The hair gradually elongates, and, reaching the neck of the follicle, its extremity lies at first under the epitrichium, but becomes free on the disappearance of the latter. This takes place about the fifth month of fetal life, and the first crop of hairs constitutes the *lanugo*, and is well developed by the seventh month. The lanugo consists of very delicate hairs, some of which are shed before, the remainder shortly after birth—the last to drop out being those of the eyelashes and scalp—and are replaced by stronger hairs. Shedding and renewal of the hairs take place during life; prior to the shedding of a hair active growth and proliferation of the cells of the hair bulb cease, and the papilla becomes atrophied, while the hair root, gradually approaching the surface, at last drops out. New hairs arise from epidermic buds, which extend downwards from the follicle, and their development is identical with that of the original hairs.

Sebaceous Glands.—These appear about the fifth month as solid outgrowths from the sides of the hair follicles, and consist of epidermal offshoots continued from the cells of the outer root sheath. Their deep ends become enlarged and lobulated, to form the secreting part of the gland, while the narrow neck connecting this with the follicle forms its duct. The sebaceous secretion, together with the cast-off epidermal cells, is collected on the surface of the body during the last months of intra-uterine life, and forms a layer of varying thickness, termed the *vernix caseosa* or *smegma embryonum*.

Sudoriferous Glands.—These, like the hairs, arise as solid downgrowths of the stratum mucosum. They descend, however, perpendicularly, instead of obliquely, and are of a yellowish colour; they appear on the palms and soles early in the fifth month, but much later over the hairy parts of the body. The downgrowths extend through the corium, and, on reaching the subcutaneous tissue, become coiled up to form the body or secreting part of the gland. The ducts of the glands do not open on the surface until the seventh month.

ENDINGS OF NERVES OF GENERAL SENSATIONS.

The peripheral endings of the nerves associated with the special senses have been described in the preceding pages. Under this heading will be considered the terminations of those sensory nerves which are widely distributed throughout the body and are associated with the muscular sense and the senses of pressure, heat, cold, and pain. These nerves may end as fine ramifications of the axis cylinders lying *free* amongst the tissues, or in *special end organs* where the terminations of the axis cylinders are surrounded by connective tissue capsules.

FREE NERVE-ENDINGS.

Free nerve-endings are found chiefly in the epithelium covering the skin or the mucous membranes. The nerve-fibres, after subdividing in the sub-epithelial connective tissue, lose successively their medullary and primitive sheaths and are continued as naked axis cylinders, which, if stained with gold chloride, are seen to consist of fine varicose filaments. The axis cylinders subdivide and form primary and secondary plexuses, and from the latter numerous fibrillæ pierce the sub-epithelial basement membrane and ramify between the overlying epithelial cells where they end in minute knobs of flattened discs. In the epidermis the nerve fibrillæ are limited to the stratum mucosum, but in the cornea they reach the surface layers of epithelium (Fig. 739). Free nerve-endings also occur around the sudoriferous glands, in the papillæ and root sheaths of the hair follicles, in the sub-epithelial and intermuscular connective tissues, and in serous membranes.

FIG. 739.—VERTICAL SECTION OF CORNEA STAINED WITH CHLORIDE OF GOLD (Ranvier).

a, b, primary plexus in connective tissue of cornea; *c*, branch passing to sub-epithelial plexus *e*; *f*, intra-epithelial plexus; *d*, terminations of fibrils.

Modifications of free nerve-endings are seen in the *tactile discs* or *cells of Merkel*; here the neuro-fibrillæ end in the deeper layers of the epidermis in crescentic or cup-shaped expansions, in contact with large, modified epithelial cells. These tactile discs are well marked in the pig's snout (Fig. 740).

SPECIAL END ORGANS.

The **special end organs** vary greatly in size and form, but in all of them the termination of the axis cylinder is enclosed within a connective tissue capsule or sheath of varying thickness. The following are the more important special end organs.

FIG. 740.—ENDING OF NERVE IN TACTILE DISCS OF THE PIG'S SNOUT (Ranvier). (From Quain's *Anatomy*.)

n, medullated fibre; *m*, terminal discs in muscle; *c*, cells from the stratum mucosum of the epidermis; *a*, somewhat modified cell to which a tactile disc is applied.

(1) **End Bulbs of Krause** (Fig. 742).—These are minute cylindrical or oval bodies which are found in the conjunctiva, in the mucous membrane of the lips, and in

the skin of the glans penis and glans clitoridis. Each consists of a thin connective tissue capsule enclosing a core of homogeneous or nucleated semifluid substance.

FIG. 741.—GRANDRY'S CORPUSCLES FROM THE DUCK'S TONGUE (Izquierdo). (From Quain's *Anatomy*.)

A, composed of three cells with two interposed discs, into which the axis cylinder of the nerve-cell is observed to pass. In B there is but one tactile disc enclosed between two tactile cells.

As the nerve-fibre pierces the capsule, it loses its medullary sheath, and the axis cylinder is continued into the core of the bulb where it may pursue a somewhat tortuous course, but more frequently divides into minute varicose fibrils which form an intricate plexus. The end bulbs of the glans penis and glans clitoridis are named *genital corpuscles* and differ from those just described in that they are larger and possess thicker capsules. Similar endings, termed *articular bulbs*, are found in the synovial membranes of certain joints, e.g. those of the fingers.

epithelial cells enclosed within a capsule, and the axis cylinder ends in flattened "tactile discs" which lie between the cells.

(2) **Corpuscles of Grandry** (Fig. 741).—These are seen in the skin covering the beaks of aquatic animals, and in the mucous membrane of the duck's palate. Each consists of two or more flattened

(3) **Corpuscles of Pacini** (Fig. 742).—These are widely distributed and consist of small oval bodies which measure from 2 to 3 mm. in length and about 1 mm. in width. They are found on the cutaneous nerves of the hand and foot, on the infra-orbital and intercostal nerves, on the cutaneous nerves of the neck, nipple, and mamma, and on the nerves of the solar plexus. They are present in the parietal peritoneum and on the nerves of the joints, and are very plentiful in the mesentery

FIG. 742.

FIG. 743.—HERBST CORPUSCLE OF DUCK (Sobotta).

n, medullated nerve-fibre; a, its axis cylinder ending in an enlargement; c, nuclei of cells of core; t, nuclei of cells of outer tunics; t', inner tunics.

of the cat. The capsule of the corpuscle consists of a number of connective tissue tunics arranged concentrically around a central core of more or less clear protoplasm; the deeper tunics are closely applied to each other, but those towards the circumference of the corpuscle are here and there separated by narrow lymphatic spaces. Each corpuscle is attached to a nerve trunk by a narrow pedicle composed of a single medullated nerve-fibre which pierces the capsule and, on reaching the core, loses its medullary sheath. The axis cylinder is continued into the core as

far as its distal end and there terminates in one or more enlargements in which the neuro-fibrillæ form a dense plexus. The corpuscles of **Herbst** (Fig. 743), which are found in the skin of birds, differ from the Pacinian corpuscles in that their cores consist of nucleated cells, between which the axis cylinder extends as a single or branched process.

(4) **Corpuscles of Golgi and Mazzoni**.—These are present in the subcutaneous tissue of the pulp of the fingers and also in other parts of the skin. Their capsules are thinner and their cores thicker than those of the Pacinian corpuscles, while their axis cylinders undergo a greater degree of ramification and their terminal filaments end in somewhat flattened expansions.

(5) **Tactile Corpuscles of Wagner and Meissner** (Fig. 742).—These are plentifully distributed in the papillæ of the corium of the hand, foot, and front of the forearm. They are found also in the skin of the lips, in the mucous membrane of the tip of the tongue, in the palpebral conjunctiva and the skin of the nipple. They are oval in shape, and their length varies from $\cdot 04$ mm. to $\cdot 15$ mm., and their thickness from $\cdot 03$ mm. to $\cdot 06$ mm. One or more nerve-fibres pierce the capsule of the corpuscle, losing, at the same time, their medullary sheaths. The axis cylinders, which are frequently varicose, assume a spiral or convoluted course and end in terminal enlargements. From the deep surface of the capsule imperfect membranous septa are continued inwards between the nerve ramifications.

FIG. 744.—AN ORGAN OF RUFFINI FROM THE SUBCUTANEOUS TISSUE (Ruffini). (From Quain's *Anatomy*.)
a, Entering nerve-fibres; b, d, endings of their axons; e, e, capsule of organ; e', core.

(6) **Organs of Ruffini** (Fig. 744).—These were found by Ruffini in the subcutaneous connective tissue of the fingers. They are of considerable size, and their shape is oval or fusiform. One or more nerve-fibres penetrate the side of the capsule, within which they pursue a curved course and then lose their medullary sheaths.

FIG. 745.—ORGAN OF GOLGI FROM THE HUMAN TENDO-CALCANEUS, CHLORIDE OF GOLD PREPARATION (Ciacceo). (From Quain's *Anatomy*.)

m, Muscular fibres; t, tendon bundles; G, Golgi's organ; n, two nerve-fibres passing into it.

The axis cylinders break up into a close-meshed network which lies between, or partly encircles, the smaller fasciculi of connective tissue.

(7) **Neuro-tendinous Spindles** (Fig. 745).—These were first described by Golgi in

1878. They consist of long spindle-shaped bodies, and are usually found near the junctions of the tendons with their muscles. Each is surrounded by a capsule which encloses a number of *intrafusal* tendon fasciculi. The nerve-fibres pierce the side of the capsule and then lose their medullary sheaths; the axis cylinders subdivide, and their terminal branches ramify between, or partly encircle, the smaller tendon bundles and end in plate-like expansions.

FIG. 746.—ENDING OF NERVE-FIBRES IN MUSCLE SPINDLE (Ruffini). (From Quain's *Anatomy*.)

Three intrafusal muscle fibres are shown: *x*, nerve-fibres entering spindle; *a*, axis cylinders terminating around and between the intrafusal fibres in *b*, ring-like; *c*, spiral; and *d*, irregularly ramified endings.

medullary sheaths and undergo subdivision; they are then prolonged in a spiral or annular manner around the individual muscular fibres and end in flattened or ovoid enlargements.

(8) **Neuro-muscular Spindles** (Fig. 746).—These are widely distributed throughout the voluntary muscles but are more numerous in the muscles of the limbs than in those of the trunk, and are plentifully found in the muscles of the hand and foot. They have not yet been seen in the intrinsic muscles of the tongue, and only a few are present in the ocular muscles. They lie in the connective tissue between the muscular bundles, and each consists of a lamellated capsule enclosing a fasciculus of striped muscular fibres (*intrafusal fibres*), together with minute blood-vessels and three or four medullated nerve-fibres. These intrafusal muscular fibres display many of the characteristics of embryonic muscle; they are smaller both in length and diameter than ordinary muscular fibres; they contain numerous nuclei near the centre of the spindle where their cross striation is less distinct; they also possess more protoplasm than ordinary muscular fibres. The nerve-fibres pierce the side of the capsule, inside which they lose their

THE VASCULAR SYSTEM.

BY THE LATE ALFRED H. YOUNG,
Professor of Anatomy, Victoria University, Manchester,
AND

ARTHUR ROBINSON,
Professor of Anatomy, University of Birmingham.

REVISED BY ARTHUR ROBINSON, F.R.S.E.,
Professor of Anatomy in the University of Edinburgh.

THE **vascular system** consists of a series of tubular vessels, with more or less distinct walls, which run through all parts of the body. Some contain blood, others are filled with a colourless fluid called lymph; hence the distinction between the **blood-vascular system** and the **lymph-vascular system**. The two systems differ, not only as regards their contents, but also in their relations to the tissues amongst which they lie; for whilst the vessels of the former system, with the possible exception of the splenic vessels, are closed, those of the latter communicate freely with intercellular spaces and serous sacs.

The **blood-vascular system** is tubular throughout; the tubes or vessels possess distinct walls; they vary in size and in the structure of their walls, but all contain blood, which is conveyed, through them, to and from the tissue elements of the body. The blood is propelled along the vessels chiefly by a central propulsive organ—the **heart**. The outgoing vessels from the heart, along which blood is transmitted to the tissues, are termed **arteries**; the vessels which return blood from the tissues to the heart are known as **veins**; whilst the smallest tubes—those which connect the arteries and veins together, constituting at once the terminations of the arteries and the commencements of the veins—are called **capillaries**.

Blood capillaries are very small (hair-like) vessels, with exceedingly thin walls which permit of the easy passage of the nutritive plasma outwards from the blood to the tissues, and, of the passage in the opposite direction, of some of the products of tissue changes and of modified food material from the alimentary canal.

Arteries and veins are simply conducting passages; structurally they differ from capillaries in the greater complexity of their walls. They vary greatly in size, but are always larger than capillaries. The calibre of each artery and vein increases progressively from the periphery up to the heart, where the vessels reach their greatest size. With the increase in calibre there is a corresponding increase in the thickness and complexity of the walls.

Structure of Blood Capillaries.—Capillaries measure from $8\ \mu$ to $12.5\ \mu$ in diameter, and about $.75\ \text{mm.}$ in length. Their walls are simple, and, in the smallest capillaries, consist principally of elongated elastic endothelial cells, with sinuous edges, pointed extremities, and oval nuclei. The cells are cemented to one another, along their margins, by intercellular cement, which readily stains with nitrate of silver. Here and there the cement substance appears to accumulate, forming minute spots indicative of the less perfect apposition of the edges of the cells. These spots, when small, form the so-called **stigmata**; when larger they are known as **stomata**.

The larger capillaries are invested by a connective tissue sheath consisting of branched cells which are united together and to the endothelial cells of the capillary wall. This sheath is termed the **tunica externa capillaris**.

Capillaries are arranged in networks, the nature and character of which differ

in different tissues. The small arteries which end in them are known as **capillary arterioles**, and the venous radicles which commence from them are appropriately termed **capillary veins**.

Structure of Arteries and Veins.—The delicate elastic endothelial membrane which forms the wall of the simplest capillaries extends also, as a continuous lining, throughout the whole of the blood-vascular system. In the arteries the constituent cells are fusiform, narrow, and pointed, whilst in the veins they are somewhat shorter and broader.

The most essential structural difference between capillaries on the one hand and the arteries and veins which they unite together on the other, is the presence, in

FIG. 747.—STRUCTURE OF BLOOD-VESSELS (diagrammatic).

A¹, Capillary—with simple endothelial walls. A², Larger capillary—with connective tissue sheath, "*adventitia capillaris*." B, Capillary arteriole—showing muscle cells of middle coat, few and scattered. C, Artery—muscular elements of the tunica media forming a continuous layer.

both of the latter, of involuntary muscular fibres which are interposed between the endothelial lining and the outer connective tissue sheath. In small vessels, *e.g.* capillary arterioles, the muscle cells are few in number and more or less scattered. In larger vessels the walls become stronger and thicker, muscular fibres increase and form a continuous layer, whilst yellow elastic and ordinary

white connective tissue are added in varying proportions. The walls of the vessels thus become more complex, and numerous strata may be distinguished; which, for convenience, are regarded as forming three layers, known as the *tunica intima* and the *middle* and *outer* tunics. Superadded to the tunics is the investing fibrous sheath or *vagina basis*.

Structure of Arteries.—The walls of arteries are stronger and thicker than those of veins of corresponding size, the tunica intima and middle tunic being particularly rich in elastic and muscular elements.

Tunica Intima.—In the tunica intima the endothelial lining is strengthened by the addition of yellow elastic tissue, the fibres of which are arranged in such a manner as to simulate a fenestrated membrane. In arteries of medium size the elastic lamina is separated from the endothelium by a layer of connective tissue consisting of branched cells and numerous fibrils. In the larger arteries the subendothelial connective tissue is considerably increased, and delicate elastic fibres appear which connect it with the more externally situated fenestrated elastic layer.

Tunica Media.—In the capillary arterioles the tunica media consists solely of scattered unstripped muscle fibres; the individual fibres are circularly disposed, but do not entirely surround the vessel. In small arteries the muscle cells are so far increased in amount that they form a continuous though thin layer. As the arteries increase in size additional layers of muscle cells are added, and the greater thickness of the arterial wall is mainly due to this increase of the muscular elements of the middle coat. In the larger vessels delicate laminae of elastic tissue alternate with the layers of muscular fibres, and in the aorta and the carotid arteries, as well as in some of the branches of the latter, the elastic elements largely preponderate. In the first part of the aorta, in the pulmonary artery, and in the arteries of the retina, the muscular fibres are entirely replaced by elastic tissue.

Tunica Externa.—The outer tunic of an artery consists almost entirely of fibrillated connective tissue, with connective tissue corpuscles lying in corre-

FIG. 748.—TRANSVERSE SECTION THROUGH THE WALL OF A LARGE ARTERY.

A, Tunica intima. B, Tunica media.
C, Tunica externa.

sponding spaces. In all but the smallest arteries numerous elastic fibres are also present. The elastic element is specially strong near the middle coat in small and medium sized vessels, and is sometimes described as the external elastic membrane. In some arteries longitudinally arranged unstripped muscular fibres are also found in the external coat.

Vagina Vasis.—In addition to the three tunics above described, arteries are enclosed in a **sheath** of the surrounding connective tissue, and are more or less connected with it by fine strands of fibrillated connective tissue.

Structure of Veins.—The walls of veins are similar in structure to those of arteries; they are, however, thinner, so much so, that, although veins are cylindrical tubes when full of blood, they collapse when empty and their lumina almost disappear. The structural details of the three tunics vary somewhat in different veins; in most the innermost tunic is marked by folds which constitute valves. Like the arteries, the veins are enclosed in connective tissue sheaths.

Tunica Intima.—In the majority of the veins the tunica intima includes an internal endothelial layer, a middle layer of subendothelial connective tissue, and an outer layer of elastic tissue. The innermost tunic of a vein is less brittle than the inner coat of an artery, and is more easily peeled off from the middle coat. The subendothelial tissue is a fine fibrillated connective tissue, less abundant than in the arteries, and in many cases it is absent. The elastic layer consists of lamellæ of elastic fibres which are arranged longitudinally; it rarely has the appearance of a fenestrated membrane.

One of the chief peculiarities of the tunica intima is the presence of folds of its substance which constitute **valves**. The valves are of semilunar shape, and they are usually arranged in pairs. Their convex borders are continuous with the vessel wall, and their free borders are turned towards the heart; whilst, therefore, they do not interfere with the free flow of blood from the periphery, they prevent any backward flow towards it, and they help to sustain the column of blood in all vessels in which there is an upward flow. Each valve consists of a fold of the endothelial layer, strengthened by a little connective tissue. As a general rule, the wall of the vein is dilated on the central side of each valve into a shallow pouch or sinus; consequently, when the veins are distended they assume a nodulated appearance. The valves are more numerous in the deep than in the superficial veins, and in the veins of children than in the veins of adults.

Tunica Media.—The middle tunic is much thinner than the corresponding tunic of an artery, and it contains a smaller amount of muscular and a larger amount of ordinary connective tissue; indeed, so much does the latter preponderate that it separates the muscular fibres into a number of bands isolated from each other by strands of connective tissue; therefore the muscle fibres do not form a continuous layer. In some of the veins the more internal muscular fibres do not retain the transverse direction which is usually met with both in arteries and veins; on the contrary, they run longitudinally. This condition is met with in the branches of the mesenteric veins, in the femoral and iliac veins, and in the umbilical veins. The middle tunic is absent in the thoracic part of the inferior vena cava; it is but slightly developed in many of the larger veins, whilst in the jugular veins its muscular tissue is very small in amount.

Tunica Externa.—This tunic consists of white fibrous and elastic tissue. In many of the larger veins a considerable amount of muscular tissue is also present; this is the case in the iliac and axillary veins, the abdominal part of the inferior vena cava, the azygos and hemiazygos veins, and in the renal, spermatic, splenic, superior mesenteric, portal, and hepatic veins. The striped muscle fibres of

FIG. 749.—TRANSVERSE SECTION OF THE WALL OF A VEIN.

A, Tunica intima. B, Tunica media.
C, Tunica externa.

the heart are prolonged into it at the terminations of the *venæ cavæ*. The external tunic is frequently thicker than the middle tunic, and the two are not easily separable from one another.

Vascular and Nervous Supply of Arteries and Veins.—Blood-vessels.—The walls of the blood-vessels are supplied by numerous small arteries, called *vasa vasorum*, which are distributed to the outer and middle tunics. They arise either from the vessels they supply or from adjacent arteries, and after a short course enter the walls of the vessels in which they end. The blood is returned by small *venæ vasorum*.

Lymphatics.—Although the cell spaces in the middle and inner tunics may be regarded as the commencement of lymphatics, definite lymphatic vessels are limited to the outer tunic.

Nerves.—Arteries and veins are well supplied with both medullated and non-medullated nerve-fibres. The fibres form dense plexuses on the outer surfaces of the vessels, from which filaments pass to the middle tunic to be distributed almost entirely to its muscular fibres.

Divisions of the Blood-Vascular System.—Blood-vessels convey blood to or from the tissues of the body generally, or to and from the lungs. The former constitute the **systemic vessels** or **general system**; the latter form the **pulmonary system**. These two systems are connected together by the heart.

The venous trunks passing to the liver, and their tributaries, form a subsidiary part of the general systemic group of vessels, which is known as the **portal system**.

COR.

The **heart** is a hollow muscular organ, which is enclosed in a fibro-serous sac known as the pericardium. It receives blood from the veins, and propels it into and along the arteries. The cavity of the fully developed heart is completely separated into right and left halves by an obliquely placed longitudinal septum, and each half is divided into an upper receiving chamber, the **atrium**, and a lower ejecting chamber, the **ventricle**. The separation of the atrium from the ventricle, however, is not complete. Externally a comparatively shallow constriction, running transversely to the long axis of the organ, indicates the distinction between the atria and ventricles; internally a wide aperture is left between the atrium and ventricle of each side. Each **atrio-ventricular aperture** is provided with a valve which allows the free passage of blood from the atrium to the ventricle, but effectually prevents its return.

It has already been pointed out that the delicate walls of the blood capillaries allow of the free passage outwards of nutritive plasma from the blood. The plasma passes into spaces, or intercellular channels, in which the tissue elements lie; thus the latter are directly bathed in blood plasma. The intercellular spaces may be looked upon as the commencement of the lymph-vascular system. They communicate together, and lymph passes from them into lymph vessels which carry the plasma back to the blood-vascular system, but in addition lymph vessels also convey new nutritive material, the product of digestive processes, from the alimentary canal.

Lymph vessels, in other words, convey material from the tissues. Blood-vessels convey material both to and from the tissues.

The removal of waste products from the blood is provided for by special organs, some of which are simply interposed in the course of the general circulation—*e.g.* the liver, the kidneys, and the skin. The lungs, however, where the impure or venous blood receives its main supply of oxygen and gives up most of its carbon dioxide, etc., do not lie in the course of the general or systemic circulation; for them a secondary or pulmonary circulation is established, by which venous blood is conveyed from the heart to the lungs by the pulmonary artery and its branches, and, after passing through the pulmonary capillaries, is returned again to the heart, as oxygenated or arterial blood, by the pulmonary veins.

The heart, anatomically a single organ, is correspondingly modified, and, as described above, it is divided by a septum into a right and a left part. The right side receives the blood from the systemic veins, and ejects it into the pulmonary artery; whilst the left side receives blood from the pulmonary veins, and ejects it into the main systemic artery—the aorta.

The **shape** of the heart is that of an irregular and somewhat flattened cone; and a base, an apex, two surfaces (inferior or diaphragmatic and antero-superior or sterno-costal), and three borders (right, left, and inferior) are distinguishable.

An oblique groove, the *sulcus coronarius*, runs transversely to the long axis of the organ, and separates the postero-superior or atrial portion from the antero-inferior or ventricular part. The separation of the atrial portion into right and left chambers is marked, externally, at the base of the heart only, where an indistinct interatrial groove exists. The division of the ventricular part into right and left ventricles is more definitely marked on the surface by anterior and an inferior longitudinal sulcus.

The heart lies in the middle mediastinum. It rests below on the diaphragm, and is enclosed in the pericardium, which intervenes between it and the neighbouring structures. Its long axis, from base to apex, runs obliquely from behind anteriorly, downwards, and to the left.

Basis Cordis.—The base which is formed by the atria, and almost entirely by

FIG. 750.—THE BASE AND DIAPHRAGMATIC SURFACE OF THE HEART, showing the openings of the great vessels and the line of reflection of the serous pericardium in a formalin hardened preparation.

the left atrium, is directed upwards, posteriorly, and to the right. It lies anterior to the descending thoracic aorta, the œsophagus, and the lower right pulmonary vein, which separate it from the bodies of the sixth, seventh, and eighth thoracic vertebrae.

On the whole the base is somewhat flattened. It is irregularly quadrilateral in form, and the terminations of the superior and inferior venæ cavæ and the four pulmonary veins pass through it. The opening of the superior vena cava is situated at the upper right angle, that of the inferior cava occupies the lower angle on the right side; between and a little to the left of these openings are the orifices of the two right pulmonary veins, and immediately to the right of the latter is the indistinct posterior interatrial sulcus, which descends to the left of the orifice of the inferior vena cava. The openings of the two left pulmonary veins are situated near the left border of the base; and the portion of the surface which lies between the right and left pulmonary veins forms the anterior boundary of the great oblique sinus of the pericardium.

The base is limited below by the inferior part of the coronary sulcus, in which the coronary sinus lies; its upper border is in relation with the pulmonary arteries. A fold of pericardium, the *vestigial fold*, descends, near the left border of the base, from the left branch of the pulmonary artery above to the left superior pulmonary vein below. It contains the ligamentum v. cavæ sinistræ, and from its lower end a small vein, the oblique vein of the left atrium, passes below the orifice of the lower left pulmonary vein, and descends to the coronary sinus. Further, it is from the base that the visceral layer of the pericardium, which elsewhere completely invests the heart, is reflected, the lines of reflection corresponding with the orifices of the great vessels.¹

FIG. 751.—THE STERNO-COSTAL SURFACE OF FORMALIN FIXED HEART.

The *apex*, bluntly rounded, is formed entirely by the left ventricle. It is directed downwards, anteriorly, and to the left, and is situated, under cover of the anterior borders of the left lung and pleura, behind the fifth left intercostal space, three and a half inches from the anterior median line.

The *diaphragmatic surface* is formed by the ventricular part of the heart. It rests upon the diaphragm, chiefly on the central tendon, but, upon the left side, on a small portion of the muscular substance also, and it is divided into two areas—a smaller to the right side and a larger to the left side—by an oblique antero-posterior groove, the *inferior interventricular sulcus*. It is separated from the base by the posterior or inferior portion of the coronary sulcus.

The *sterno-costal surface* is directed upwards, anteriorly, and to the left. It lies posterior to the body of the sternum and the medial extremities of the cartilages of the third, fourth, fifth, and sixth ribs on the right side, and a greater extent of the corresponding cartilages on the left side. This surface is separated into upper and lower sections by the anterior portion of the

¹ In the foetus and young child the atrial portion of the heart forms not only the base, but also the posterior part of the inferior or diaphragmatic surface.

coronary sulcus, which runs obliquely from above downwards, and from left to right, from the level of the third left to that of the sixth right costal cartilage. The upper section of the surface, which is concave anteriorly, is formed by the atria; it is separated from the sternum by the ascending aorta and the pulmonary artery, and is continuous laterally with the auricles of the atria which, projecting forwards, embrace the great vessels. The lower section of the sterno-costal surface is convex; it is formed by the ventricular part of the heart, and is divided, by an anterior interventricular sulcus, into a smaller left and a larger right part. At the junction of the atrial and ventricular parts of this surface are the orifices of the pulmonary artery and the aorta, the former lying anterior to the latter.

The *right margin* of the heart is formed by the right atrium. It lies posterior to the cartilages of the third, fourth, fifth, and sixth ribs on the right side, about half an inch from the margin of the sternum; it is in relation with the right pleura and lung, the phrenic nerve with its accompanying vessels intervening, and it is marked by a shallow groove—the *sulcus terminalis*—which passes from the front of the superior vena cava to the front of the inferior vena cava.

The *inferior margin* of the sterno-costal surface is sharp, thin, and usually concave corresponding with the curvature of the anterior part of the diaphragm; it is formed by the right ventricle, and it lies, almost horizontally, in the angle between the diaphragm and the anterior wall of the thorax, passing from the sixth right costal cartilage, posterior to the lower part of the body of the sternum, or the xiphoid process, and the cartilages of the sixth and seventh ribs on the left side, to the apex of the heart.

The *left margin* is formed mainly by the left ventricle, and only to a small extent by the left atrium, and is thick and rounded. It lies in relation with the left pleura and lung, the phrenic nerve and its accompanying vessels intervening, and it passes from just above the third left costal cartilage, about an inch from the sternum, to the apex of the heart, descending obliquely and with a convexity to the left.

FIG. 752.—THE RELATION OF THE HEART TO THE ANTERIOR WALL OF THE THORAX.

I, II, III, IV, V, VI, the upper six costal cartilages.

THE CHAMBERS OF THE HEART.

Atria.—The atrial or basal portion of the heart is cuboidal in form. Its long axis, which lies transversely, is curved, with the concavity of the curve forwards. It is divided into two chambers—the right and left atria—by a septum which runs from the anterior wall backwards and to the right, so obliquely that the right atrium lies anterior and to the right, and the left atrium posterior and to the left.

Each atrium is also somewhat cuboidal in form, the long axes of both being vertical, and each chamber possesses a well-marked ear-shaped, forward prolongation, which projects from its anterior and upper angle, and is known as the auricle.

Atrium Dextrum.—The right atrium receives, posteriorly, the superior vena cava above and the inferior vena cava below. Between these, and a little above its middle, it is crossed posteriorly by the lower right pulmonary vein. It is continuous below and anteriorly with the right ventricle at the atrio-ventricular

aperture. Above and anteriorly it is in relation with the ascending aorta, and from the junction of this aspect with the right lateral boundary the right auricle is prolonged anteriorly and to the left. Its right side forms the right margin of the heart, and is in relation with the right phrenic nerve and its accompanying vessels, and with the right pleura and lung, the pericardium intervening. On the left this atrium is limited by the oblique septum which separates it from the left atrium. The **sulcus terminalis** is a shallow groove on the surface of the right atrium, which passes from the front of the superior vena cava to the front of the inferior vena cava. It indicates the junction of the primitive sinus venosus with the atrium proper.

The interior of the right atrium is lined with a glistening membrane, the **endo-**

FIG. 753.—THE CAVITIES OF THE RIGHT ATRIUM AND RIGHT VENTRICLE OF THE HEART.
From a formalin fixed heart.

cardium; its walls are smooth, except anteriorly and in the auricle where muscular bundles, the **musculi pectinati**, form a series of small vertical columns. These terminate above in a crest, the **crista terminalis**, which corresponds in position with the **sulcus terminalis** externally.

At the upper and posterior part of the cavity is the opening of the superior vena cava, devoid of a valve. At the lower and posterior part is the orifice of the inferior vena cava, bounded, anteriorly, by the rudimentary **valve of the vena cava** (O.T. Eustachian); and immediately anterior and to the left of this valve, between it and the atrio-ventricular orifice, is the opening of the coronary sinus, guarded by the coronary valve. The atrio-ventricular aperture, guarded by a tricuspid valve, is known as the **tricuspid orifice**. It is situated in the inferior part of the anterior boundary, and admits three fingers. A number of small fossæ, **foramina venarum minimarum**, are scattered over the walls, and into some of these the **venæ cordis minimæ** open. In the septal wall is an oval depression, the **fossa ovalis**, bounded above and anteriorly by a raised margin, the **limbus fossæ ovalis**, which is continuous inferiorly with the valve of the vena cava; this fossa

is the remains of an aperture, the **foramen ovale**, through which the two atria communicated with each other before birth. Even in the adult a portion of the aperture persists at the upper part of the fossa in about one in five cases. Between the apertures of the superior and inferior venæ cavæ, and posterior to the upper part of the fossa ovalis, a small eminence may be distinguished, which is called the **tuberculum intervenosum**; it probably directs the blood from the superior vena cava to the tricuspid orifice during foetal life.

The **valvula venæ cavæ inferioris** is a thin and sometimes fenestrated fold of endocardium and subendocardial tissue, which extends from the anterior and lower margin of the orifice of the inferior vena cava to the anterior part of the limbus ovalis. It varies very much in size; is usually of falciform shape; its apex is attached to the limbus and its base to the margin of the inferior caval orifice. It is an important structure in the foetus, directing the blood from the inferior vena cava through the foramen ovale into the left atrium.

The **valvula sinus coronarii** is usually a single fold of endocardium which is

FIG. 754.—THE BASES OF THE VENTRICLES OF THE HEART, showing the auriculo-ventricular, aortic, and pulmonary orifices and their valves.

placed at the right margin of the orifice of the coronary sinus. It is almost invariably incompetent.

Atrium Sinistrum.—The left atrium is in relation posteriorly with the descending thoracic aorta and the œsophagus, but is separated from them by the pericardium. Below and anteriorly it is continuous with the left ventricle. Its sterno-costal surface is concave, and lies in close relation to the ascending aorta, the pulmonary artery, and the left coronary artery. Its right side, formed by the interatrial septum, is directed anteriorly and to the right. Its left side forms a very small portion of the left margin of the heart, and from it, at its junction with the antero-superior surface, the long and narrow auricle is prolonged forwards round the left side of the ascending portion of the aorta and the trunk of the pulmonary artery.

The four pulmonary veins enter the upper part of the posterior surface, two on each side.

The interior of the left atrium is lined with endocardium, and its walls are smooth, except in the auricle, where *musculi pectinati* are present, and on the septum, in a position corresponding with the upper part of the fossa ovalis on the right side, where there are several musculo-fibrous bundles radiating anteriorly and upwards. These septal bundles are separated at their bases by small semi-lunar depressions, in the largest of which remains of the foramen ovale may be found. Foramina venarum minimarum, and the apertures of venæ cordis minimæ, are scattered irregularly over the inner aspect, whilst in the inferior

part of the anterior boundary is the atrio-ventricular aperture. The latter is oval in form; its long axis is placed obliquely antero-posteriorly, and from left to right, and is capable of admitting two fingers. It is guarded by a valve formed of two large cusps, and is known as the **mitral orifice**.

Ventriculi.—The ventricular portion of the heart is conical and somewhat flattened. The base, directed upwards and posteriorly, is partly continuous with the atrial portion and partly free. It is perforated by four orifices, the two atrio-ventricular, the aortic, and the pulmonary. The atrio-ventricular orifices are placed, one on each side, inferiorly and posteriorly; anteriorly and between

them is the aortic orifice, whilst the orifice of the pulmonary artery is still more anterior, and slightly to the left of the aortic orifice.

In the triangle between the atrio-ventricular and the aortic orifices is embedded a mass of dense fibrous tissue which is the representative of the os cordis of the ox. It is continuous with the upper part of the interventricular septum, and with fibrous rings which surround the apertures at the bases of the ventricles.

The diaphragmatic surfaces and the sterno-costal surfaces of the two ventricles constitute respectively the greater portions of the corresponding surfaces of the heart; the former rest upon the diaphragm, whilst the latter are directed upwards and anteriorly towards the sternum and the costal cartilages of the left side. The apex of the left ventricle forms the **apex** of the heart.

The inferior margin, which is thin, forms the inferior margin of the heart; and the left margin, which is thick and rounded, forms the greater part of the left margin of the heart.

The ventricular portion of the heart is divided into right and left chambers by the **ventricular septum**, which is placed obliquely, with one surface directed anteriorly and to the right, and the other posteriorly and to the left; it bulges into the right ventricle, and its lower margin lies to the right of the apex of the heart, which is, therefore, formed entirely by the left ventricle. The margins of the septum are indicated on the two surfaces of the ventricular part of the heart by anterior and inferior interventricular sulci.

Ventriculus Dexter.—The **right ventricle** is triangular in form. Its base is directed upwards and to the right, and, in the greater part of its extent, it is continuous with the right atrium, with which it communicates by the atrio-ventricular orifice; but its left and anterior angle is free from the atrium, and gives origin to the pulmonary artery. Its inferior wall rests upon the diaphragm. The sterno-costal wall lies posterior to the lower part of the left half of the sternum and the cartilages of the fourth, fifth, and sixth ribs of the left side. The left or septal wall, which is directed posteriorly and to the left, bulges into its interior, and on this account the transverse section of the cavity has a semi-lunar outline. The cavity itself is a bent tube consisting of an inferior portion or **body** into which the atrio-ventricular orifice opens, and of an antero-superior part, the **infundibulum** or **conus arteriosus**, which terminates in the pulmonary artery.

A, Aortic orifice.

Ao, Aorta.

C, Clavicle.

LA, Left atrium.

LV, Left ventricle.

M, Mitral orifice.

P, Pulmonary orifice.

RA, Right atrium.

RV, Right ventricle.

SVC, Superior vena cava.

T, Tricuspid orifice.

The angle between the two limbs is formed by a thick ledge of muscle, the **supra-ventricular crest**.

The **right atrio-ventricular orifice** is guarded by a **tricuspid valve**. The three cusps of this valve are an *anterior*, which intervenes between the atrio-ventricular orifice and the infundibulum, a *medial* or *septal*, and an *inferior*. Each cusp consists of a fold of endocardium, strengthened by a little intermediate fibrous tissue. The bases of the cusps are generally continuous with each other at the atrio-ventricular orifice, where they are attached to a fibrous ring, but they may be separated by small intermediate cusps which fill the angles between the main segments. The apices of the cusps project into the ventricle. The margins, which are thinner than the central portions, are notched and irregular. The atrial surfaces are smooth. The ventricular surfaces are roughened, and, like the margins and apices, they give attachment to fine tendinous cords, the **chordæ tendineæ**. The opposite extremities of the chordæ tendineæ are attached to muscular bundles, the **musculi papillares**, which project from the wall into the cavity of the ventricle.

The **pulmonary orifice**, which lies anterior and to the left of the tricuspid orifice, is guarded by a **pulmonary valve** composed of three semilunar segments, two of which are placed anteriorly and one posteriorly. The convexity or outer border of each semilunar segment is attached to the wall of the pulmonary artery. The inner border is free, and it presents at its centre a small nodule, the **nodulus valvulæ semilunaris**, and on each side of this body a small, thin marginal segment of semilunar form, the **lunule**. Each segment of the valve is formed by a layer of endocardium on its ventricular surface, an endothelial layer of the inner coat of the artery on its arterial surface, and an intermediate stratum of fibrous tissue. Both the attached and the free margins of the cusps are strengthened by fibrous bands, and strands of condensed fibrous tissue radiate from the outer borders to the noduli, but they do not enter the lunulæ. When the valve closes the noduli are closely apposed, the lunulæ of the adjacent segments of the valve are pressed together, and both noduli and lunulæ project vertically upwards into the interior of the artery.

The cavity of the right ventricle is lined with endocardium; the walls are smooth in the *conus arteriosus*, but are rendered rugose and sponge-like in the body by the inward projection of numerous muscular bundles, the **trabeculæ carneæ**. These bundles are of two kinds: the simpler are merely columns raised in relief on the wall of the ventricle; the other class are rounded bundles, free in the middle, but attached at each end to the wall of the ventricle. One special bundle of the second group, called the **moderator band**, is attached by one extremity to the septum, and by the other to the sterno-costal wall, at the base of the anterior papillary muscle; it tends to prevent over-distension of the cavity. In addition to the trabeculæ carneæ conical muscular eminences, the **musculi papillares**, project into the cavity of the ventricle. The bases of the papillary muscles are continuous with the wall of the ventricle, and their apices terminate in numerous chordæ tendineæ which are attached to the apices, the borders, and ventricular surfaces of the cusps of the tricuspid valve.

The **musculi papillares** of the right ventricle are—(1) a large anterior muscle, from which the chordæ pass to the anterior and inferior segments of the valve; (2) a smaller and more irregular inferior muscle, sometimes represented by two or more segments, from which chordæ pass to the inferior and medial cusps; and (3) a group of muscular bundles, varying in size and number, which spring from the septum and are united by chordæ to the anterior and medial cusps.

The walls of the right ventricle, the septal excepted, are much thinner than those of the left, but the trabeculæ carneæ are coarser and less numerous in the right than in the left ventricle.

Ventriculus Sinister.—The left ventricle is a conical chamber, and its cavity is oval in transverse section. The base is directed upwards and posteriorly, and in the greater part of its extent it is continuous with the corresponding atrium, with which it communicates through the mitral orifice; but anteriorly and to the

right of its communication with the atrium it is continued into the ascending aorta.

The **mitral orifice** is oval; its long axis runs obliquely from above downwards and to the right, and it is guarded by a valve consisting of two cusps, which is known as the **bicuspid** or **mitral valve**. The two cusps of the valve are triangular and of unequal size. The smaller of the two is placed to the left and inferiorly; and the larger, placed to the right and anteriorly, between the mitral and aortic orifices, is known as the **aortic cusp**. The bases of the cusps are either continuous with each other at their attachments to the fibrous ring around the mitral orifice, or they are separated by small intermediate cusps of irregular form and size. The apices of the cusps project into the cavity of the ventricle. The atrial surfaces are smooth; the ventricular surfaces are roughened by the attachments of the chordæ tendineæ, which are connected also with the irregular and notched margins and with the apices. The structure is the same as that of the cusps of the tricuspid valve, but the ventricular surface of the anterior cusp is relatively smooth; therefore the blood flow into the aorta is not impeded.

The **aortic orifice** is circular; it lies immediately anterior and to the right of the mitral orifice, from which it is separated by the anterior cusp of the mitral valve, and it is guarded by the **aortic valve**, formed of three semilunar segments, one of which is placed anteriorly and the other two posteriorly. The structure of these cusps and their attachments are similar to those of the cusps of the pulmonary valve.

The cavity of the left ventricle is separable, like that of the right, into two portions, the body and the aortic vestibule; the latter is a small section placed immediately below the aortic orifice; its walls are non-contractile, consisting of fibrous and fibro-cartilaginous tissue. The wall of the cavity is lined by endocardium. The inferior wall and the apex are rendered sponge-like by numerous fine trabeculæ carneæ, whilst the upper part of the sterno-costal wall and the septum are relatively smooth.

There are two papillary muscles of much larger size than those met with in the right ventricle—an anterior and an inferior; each is connected by chordæ tendineæ with both cusps of the mitral valve.

The walls of the left ventricle are three times as thick as those of the right ventricle, and they are thickest in the region of the widest portion of the cavity, which is situated about a fourth of its length from the base. The muscular portion of the wall is thinnest at the apex, but the thinnest portion of the boundary is at the upper part of the septum, which consists entirely of fibrous tissue; this part is occasionally deficient, and an aperture is left through which the cavities of the two ventricles communicate.

The **ventricular septum** is a musculo-membranous partition. It is placed obliquely, one surface looking anteriorly and to the right, and bulging into the right ventricle, and the other looking posteriorly and to the left towards the left ventricle. Its sterno-costal and inferior margins correspond respectively with the anterior and the inferior portions of the interventricular sulcus, and it extends from the right of the apex to the interval between the pulmonary, the aortic, and the atrio-ventricular orifices. In the main part of its extent it is muscular, and this portion is developed from the wall of the ventricular part of the heart; but its upper and posterior portion, the **pars membranacea**, which is developed from the septum of the tunicus arteriosus, is entirely fibrous, and constitutes the thinnest portion of the ventricular walls. The **pars membranacea** lies between the aortic vestibule of the left ventricle, on the left, and the upper part of the right ventricle, and the lower and left part of the right atrium, on the right.

STRUCTURE OF THE HEART.

The walls of the heart consist mainly of peculiar striped muscle, the **myocardium**, which is enclosed between the visceral layer of the pericardium, or **epicardium**, externally, and the **endocardium** internally. The muscular fibres differ from those of ordinary voluntary striped

muscle in several ways: they are shorter, many of them being oblong cells with forked extremities which are closely cemented to similar processes of adjacent cells; they form a reticulum, and the nuclei lie in the centres of the cells. Moreover, still more peculiar fibres, the fibres of Purkinje, are found immediately beneath the subendocardial tissue. These are large cells which unite with each other at their extremities; their central portions consist of granular protoplasm, in which sometimes one but more frequently two nuclei are embedded, and the peripheral portion of each cell is transversely striated. These cells, in short, present in a permanent form a condition which is transitory in all other striped muscle cells.

The reticulating cardiac muscle cells are grouped in sheets and strands which have a more or less characteristic and definite arrangement in different parts of the heart; by careful dissection, and after special methods of preparation, it is possible to recognise many layers and bundles, some of which are, however, probably artificially produced.

In the **atria** the muscular fasciculi fall naturally into two groups: (a) superficial fibres common to both atria; (b) deep fibres special to each atrium.

The **superficial fibres** are most numerous on the sterno-costal aspect and in the neighbourhood of the coronary sulcus. They run transversely across the atria and a few of them dip into the interatrial septum.

The deep fibres are—(1) looped fibres. The extremities of the looped fibres are attached to the fibrous rings around the atrio-ventricular orifices and the fibres pass antero-posteriorly over the atria. (2) Annular fibres which surround (a) the extremities of the large vessels which open into the atria; (b) the auricles; (c) the fossa ovalis.

In the **ventricles** the muscular fasciculi form more or less definite V-shaped loops which commence from and end at the fibrous rings which surround the large orifices at the bases of the ventricles. In their courses the loops embrace the cavities of either one or both ventricles, one stem of each loop lying on the outer surface of the heart and the other in the interior, and some of the loops possessing very acute whilst others have very open bends.

The superficial fibres on the sterno-costal surface pass towards the left, those on the inferior surface towards the right. At the apex all are coiled into a whorl or *vortex* through which they pass into the interior of the ventricular walls and ascend towards the base, some in the septum and others in the papillary muscles. The various bundles which have been described can, according to Mall, be resolved into two main systems. One system arises from the conus arteriosus and the root of the aorta, that is from the remains of the primitive aortic trunk: it is called the "bulbo-spiral" system. The other springs from the region of the primitive venous sinus and is termed the "sino-spiral." Both systems are separable into superficial and deep portions, and the general plan of more or less spirally curved V-shaped loops is retained in each, but the details of the arrangement are too complicated for consideration within the limits of an ordinary text-book (see *Amer. Journ. of Anat.* vol. ii. 1910-1911).

The **Atrio-Ventricular Bundle**.—It would appear from the preceding description that the muscle-fibres of the atria and the ventricles are entirely separated from each other by the fibrous rings which surround the atrio-ventricular orifices; that, however, is not the case, for the two groups are connected together by a bundle of muscle fibres of pale colour and rudimentary structure, which lies immediately adjacent to the endocardium and constitutes the atrio-ventricular bundle.

The bundle commences in a nodular enlargement which lies in the lower part of the wall of the right atrium, close to the base of the medial cusp of the tricuspid valve. From this point the bundle runs along the posterior and lower borders of the membranous part of the ventricular septum to the upper and posterior part of the muscular portion of the septum, where it divides into right and left branches. The right branch runs along the right side of the ventricular septum to the moderator band, along which it passes into the anterior papillary muscle of the right ventricle. The left branch runs along the left side of the septum and both branches give off numerous ramifications, by means of which the main bundle is associated with all parts of the walls of the two ventricles.

Both the function and the origin of the atrio-ventricular bundle are uncertain. After the discovery of the bundle it was asserted that impulses were conveyed from the atria to the ventricles by the muscle fibres of the atrio-ventricular bundle and by them alone; more recently it has been shown that minute nerve fibrils are intimately intermingled with the muscle fibres of the bundle, and it has yet to be decided whether the impulses which pass from the atria to the ventricles, for the purpose of maintaining the proper sequence of the movements of the chambers, travel by the nerve fibrils or the muscle fibres or by both.

The atrio-ventricular bundle is probably a remnant of the muscular continuity which existed in the early stages of development between the atrial and ventricular chambers of the heart, but it may be, wholly or in part, a new formation.

The **epicardium**, or visceral portion of the pericardium, consists of white connective and of elastic tissue, the latter forming a distinct reticulum in the deeper part. The surface which looks towards the pericardial cavity is covered with flat polygonal endothelial plates, which are partially separated, here and there, by stomata, through which the pericardial cavity communicates with the lymphatics of the epicardium.

The **endocardium** lines the cardiac cavities and is continuous with the inner coats of the vessels which enter and leave the heart. It consists, like the epicardium, of white connective tissue and elastic fibres, but it is much thinner than the epicardium, and its elastic fibres are in some places blended into a fenestrated membrane. Its inner surface is covered with endothelial cells, and it rests externally upon the subendocardial tissue, in which there are blood-vessels and nerves; the endocardium itself is entirely devoid of vessels.

Size of the Heart.—The heart is about 125 mm. (five inches) long, 87 mm. (three and a half inches) broad; its greatest depth from its sterno-costal to its diaphragmatic surface is 62 mm. (two and a half inches), and it is roughly estimated as being about the same size as the closed fist. The size, however, is variable, the volume increasing at first rapidly, and then gradually, with increasing age, from 22 cc. at birth to 155 cc. at the fifteenth year, and to 250 cc. by the twentieth year. From this period to the fiftieth year, when the maximum volume (280 cc.) is attained, the increase is much more gradual, and after fifty a slight decrease sets in. The volume is the same in both sexes up to the period of puberty, but thereafter it preponderates in the male.

Weight.—The average weight of the heart in the male adult is 310 grms. (11 ounces), and in the female adult 255 grms. (9 ounces); but the weight varies greatly, always, however, in definite relation to the weight of the body, the relative proportions changing at different periods of life. Thus at birth the heart weighs 24 grms. ($13\frac{1}{2}$ drachms), and its relation to the body weight is as 1 to 130, whilst in the adult the relative proportion is as 1 to 205. The heart is said to increase rapidly in weight up to the seventh year, then more slowly up to the age of puberty, when a second acceleration sets in; but after the attainment of adult life the increase, which continues till the seventieth year, is very gradual.

The above changes affect the whole heart, but the several parts also vary in their relation to each other at different periods of life. During fetal life the right atrium is heavier than the left; in the first month after birth the two become equal, and at the second year the right again begins to preponderate, and it is heavier than the left during the remainder of life. In the latter part of fetal life the two ventricles are equal; after birth the left grows more rapidly than the right, until, at the end of the second year, a position of stability is gained, when the right is to the left as 1 to 2, and this proportion is maintained until death.

Capacity.—During life the capacity of the ventricles is probably the same, and each is capable of containing about four ounces of blood, whilst the atria are a little less capacious. After death the cavity of the right ventricle appears larger than that of the left.

Vascular Supply of the Heart.—The walls of the heart are supplied by the coronary arteries (p. 887), the branches of which pass through the interstitial tissue to all parts of the muscular substance and to the subendocardial and subepicardial tissues; the endocardium and the valves are devoid of vessels. The capillaries, which are numerous, form a close-meshed network around the muscular fibres. Sometimes the valves contain a few muscular fibres, and in these cases they also receive some minute vessels. The majority of the veins of the heart end in the coronary sinus, which opens into the lower part of the right atrium; some few very small veins, however, open directly into the right atrium, and others are said to end in the left atrium, and in the cavities of the ventricles.

Lymphatics of the Heart.—Lymphatic vessels are freely distributed throughout the whole substance of the heart. They all communicate with the superficial network which lies beneath the epicardium. The efferent vessels from this network accompany the coronary arteries to the atrio-ventricular sulcus and pass thence to the anterior mediastinal glands.

Nerves of the Heart.—The heart receives its nerves from the superficial and deep cardiac plexuses. The former lies beneath the aortic arch and the latter between the arch and the bifurcation of the trachea, and through the plexuses it is connected with the vagus, the accessory (through the vagus), and the sympathetic nerves. After leaving the cardiac plexuses many of the nerve-fibres enter the walls of the atria and anastomose together in the subepicardial tissue, forming a plexus in which many ganglion cells are embedded, especially near the terminations of the inferior vena cava and the pulmonary veins. From the subepicardial atrial plexus, nerve filaments, on which nerve ganglion cells have been found, pass into the substance of the atrial walls.

Other fibres from the cardiac plexuses accompany the coronary arteries to the ventricles, and upon these also ganglion cells are found in the region immediately below the coronary sulcus.

The nerve-fibres which issue from the ganglionated plexuses of the heart are non-medullated. They form fine plexuses round the muscle fibres, and they terminate either in fine fibrils on the surfaces of the muscle fibres, or in nodulated ends which lie in contact with the muscle cells.

PERICARDIUM.

The **pericardium** is a fibro-serous sac which surrounds the heart. It lies in the middle mediastinum, and is attached below to the diaphragm, and above and posteriorly to the roots of the great vessels. Anteriorly and posteriorly it is in relation with the structures in the corresponding mediastina and laterally it is in close apposition with the pleural sacs.

The **fibrous pericardium** is a strong fibrous sac of conical form; its base is attached to the central tendon and to the adjacent part of the muscular substance of the diaphragm, and it is pierced by the inferior vena cava. At its apex and posteriorly it is gradually lost upon the great vessels which enter and emerge from the heart, giving sheaths to the aorta, the two branches of the pulmonary artery, the superior vena cava, the four pulmonary veins, and the ligamentum arteriosum. Its anterior surface forms the posterior boundary of the anterior

mediastinum, and it gives attachment, above and below, to the superior and inferior sterno-pericardial ligaments. In the greater part of its extent it is separated from the anterior wall of the thorax by the anterior margins of the lungs and pleural sacs, but it is in direct relation with the left half of the lower portion of the body of the sternum and, in many cases, with the medial ends of the cartilages of the fourth, fifth, and sixth ribs of the left side and the left transversus thoracis muscle. Its posterior surface forms the anterior boundary of the posterior mediastinum; it

FIG. 756.—POSTERIOR WALL OF THE PERICARDIUM AFTER THE REMOVAL OF THE HEART. Showing the relation of the serous pericardium to the great vessels.

is in relation with the cesophagus and the descending aorta, both of which it separates from the back of the left atrium. Each lateral aspect is in close contact with the mediastinal portion of the parietal pleura, the phrenic nerve and its accompanying vessels intervening. The inner surface of the fibrous sac is lined by the serous pericardium, which is closely attached to it.

The serous pericardium is a closed sac containing a little fluid (liquor pericardii). It is surrounded by the fibrous pericardium and invaginated by the heart. It is, therefore, separable into two portions—the parietal, which lines the inner surface of the fibrous sac, and the visceral, which ensheaths, or partially ensheaths, the heart and the great vessels; but the two portions are, of course, continuous with each other where the serous layer is reflected on to the great vessels as they pierce the fibrous layer. The majority of the great vessels receive only partial coverings from the visceral layer: thus, the superior vena cava is covered anteriorly and on

each side; the pulmonary veins anteriorly, above, and below; and the inferior vena cava anteriorly and on each side. The aorta and the pulmonary artery are enclosed together in a complete sheath of the visceral layer. Therefore, when the pericardial sac is opened from the front, it is possible to pass the fingers behind them and in front of the atria, from the right to the left side, through a passage called the **great transverse sinus** of the pericardium (Fig. 756). The spaces or pouches which intervene between the vessels which receive partial coverings from the serous pericardium are also called sinuses; and the largest of them, which is bounded below and on the right by the inferior vena cava, and above and on the left by the left inferior pulmonary vein, is known as the **great oblique sinus**. It passes upwards and to the right behind the left atrium, and lies anterior to the œsophagus and the descending thoracic aorta.

A small fold of the serous pericardium, the **vestigial fold**, passes from the left pulmonary artery to the left superior pulmonary vein, posterior to the left extremity of the transverse sinus. It merits special attention because it encloses a fibrous strand, the *ligamentum venæ cavæ sinistræ*. This is a remnant of the left superior vena cava or duct of Cuvier, which atrophied at an early period of foetal life.

Structure.—The fibrous pericardium consists of ordinary connective tissue fibres felted together into a dense, unyielding membrane. The serous pericardium is covered on its inner aspect by a layer of flat endothelial cells. These rest upon a basis of mixed white and elastic fibres in which run numerous blood-vessels, lymphatics, and nerves.

ARTERIÆ.

ARTERIA PULMONALIS.

The **pulmonary artery** springs from the anterior and left angle of the base of the right ventricle, at the termination of the *conus arteriosus*. It is slightly larger at its commencement than the aorta, and is dilated, immediately above the valves, into three pouches, the **sinuses** of the pulmonary artery. It runs upwards and posteriorly, towards the concavity of the aortic arch, curving from the front round the left side of the ascending aorta to reach a plane posterior to the latter; and it terminates, by dividing into right and left branches, opposite the sixth thoracic vertebræ. Its length is a little more than two inches.

Relations.—The pulmonary artery is enclosed within the fibrous pericardium, and is enveloped, along with the ascending aorta, in a common sheath of the visceral layer of the serous pericardium. It lies behind the anterior extremity of the second left intercostal space, from which it is separated by the anterior margins of the left lung and pleural sac.

Its posterior relations are the bulb of the aorta, the anterior wall of the left atrium, and the first part of the left coronary artery. To the right it is in relation with the right coronary artery, the auricle of the right atrium, and the ascending aorta, and to the left with the left coronary artery and the auricle of the left atrium. Immediately above its bifurcation, between it and the aortic arch, is the superficial cardiac plexus.

The **right branch of the pulmonary artery** is longer and larger than the left. It passes to the hilus of the right lung, forming one of the constituents of its root, and, entering the lung, descends, with the main bronchus, to the lower extremity of the organ.

Relations.—Before it enters the lung the right pulmonary artery passes posterior to the ascending aorta, the superior vena cava, and the upper right pulmonary vein. At first it lies below the arch of the aorta and the right bronchus, anterior to the œsophagus, and above the left atrium and the lower right pulmonary vein; then it crosses anterior to the right bronchus, immediately below the eparterial branch, and reaches the hilus of the lung. After entering the lung the artery descends, posterior and lateral to the main bronchus and between its ventral and dorsal branches.

Branches.—Before entering the hilus it gives off a large branch to the upper lobe of the right lung which accompanies the eparterial bronchus, and in the substance of

the lung it gives off numerous branches which correspond with and accompany the dorsal, ventral, and accessory branches of the right bronchus.

The **left branch of the pulmonary artery**, shorter, smaller, and somewhat higher in position than the right, passes laterally and posteriorly from the bifurca-

tion of the pulmonary stem, and runs, in the root, to the hilus of the left lung; it then descends, in company with the main bronchus, to the lower end of the lung.

Relations.—Before it enters the lung it is crossed, *anteriorly*, by the upper left pulmonary vein; *posterior to* it, are the left bronchus and the descending aorta; *above*, are

the aortic arch, to which it is connected by the ligamentum arteriosum, and the left recurrent nerve; *below*, it is in relation with the lower left pulmonary vein. After entering the lung it descends, like the right pulmonary artery, posterior and lateral to the stem bronchus, and between its ventral and dorsal branches.

Branches.—Just before passing through the hilus it gives off a branch to the upper lobe of the left lung, and in the substance of the lung its branches correspond with the ventral, dorsal, and accessory branches of the bronchial tube.

THE SYSTEMIC ARTERIES.

AORTA.

The **aorta** is the main trunk of the general arterial system. It commences at the base of the left ventricle and ascends, with an inclination to the right, to the level of the second right costal cartilage; then, curving backwards and to the left, it reaches the left side of the lower border of the fourth thoracic vertebra; finally it descends, through the thorax into the abdomen, and terminates, on the left of the median plane, at the level of the fourth lumbar vertebra, by bifurcating into the two common iliac arteries. The portion of the aorta which is situated in the thorax is, for convenience, termed the *thoracic aorta*, and the rest of the vessel is known as the *abdominal aorta*.

AORTA THORACALIS.

The thoracic aorta is subdivided into aorta ascendens, arcus aortæ, and aorta descendens.

Aorta Ascendens.—The ascending aorta lies in the middle mediastinum. It springs from the base of the left ventricle, posterior to the left margin of the sternum, opposite the lower border of the third left costal cartilage and the body of the sixth thoracic vertebra. From its origin it passes upwards, anteriorly, and to the right, and it terminates in the arch of the aorta, posterior to the right margin of the sternum, at the level of the second costal cartilage. Its *length* is from 50 to 56 mm. (2 to 2¼ inches), and its breadth is 28 mm. (1½ inches). In the adult it is a little narrower at its commencement than the pulmonary artery is, but in old age it enlarges and exceeds the latter vessel in size. The diameter, however, is not uniform throughout the whole length of the ascending aorta. Its dilated commencement, the **bulbus aortæ**, has three secondary dilatations, the **sinus aortæ** (Valsalva) in its wall, immediately above the semilunar cusps of the aortic valve; one is anterior in position, and two are situated posteriorly. At a higher level there is a diffuse bulging of the right wall, which is known as the *great sinus* of the aorta.

Relations.—The ascending aorta is completely enclosed within the fibrous pericardium which blends above with the sheath of the vessel, and it is enveloped, together with the stem of the pulmonary artery, in a tubular prolongation of the serous pericardium. At its origin it has the pulmonary artery in front, the anterior wall of the left atrium behind, and the auricle of the right atrium on its right side. In the upper part of its course the ascending aorta is overlapped by the anterior margins of the right lung and right pleural sac, whilst posterior to it are the right atrium, the right branch of the pulmonary artery, the right bronchus, and the left margin of the superior vena cava. The superior vena cava lies on the right side, and partly posterior to the upper part of the ascending aorta, whilst the pulmonary artery is at first anterior to it and then, at a higher level, on its left side.

Branches.—Two branches arise from the ascending aorta, viz., the right and the left coronary arteries. The right coronary artery springs from the anterior, and the left from the left posterior sinus of the aorta (Valsalva) (Fig. 751).

Arcus Aortæ.—The arch of the aorta lies in the superior mediastinum, posterior to the lower part of the manubrium sterni, and connects the ascending with the descending aorta. It commences posterior to the right margin of the sternum, on a level with the second costal cartilage, and extends to the left side of the lower

border of the fourth thoracic vertebra. As its name implies, it forms an arch; and the arch makes two curves, one with the convexity upwards, and the other with the convexity forwards and to the left. From its origin it runs for a short distance upwards, posteriorly, and to the left, anterior to the trachea; then it passes posteriorly, round the left side of the trachea to the left side of the body of the fourth thoracic vertebra. Finally it turns downwards to become continuous with the descending aorta.

At its commencement it has the same diameter as the ascending aorta, 28 mm. ($1\frac{1}{8}$ inches), but after giving off three large branches, the diameter is reduced to 23 mm. (a little less than one inch).

Relations.—It is overlapped anteriorly and on the left side by the right and left lungs and pleural sacs, but much more by the left than the right, and in the interval between and posterior to the anterior borders of the pleural sacs it is covered by the remains of the thymus. As it turns backwards it is crossed vertically, on the left side, by four nerves in the following order from before backwards:—the left phrenic, the inferior cervical cardiac branch of the left vagus, the superior cardiac branch of the left sympathetic, and the trunk of the left vagus. The left superior intercostal vein passes obliquely upwards and to the right, across it, between the left vagus and left phrenic nerves.

Posterior to, and *to the right side* of the arch, are the trachea, the deep cardiac plexus, the left recurrent nerve, the left border of the œsophagus, and the thoracic duct. *Above* are its three large branches—the innominate, the left common carotid, and the left subclavian arteries; and crossing anterior to the roots of these is the left innominate vein. *Below* is the bifurcation of the pulmonary artery and the root of the left lung; the ligamentum arteriosum, which is also below, attaches it to the commencement of the left pulmonary artery, whilst to the right of the ligament is the superficial cardiac plexus, and to its left is the left recurrent nerve.

Branches.—The three great vessels which supply the head and neck, part of the thoracic wall, and the upper extremities—viz. the innominate, the left common carotid, and the left subclavian arteries—arise from the aortic arch.

Aorta descendens.—The thoracic portion of the **descending aorta** lies in the posterior mediastinum; it extends from the termination of the arch, at the lower border of the left side of the fourth thoracic vertebra, to the aortic opening in the diaphragm, where, opposite the twelfth thoracic vertebra, it becomes continuous with the abdominal portion. Its length is from 17.5 to 20 cm. (seven to eight inches), and its diameter diminishes from 23 mm. at its commencement to 21 mm. at its termination.

Relations.—Immediately *posterior to* it are the vertebral column and the anterior longitudinal ligament. It rests also on the accessory hemiazygos and the hemiazygos veins, whilst from its posterior aspect the aortic intercostal branches are given off.

Anteriorly it is in relation, from above downwards, with the root of the left lung, the pericardium, which separates it from the back of the left atrium, the œsophagus with the œsophageal plexus of nerves, and the crura of the diaphragm which separate it from the caudate lobe of the liver. On the *left side* are the left lung and pleura. On the *right side* the thoracic duct and the vena azygos form immediate relations along its whole length. The œsophagus also lies to the right of the upper part of the descending aorta, whilst the right lung and pleura are in relation below.

Branches.—Nine pairs of aortic intercostal arteries, two left bronchial arteries, four or five œsophageal, some small pericardial, and a few posterior mediastinal and superior phrenic branches, usually arise from the descending aorta.

AORTA ABDOMINALIS.

The abdominal portion of the descending aorta lies in the epigastric and umbilical regions of the abdomen. It extends from the middle of the lower border of the last thoracic vertebra to the body of the fourth lumbar vertebra, where, to the left of the median plane, it bifurcates into the right and left common iliac arteries. The point of division is a little below and to the left of the umbilicus, opposite

a line drawn transversely across the abdomen on a level with the highest points of the iliac crests.

At its commencement it is 21 mm. in diameter, but after the origin of two large branches, the celiac and the superior mesenteric arteries, it diminishes considerably, and then retains a fairly uniform diameter to its termination.

Relations.—*Posteriorly*, it is in contact with the upper four lumbar vertebræ and intervening fibro-cartilages, the anterior longitudinal ligament, and the left lumbar veins ;

FIG. 758.—THE ABDOMINAL AORTA AND ITS BRANCHES IN A FORMALIN-HARDENED PREPARATION.

the lumbar and the middle sacral arteries spring from the posterior surface of the vessel. *Anteriorly*, and in close relation with it, there are from above downwards the following structures: the celiac axis and celiac plexus, the pancreas and splenic vein, the superior mesenteric artery, the left renal vein, the third part of the duodenum, the root of the mesentery, the aortic plexus, the inferior mesenteric artery, the peritoneum and coils of small intestine. More superficially the stomach, the transverse colon, and the greater and lesser omenta are in front. On the *right side*, in the upper part of its extent, are the thoracic duct and cisterna chyli, the vena azygos, and the right crus of the diaphragm, the latter separating it from the right celiac ganglion and from the upper part of the

inferior vena cava. In its lower part it is in direct relation with the inferior vena cava. On the *left side*, the left crus of the diaphragm with the left cœliac ganglion, and the terminal portion of the duodenum, are in close relation with its upper part, whilst in the lower portion of its extent the peritoneum and some coils of the small intestine are in contact with it. Lumbar lymph glands lie around it on all sides.

Branches.—The branches form two groups, visceral and parietal, and each group consists of paired and unpaired vessels, as follows :—

Visceral.		Parietal.	
Unpaired.	Paired.	Unpaired.	Paired.
Cœliac	Suprarenal	Middle sacral (which is the original continuation)	Inferior phrenic
Superior mesenteric	Renal		
Inferior mesenteric	Testicular or ovarian		Lumbar (four pairs) Common iliac

BRANCHES OF THE ASCENDING AORTA.

ARTERIÆ CORONARIÆ.

The coronary arteries are two in number, a right and a left ; they are distributed almost entirely to the heart, but give also some small branches to the roots of the great vessels, and to the pericardium (Figs. 750, 751, and 754).

The **right coronary artery** springs from the anterior aortic sinus. It runs forwards, between the root of the pulmonary artery and the auricle of the right atrium, to the coronary sulcus, in which it passes to the right, and then, turning round the right margin of the heart, is continued to the left as far as the posterior end of the inferior interventricular sulcus, where it gives off its interventricular branch and then ends by anastomosing with the circumflex branch of the left coronary artery. It is accompanied by branches from the cardiac plexus, and is in relation with the right coronary vein.

Branches.—The **interventricular branch** runs forwards in the inferior interventricular sulcus, supplies both ventricles, and anastomoses, at the apex of the heart, with the interventricular branch of the left coronary artery.

Aortic and pulmonary twigs are distributed to the roots of the aorta and pulmonary artery respectively. A **right atrial branch** passes upwards on the anterior surface of the right atrium, between it and the ascending aorta ; one or more **anterior ventricular branches**, of small size, descend on the anterior surface of the right ventricle ; a branch of larger size, the **right marginal artery**, runs along the inferior margin and gives branches to both surfaces of the right ventricle.

The **left coronary artery** arises from the left posterior aortic sinus. Its trunk is short, and it runs forwards, between the root of the pulmonary artery and the left auricle, to the coronary sulcus at the upper end of the anterior interventricular groove, where it divides into a circumflex and an interventricular branch.

Branches.—The **circumflex branch** runs to the left margin of the heart, and there turns to the inferior surface where it comes into relation with the coronary sinus ; it ends by anastomosing with the right coronary artery. It supplies branches to the left atrium, the left margin of the heart, and the posterior part of the inferior surface of the left ventricle. The **interventricular terminal branch** passes down the anterior interventricular sulcus to the apex of the heart, where it anastomoses with the interventricular branch from the right coronary ; it supplies both ventricles, and is accompanied by cardiac nerves and by the great cardiac vein.

A **left atrial branch** or branches of small size pass to the wall of the left atrium, and small **aortic and pulmonary branches** are also given to the roots of the aorta and pulmonary artery.

BRANCHES OF THE ARCH OF THE AORTA.

The branches which arise from the arch of the aorta supply the head and neck, the upper extremities, and part of the body wall.

They are three in number, viz., the **innominate**, the **left common carotid**, and the **left subclavian arteries**. The innominate is a short trunk, from the termination of which the right common carotid and the right subclavian arteries spring (Figs. 756 and 757); thus there is, at first, a difference between the stem vessels of opposite sides, but beyond this the subsequent course and the ultimate distribution of these vessels closely correspond.

ARTERIA ANONYMA.

The **innominate artery** (Fig. 757) arises, posterior to the middle of the manubrium sterni, from the convexity of the arch of the aorta near its right or anterior extremity, and it terminates opposite the right sterno-clavicular articulation, where it divides into the right subclavian and right common carotid arteries.

Course.—The trunk, which measures from 37 to 50 mm. ($1\frac{1}{2}$ to 2 inches) in length, runs upwards, posteriorly, and laterally in the superior mediastinum and the root of the neck.

Relations.—*Posterior.*—It is in contact behind, with the trachea below and with the right pleural sac above.

Anterior.—The left innominate vein crosses in front of the lower part of the artery, and above this the sterno-thyroid muscle separates it from the sterno-hyoid and the right sterno-clavicular joint. The remains of the thymus, which separate it from the manubrium sterni, are also in front.

Right Lateral.—The right innominate vein and the upper part of the superior vena cava are on the right side of the artery.

Left Lateral.—On its left side is the origin of the left common carotid artery, whilst at a higher level the trachea is in contact with it.

Branches.—As a rule the innominate artery does not give off any branches except its two terminals, but occasionally it furnishes an additional branch, the thyreoidea ima.

The **thyreoidea ima** is an inconstant and slender vessel. When present it sometimes arises from the arch of the aorta, but it springs usually from the lower part of the innominate. It passes upwards, anterior to the trachea, through the anterior part of the superior mediastinum and the lower part of the neck, and gives off branches to the lateral lobes and isthmus of the thyreoid body and to the trachea.

THE ARTERIES OF THE HEAD AND NECK.

The vessels distributed to the head and neck are chiefly derived from the carotid trunks; there are, however, in addition, other vessels which arise from the main arterial stems of the upper extremities, and it will be advantageous to describe the most important of these, viz., the vertebral arteries, with the carotid system. The smaller additional branches will be considered along with the remaining branches of the subclavian arteries.

The **carotid system of arteries** consists, on each side, of a **common carotid trunk**, which divides into **internal** and **external carotid arteries**, from which numerous branches are given off.

The internal carotid arteries are distributed, almost entirely, to the contents of the cranial cavity, internal to the dura mater, and to the structures in the cavity of the orbit. The external carotid arteries, on the other hand, supply structures of the head and neck more externally situated.

It is to be observed, however, that the vascular supply of the brain is not wholly derived from the internal carotid vessels, but that the vertebral arteries also contribute largely to it.

ARTERIE CAROTIDES COMMUNES.

The right and the left **common carotid arteries** are of unequal length. The right common carotid commences at the bifurcation of the innominate artery

posterior to the right sterno-clavicular articulation; the left arises in the superior mediastinum, from the arch of the aorta; but each terminates at the level of the upper border of the thyroid cartilage; the left artery has thus a short intra-thoracic course, and, so far, its relations call for separate consideration; whilst in the rest of its course it passes upwards in the neck, like the right common carotid, and has almost similar relations.

Thoracic Portion of the Left Common Carotid.—The thoracic or mediastinal portion of the left common carotid artery extends from the upper aspect of the aortic arch, immediately posterior and to the left of the origin of the innominate artery, to the left sterno-clavicular articulation, where the cervical portion commences. It is from 25 to 37 mm. (1 or $1\frac{1}{2}$ inches) in length, and it runs upwards and slightly laterally through the upper part of the superior mediastinum, lying on a more posterior plane than the innominate artery.

Relations.—*Posterior.*—The vessel is in contact posteriorly, and from below upwards, with the trachea, the left recurrent nerve, the œsophagus, and the thoracic duct; and the thoracic part of the left subclavian artery is a postero-lateral relation.

Anterior.—The left innominate vein runs obliquely across the anterior aspect of the artery, upon which cardiac branches from the left vagus and sympathetic descend vertically. These structures, together with the remains of the thymus and the anterior margins of the left lung and pleura, separate the artery from the manubrium sterni, and from the origins of the sterno-hyoid and sterno-thyroid muscles.

Medial.—The innominate artery below, and the trachea above, are on the right side.

Lateral.—The left pleura, and, on a posterior plane, the left phrenic and vagus nerves and the left subclavian artery are on its left side.

Cervical Portion of the Left Common Carotid Artery.—The cervical part of the left common carotid artery is about 85 mm. (three and a half inches) long; it extends from the left sterno-clavicular articulation to the level of the upper border of the thyroid cartilage and the lower border of the third cervical vertebra, where it ends by dividing into the external and internal carotid arteries.

Course.—It runs upwards, laterally, and backwards, through the muscular and the lower portion of the carotid divisions of the anterior triangle of the neck. In the lower part of its extent it is separated from its fellow of the opposite side by the trachea and the œsophagus, and in the upper part by the relatively wide pharynx.

Relations.—It is enclosed, together with the internal jugular vein and the vagus nerve, in a sheath of deep cervical fascia—the **carotid sheath**.

Posterior.—The longus colli and scalenus anterior below, and the longus capitis above, are separated from the posterior surface of the artery and its sheath by the prevertebral fascia and the sympathetic trunk. The vertebral artery and the thoracic duct are posterior to it at the level of the seventh cervical vertebra; the inferior thyroid artery crosses behind it, either between it and the vertebral or between it and the transverse process of the sixth cervical vertebra, and the vagus nerve lies postero-lateral to it.

Superficial.—The descendens branch of the hypoglossal nerve lies superficial to the artery, usually outside the sheath, but sometimes enclosed in it. Opposite the sixth cervical vertebra the omo-hyoid muscle and the sterno-mastoid branch of the superior thyroid artery cross superficial to the carotid artery, which is overlapped, above the omo-hyoid muscle, by the anterior border of the sterno-mastoid and by cervical lymph glands. It is frequently crossed, in this part of its extent, by the superior thyroid vein. Below the omo-hyoid the artery is covered by the sterno-thyroid, the sterno-hyoid, and the sterno-mastoid muscles, and it may be overlapped by the lateral lobe of the thyroid gland; it is also crossed, deep to the muscles, by the middle thyroid vein, whilst occasionally a communication between the common facial and anterior jugular veins descends anterior to the artery along the anterior border of the sterno-mastoid. Just above the sternum the anterior jugular vein is in front of the artery, but separated from it by the sterno-hyoid and sterno-thyroid muscles.

Medial.—The trachea and œsophagus, with the recurrent nerve in the angle between them, are medial to the lower part of the artery; the pharynx and larynx are medial to its upper part. The carotid gland or glomus caroticum lies on the medial side of the termination of the artery.

Lateral.—The internal jugular vein occupies the lateral part of the carotid sheath, and lies not only to the lateral side of the artery, but also overlaps it, especially in the lower part of its extent.

Branches.—As a rule no branches are given off from either of the common carotid arteries, except the terminal branches and some minute twigs from each to the corresponding carotid sheath and carotid gland.

The **right common carotid artery**, as already stated, differs as regards origin

FIG. 759.—DISSECTION OF THE CAROTID AND SUBCLAVIAN ARTERIES AND THEIR BRANCHES.

from the left common carotid. In length and general position it corresponds with the cervical portion of the left common carotid, and its relations also are very similar. Such differences as exist may be briefly summarised as follows:—The internal jugular vein on both sides lies lateral to the artery; on the left side in the lower part of the neck it is anterior to the artery, whilst on the right side the vein is separated from the lateral surface of the artery, at its lower end, by a well-marked interval in which the vagus nerve appears. The thoracic duct does not come into relation with the right common carotid, and there is also a difference in the relations of the recurrent nerves to the arteries on the two sides. On the left side the nerve crosses posterior to the mediastinal part of the left artery, and lies medial to its cervical part, whilst the corresponding nerve on the right side

passes posterior to the lower part of the carotid artery in the neck to reach its medial side, and the œsophagus has a less intimate relation with the right than with the left common carotid artery.

ARTERIA CAROTIS EXTERNA.

The **external carotid artery** (Fig. 759) is the smaller of the two terminal branches of the common carotid; its length is about 62 mm. (2½ inches). It extends from the upper border of the thyroid cartilage to the back of the neck of the mandible, where it terminates by dividing into the superficial temporal and the internal maxillary arteries.

Course.—It commences in the carotid triangle, passes upwards, medial to the posterior belly of the digastric and the stylo-hyoid muscles and the lower part of the postero-medial surface of the parotid gland, then it enters a groove in the medial border of the gland, through which it passes to the upper part of the antero-medial surface, posterior to the neck of the mandible, where it terminates.

At its commencement it lies somewhat anterior and medial to the internal carotid artery, but, inclining posteriorly as it ascends, it becomes superficial to the latter vessel. Its course is indicated by a line drawn from the lobule of the ear to the posterior extremity of the greater cornu of the hyoid bone.

Relations.—*Posterior.*—In the lower part of its extent it is in close relation with the internal carotid; and in the upper part of its course with the antero-medial surface of the parotid gland.

Medial.—At its commencement the fibres of the inferior constrictor muscle are in contact with its medial side, but at a higher level the structures which intervene between it and the internal carotid—viz., the stylo-pharyngeus muscle, the tip of the styloid process, the stylo-glossus muscle, the glosso-pharyngeal nerve, and the pharyngeal branch of the vagus—separate it from the wall of the pharynx; whilst medial both to it and to the internal carotid artery are the external and internal laryngeal branches of the superior laryngeal nerve.

Superficial.—In the carotid triangle the lingual, common facial, and sometimes the superior thyroid veins are superficial to it, and the hypoglossal nerve crosses the artery immediately below the origin of its occipital branch. At a higher level it is crossed superficially by the posterior belly of the digastric and the stylo-hyoid muscles, and from the tip of the mastoid process downwards it is overlapped by the anterior border of the sterno-mastoid muscle. Above the posterior belly of the digastric the parotid gland is superficial to the artery, while still more superficially are the superficial fascia and the skin. In the substance of the parotid gland the posterior facial vein (O.T. temporo-maxillary) descends on the lateral side of the artery, and the facial nerve crosses on the lateral side of the vein, at right angles to it.

Branches.—Eight branches arise from the external carotid artery; of these, three—the superior thyroid, the lingual, and the external maxillary—spring from its anterior aspect in the carotid triangle; two arise from its posterior aspect, viz., the occipital and the posterior auricular, the former commencing below the posterior belly of the digastric and the latter above it; one from its medial side, viz., the ascending pharyngeal, which arises in the carotid triangle; and two from its termination, viz., the superficial temporal and the internal maxillary.

BRANCHES OF THE EXTERNAL CAROTID ARTERY.

(1) **Arteria Thyreoidea Superior.**—The **superior thyroid artery** (Figs. 759 and 761) springs from the anterior aspect of the lower part of the external carotid artery, just below the tip of the greater cornu of the hyoid bone, and terminates at the upper extremity of the lateral lobe of the thyroid gland by dividing into its terminal branches.

Course.—From its commencement, in the carotid triangle, the artery runs downwards and forwards to its termination.

Relations.—*Medially* it is in relation with the inferior constrictor muscle and the external laryngeal branch of the superior laryngeal nerve.

Superficially it is covered at its origin by the anterior border of the sterno-mastoid;

afterwards, for a short distance, by fascia, platysma, and skin, and in the lower part of its extent by the omo-hyoid, the sterno-hyoid, and the sterno-thyroid muscles, and it is overlapped by an accompanying vein.

Branches.—(1) *In the carotid triangle*—(a) A **hyoid branch** runs along the lower border of the greater cornu of the hyoid bone, under cover of the thyreo-hyoid muscle, to anastomose with its fellow of the opposite side and with the hyoid branch of the lingual artery. It supplies the thyreo-hyoid muscle and membrane.

(b) The **superior laryngeal branch** runs forwards, deep to the thyreo-hyoid muscle. It pierces the thyreoid hyo-membrane, in company with the internal laryngeal nerve, supplies the muscles, ligaments, and mucous membrane of the larynx, and anastomoses with its fellow of the opposite side, with branches of the crico-thyroid artery, and with the terminal branches of the inferior thyreoid artery.

(c) The **sterno-cleido-mastoid branch** passes downwards and posteriorly, along the upper border of the anterior belly of the omo-hyoid muscle and across the common carotid artery, to the deep surface of the sterno-mastoid muscle. It anastomoses, in the sterno-mastoid, with branches of the occipital and transverse scapular arteries.

(2) *In the muscular triangle*—(d) A **crico-thyroid branch** passes anteriorly, either superficial or deep to the sterno-thyroid, and crosses the crico-thyroid muscle to anastomose in front of the crico-thyroid ligament with its fellow of the opposite side, and, by branches which perforate the crico-thyroid ligament, with laryngeal branches of the superior and inferior thyreoid arteries. It supplies the adjacent muscles and membrane.

(e) The **terminal branches** are **anterior** and **posterior**.

The **anterior terminal branch** descends along the anterior border of the lateral lobe of the thyreoid gland, and, extending on to the upper border of the thyreoid isthmus, anastomoses with its fellow of the opposite side. The **posterior branch**, larger than the anterior, descends along the posterior border of the lateral lobe. It is not uncommonly represented by a medial and a lateral branch. Both terminal branches supply glandular branches to the thyreoid gland. They anastomose with each other and with branches from the inferior thyreoid artery.

(2) **Arteria Lingualis.**—The **lingual artery** (Figs. 759 and 761) springs from the anterior aspect of the external carotid, opposite the tip of the greater cornu of the hyoid bone, and terminates, as the *arteria profunda linguæ* (O.T. *ranine artery*), which ends beneath the tip of the tongue, where it anastomoses with its fellow of the opposite side.

Course.—Whilst in the carotid triangle, the first part of the artery forms a loop with the convexity upwards. The second part passes forwards, medial to the hyo-glossus muscle, immediately above the greater cornu of the hyoid bone, to the anterior border of the muscle, where it gives off a sublingual branch and becomes the *arteria profunda linguæ*. The profunda linguæ artery passes obliquely forwards and upwards, under cover of the anterior border of the hyo-glossus, and then turns directly forwards on the under surface of the tongue to the tip, lying between the inferior lingualis laterally and the genio-glossus medially.

Relations.—The first part of the lingual artery is crossed superficially by the hypoglossal nerve, and is covered by skin, fascia, and the platysma; it rests medially against the middle constrictor of the pharynx. The second part is deeper. It lies between the middle constrictor medially and the hyo-glossus laterally, and is separated by the latter from the hypoglossal nerve, the vena comitans hypoglossi, and the lower part of the sub-maxillary gland. The profunda artery of the tongue ascends almost vertically, parallel with and medial to the anterior fibres of the hyo-glossus, which is here covered by the mylo-hyoid, and between the hyoglossus and the genio-glossus; then it runs forwards between the inferior lingualis and the genio-glossus muscles, and is covered, on its lower surface, by the mucous membrane of the tongue. Thus, at its termination, near the frenulum linguæ, it is comparatively superficial.

Branches.—(a) The **ramus hyoideus**, a small branch which arises in the carotid triangle and runs along the upper border of the great cornu of the hyoid bone. It anastomoses with its fellow of the opposite side and with the hyoid branch of the superior thyreoid artery.

(b) The **dorsalis linguæ** is a branch of moderate size which arises from the second part of the artery and is not uncommonly double. It ascends between the hyo-glossus and the genio-glossus to the dorsum of the tongue, where it branches and anastomoses with its fellow of the opposite side around the foramen cæcum. It supplies the posterior part of

the tongue as far back as the epiglottis, and sends branches, posteriorly, to the palatine tonsil which anastomose with the tonsillar twigs of the ascending palatine branch of the external maxillary and with the ascending pharyngeal artery.

(c) A **sublingual branch** arises at the lower part of the anterior border of the hyoglossus muscle and runs anteriorly and upwards, between the mylo-hyoid and the genio-glossus, to the sublingual gland, which it supplies; it also supplies the mylo-hyoid, the genio-glossus, and the genio-hyoid muscles. It anastomoses with its fellow of the opposite side, with the *arteria profunda* by a branch which it sends along the *frenulum linguae*, and through the mylo-hyoid muscle with the submental branch of the external maxillary.

(3) **Arteria Maxillaris Externa (O.T. Facial).**—The external maxillary artery (Fig. 759) springs from the front of the external carotid, immediately above the lingual, and terminates at the angle of the mouth, where it becomes the angular artery.

Course.—It commences in the carotid triangle immediately above the lingual, and passes upwards to the angle of the mandible, on the lateral surface of the middle constrictor muscle. Still ascending, it lies between the posterior belly of the digastric and the stylo-hyoid muscles laterally, and the superior constrictor medially, and it is separated from the palatine tonsil by the superior constrictor. When it reaches the upper border of the stylo-hyoid it enters a groove in the posterior end of the submaxillary gland through which it ascends. Then it turns downwards and anteriorly, between the lateral surface of the gland and the internal pterygoid muscle, and reaches the lower border of the masseter. There it pierces the deep cervical fascia, and, turning round the inferior border of the mandible, enters the face and continues upwards and medially to its termination.

Relations.—In the carotid triangle the artery is comparatively superficial, except just at its origin, which is overlapped by the anterior fibres of the sterno-mastoid muscle. As it ascends it is in relation, on the medial side, with the middle and superior constrictor muscles, and, as already stated, the superior constrictor separates it from the palatine tonsil. Its relations between its entrance into the groove in the posterior end of the submaxillary gland and the lower border of the mandible have been given in the description of its course.

After turning round the lower border of the body of the mandible, which it grooves slightly, the artery becomes more superficial than in any other part of its course, being covered only by platysma, fascia, and skin. At this point the anterior facial vein is immediately posterior to the artery, lying on the surface of the masseter. In the face the artery lies between the platysma, the risorius, the zygomaticus major, and the infra-orbital section of the quadratus labii superioris (O.T. levator labii superioris), which, with skin and fascia, are superficial to it, and the buccinator and the musculus caninus (O.T. levator anguli oris), which are deeper. The termination of the artery is in the substance of the quadratus labii superioris.

The anterior facial vein, though still posterior to the artery in the face, runs a somewhat straighter course, and is situated at some little distance from it.

Branches.—Four named branches are given off in the neck, and several in the face.

In the Neck.—(a) The **ascending palatine branch** (Fig. 761) is a small artery which arises from the external maxillary under cover of the posterior belly of the digastric. It ascends, and, passing between the stylo-glossus and the stylo-pharyngeus muscles, reaches the apex of the petrous portion of the temporal bone, where it turns downwards, accompanying the levator veli palatini muscle, pierces the pharyngeal aponeurosis, and enters the soft palate.

It supplies the lateral wall of the upper part of the pharynx, the soft palate, the palatine tonsil, and the auditory (O.T. Eustachian) tube, and it anastomoses with the tonsillar branch of the external maxillary, the *dorsalis linguae*, the descending palatine branch of the internal maxillary, and with the ascending pharyngeal artery, which sometimes replaces it.

(b) The **tonsillar branch**, a small artery which arises close to the ascending palatine. It passes upwards between the internal pterygoid and the stylo-glossus, pierces the superior constrictor, and terminates in the palatine tonsil. It supplies the middle and superior constrictor muscles, and it anastomoses with the *dorsalis linguae*, with the ascending palatine branch, and with the ascending pharyngeal artery.

(c) The **submaxillary or glandular branch** is frequently represented by two or three small twigs which pass directly into the submaxillary gland.

(*d*) The **submental branch** arises from the external maxillary just as the latter vessel turns round the inferior border of the mandible. It is the largest branch given off in the neck, and it runs forwards, on the lateral surface of the mylo-hyoid muscle, and medial to the upper part of the submaxillary gland, to the symphysis menti, where it turns upwards, round the margin of the mandible, and terminates by anastomosing with branches of the mental and inferior labial arteries. In the neck the submental artery supplies the mylo-hyoid muscle, and the submaxillary and sublingual glands, the latter by a branch which perforates the mylo-hyoid muscle. It anastomoses with the mylo-hyoid branch of the inferior dental and with the sublingual artery. In the face it supplies the structures of the lower lip, and anastomoses with the mental branch of the inferior dental, and with the inferior labial branches of the external maxillary artery.

In the Face.—(*e*) The **inferior labial branch** (O.T. **inferior coronary**) arises from the front of the external maxillary artery below the level of the angle of the mouth. It runs medially, deep to the triangularis, the quadratus labii inferioris, and the orbicularis oris. In the substance of the lower lip it lies close to the mucous membrane and anastomoses, in the median plane, with its fellow of the opposite side. It supplies the structures in its immediate neighbourhood.

(*f*) The **superior labial** (O.T. **superior coronary**) springs from the front of the external maxillary about the level of the angle of the mouth. It runs medially, between the orbicularis oris and the mucous membrane of the upper lip, to the median plane, supplying the skin, muscles, and mucous membrane of the upper lip, and, by a *septal branch*, the lower and anterior part of the septum of the nose. It anastomoses with its fellow of the opposite side, with the lateral nasal, and, on the septum nasi, with the septal branch of the sphenopalatine artery.

(*g*) The **masseteric branch**, sometimes represented by several twigs, arises from the posterior aspect of the facial trunk a short distance above the lower margin of the mandible. It passes upwards and posteriorly, across the masseter, and anastomoses with the transverse facial artery.

(*h*) The **buccal** is an inconstant branch which, when present, arises from the posterior aspect of the external maxillary artery above the masseteric branch. It runs upwards and posteriorly, across the buccinator muscle, to anastomose with the buccinator branch of the internal maxillary artery.

(*i*) The **lateral nasal** springs from the external maxillary at the point where it becomes the angular. It ramifies on the ala of the nose, supplying the skin, muscles, and alar cartilages, and anastomosing with the angular branch, with the dorsal nasal branch of the ophthalmic, and with branches of the sphenopalatine artery.

(*j*) The **angular artery** is the continuation of the external maxillary beyond the origin of the lateral nasal branch. It runs upwards, in the angular head of the quadratus labii superioris, to the medial commissure of the eye, where it anastomoses with the lateral nasal, and with the nasal and palpebral branches of the ophthalmic artery.

In addition to the above-named branches another branch, formerly called the inferior labial, springs from the anterior aspect of the external maxillary below the level of the alveolar border of the mandible. This vessel runs medially, under cover of the muscles of the lower lip, and it anastomoses with the mental branch of the inferior alveolar artery, with the inferior labial (O.T. inferior coronary), and with its fellow of the opposite side.

(4) **Arteria Occipitalis.**—The **occipital artery** (Figs. 759, 760) arises from the posterior aspect of the external carotid artery, below the posterior belly of the digastric muscle, and terminates near the medial end of the superior nuchal line of the occipital bone by dividing into medial and lateral terminal branches.

Course.—It commences in the carotid triangle and runs upwards and posteriorly, parallel with and under cover of the posterior belly of the digastric, to the interval between the transverse process of the atlas and the base of the skull, where it turns posteriorly in a groove on the lower surface of the mastoid portion of the temporal bone; as it leaves the groove it alters its direction and runs upwards and medially, on the superior oblique muscle, to the junction of the medial and intermediate thirds of the superior nuchal line of the occipital bone, where it pierces the deep fascia of the neck and enters the superficial fascia of the scalp.

Relations.—In the first or ascending part of its course the occipital artery crosses successively the internal carotid artery, the hypoglossal nerve, the vagus nerve, the internal jugular vein, and the accessory nerve; it is covered by the lower fibres of the posterior

belly of the digastric and the anterior part of the sterno-mastoid muscle, and, close to its origin, it is crossed by the hypoglossal nerve. In the second, or more horizontal part of its course, it is still under cover of the sterno-mastoid and digastric, and lies, medially, against the rectus capitis lateralis, which separates it from the vertebral artery. In the third part of its course it rests upon the superior oblique and semispinalis capitis (O.T. complexus), and is under cover of the sterno-mastoid, the splenius capitis, and the longissimus capitis muscles. At its termination it is crossed by the great occipital nerve; it passes either through the trapezius or between the trapezius and the sterno-mastoid, and pierces the deep fascia of the neck before it enters the superficial fascia of the scalp.

Branches.—(a) **Muscular branches** go to the surrounding muscles. The **sterno-mastoid branch** is the most important of this group; it springs from the commencement of the occipital, is looped downwards across the hypoglossal nerve, and is continued downwards and posteriorly, below and anterior to the accessory nerve, into the sterno-mastoid muscle, where it anastomoses with the sterno-mastoid branch of the superior thyroid artery.

(b) The **meningeal** are irregular branches given off from the occipital, anterior to the mastoid process. They enter the posterior fossa of the skull through the hypoglossal canal, or through the jugular foramen; they supply the upper part of the internal jugular vein, the transverse sinus, and the dura mater in the posterior fossa of the skull, and they anastomose with the middle meningeal and with meningeal branches of the ascending pharyngeal artery.

(c) The **mastoid**, a small and inconstant branch given off from the occipital posterior to the mastoid process. It enters the posterior fossa of the skull through the mastoid foramen, supplies the dura mater, and anastomoses with branches of the middle meningeal artery.

(d) The **descending branch** (O.T. *princeps cervicis*) is given off from the occipital upon the surface of the superior oblique. It passes medially to the lateral border of the semispinalis capitis, where it divides into superficial and deep branches. The superficial branch runs over the semispinalis capitis, between it and the trapezius, and anastomoses with the superficial cervical artery. The deep branch runs between the semispinalis capitis and the underlying semispinalis cervicis, and anastomoses with branches of the vertebral and profunda cervicis arteries.

(e) The **auricular** is an inconstant branch which, as a rule, is only given off from the occipital when the posterior auricular artery is absent. It ramifies over the mastoid process, and supplies the medial surface of the auricle.

(f) The **terminal branches** (*rami occipitales*) are medial and lateral. They ramify in the superficial fascia of the posterior part of the scalp, anastomosing with the posterior auricular and superficial temporal arteries, and both are accompanied by branches of the great occipital nerve. The medial branch gives off a meningeal twig, which passes into the skull through the parietal foramen, to supply the walls of the superior sagittal sinus and to anastomose with the middle meningeal artery.

(5) **Arteria Auricularis Posterior.**—The **posterior auricular artery** (Figs. 759, 760) springs from the posterior aspect of the external carotid immediately above the posterior belly of the digastric muscle, and terminates between the mastoid process and the back of the auricle by dividing into mastoid and auricular branches.

Course and Relations.—Commencing at the upper border of the posterior belly of the digastric, it runs upwards and posteriorly, under cover of the postero-medial surface of the parotid gland, to the interval between the mastoid process and the external acoustic meatus. It is accompanied in the terminal part of its course by the posterior auricular branch of the facial nerve.]

Branches.—(a) **Muscular branches** are given to the sterno-mastoid, the digastric, and the styloid group of muscles.

(b) **Parotid branches** pass to the lower and posterior part of the parotid gland.

(c) A **stylo-mastoid branch** is given off at the lower border of the external acoustic meatus. It runs upwards, by the side of the facial nerve, enters the stylo-mastoid foramen, and ascends, in the canalis facialis (Fallopian), to the upper part of the medial wall of the tympanum, where it terminates by anastomosing with the petrosal branch of the middle meningeal artery. It supplies branches to the external acoustic meatus, the mastoid cells, the vestibule, and semicircular canals, the stapedius muscle, and a *posterior tympanic branch* which anastomoses with the anterior tympanic branch of the internal maxillary, forming, in young subjects, a vascular circle around the membrana tympani; other branches

anastomose with tympanic branches from the internal carotid and the ascending pharyngeal arteries, and with the internal auditory branch of the basilar.

(*d*) The **auricular branch** ascends medial to the posterior auricular muscle. It gives branches to the auricle and to the scalp in the posterior part of the temporal region, which anastomose with the superficial temporal and occipital arteries. The auricular branches supply both surfaces of the auricle, piercing or turning round the margins of the cartilage to gain the lateral surface, and they anastomose with the anterior auricular branches of the superficial temporal artery.

(*e*) The **occipital branch** runs upwards and posteriorly along the insertion of the sterno-mastoid muscle. It supplies the sterno-mastoid and occipitalis muscles, and the skin, and it anastomoses with the occipital artery.

(6) **Arteria Pharyngea Ascendens—The Ascending Pharyngeal Artery** (Fig. 761).—This artery arises from the medial surface of the lower part of the external carotid, and its terminal branches are distributed to the wall of the pharynx and in the soft palate.

Course.—Commencing in the carotid triangle, usually as the first or second branch of the external carotid, it ascends on the wall of the pharynx to the apex of the petrous portion of the temporal bone.

Relations.—Medially it is in relation with the constrictor muscles of the pharynx. Posterior to it are the transverse processes of the cervical vertebræ, the sympathetic trunk, and the longus capitis. Laterally it is in relation with the internal carotid artery, and it is crossed by the stylo-pharyngeus muscle, the glossopharyngeal nerve, and the pharyngeal branch of the vagus.

Branches.—The branches of this artery are very irregular and inconstant, but the following have received names:—

(*a*) **Pharyngeal Branches.**—Small twigs which ramify on the walls of the pharynx and supply the middle and superior constrictor muscles, the palatine tonsil, and the lower part of the auditory tube (O.T. Eustachian). They anastomose with branches of the superior thyreoid, lingual, and external maxillary arteries.

(*b*) **Prevertebral.**—Small branches distributed to the prevertebral muscles and fascia, the deep cervical glands, and the large nerve trunks. They anastomose with the ascending cervical and vertebral arteries.

(*c*) **Posterior Meningeal.**—One or more small branches which enter the cranium by the hypoglossal canal, the jugular, or the lacerate foramen, and supply the dura mater. They anastomose with branches of the middle meningeal and vertebral arteries.

(*d*) **Inferior Tympanic.**—A small artery which accompanies the tympanic branch of the glossopharyngeal nerve to the tympanic cavity, where it anastomoses with the other tympanic arteries.

(*e*) **Palatine.**—A very variable artery which sometimes replaces the ascending palatine branch of the external maxillary artery. When present it springs from the upper part of the ascending pharyngeal artery, pierces the pharyngeal aponeurosis above the upper border of the superior constrictor muscle, and descends into the soft palate with the levator veli palatini muscle. It supplies the mucous membrane of the supero-lateral part of the pharyngeal wall and the tissues of the soft palate, and it anastomoses with the palatine branches of the internal maxillary, the external maxillary and the lingual arteries.

(7) **Arteria Temporalis Superficialis** (Fig. 759).—The **superficial temporal artery**, one of the terminal branches of the external carotid, commences between the upper part of the antero-medial surface of the parotid gland, and the neck of the mandible, and terminates in the scalp, from 25 to 50 mm. (1 or 2 inches) above the zygomatic arch, by dividing into a parietal and a frontal branch.

Course.—The artery ascends over the posterior root of the zygoma, and passes into the superficial fascia of the temporal region. It is accompanied by the auriculo-temporal nerve and by the superficial temporal vein, which usually lies posterior to it. As it crosses the zygoma it is covered by the skin alone, and it may be easily compressed against the subjacent bone.

Branches.—(*a*) **Parotid.**—Small branches to the upper part of the parotid gland.

(*b*) **Articular**—to the mandibular articulation.

(*c*) **Anterior Auricular.**—Small branches to the lateral surface of the auricle and to the external acoustic meatus. They anastomose on the surface of the auricle with branches

of the posterior auricular artery, and in the external acoustic meatus with branches of the internal maxillary artery.

(*d*) **Transverse Facial.**—A branch of moderate size which emerges from under cover of the upper part of the anterior border of the parotid gland, runs forwards across the masseter, below the zygoma and above the parotid duct, accompanied by zygomatic branches of the facial nerve, which may lie either above or below it. It is distributed to the parotid gland, the masseter, parotid duct, and the skin, and it terminates in branches which anastomose with the infra-orbital and buccinator branches of the internal maxillary artery and with the buccal and masseteric branches of the external maxillary artery.

(*e*) **Middle Temporal.**—A branch which usually springs from the commencement of the superficial temporal. It crosses the zygoma, pierces the temporal fascia and the temporal

FIG. 760.—THE EXTERNAL CAROTID, INTERNAL MAXILLARY, AND MENINGEAL ARTERIES.

muscle, and terminates in the temporal fossa by anastomosing with the deep temporal branches of the internal maxillary artery.

(*f*) **Zygomatico-orbital.**—This branch may spring directly from the superficial temporal, but it is frequently a branch of the middle temporal. It runs anteriorly, above the zygoma, between the two layers of the temporal fascia. It supplies branches to the orbicularis oculi, and anastomoses, through the zygomatic bone and round the outer margin of the orbit, with the lacrimal and palpebral branches of the ophthalmic artery.

(*g*) The **frontal branch** runs forwards and upwards, in a tortuous course, through the superficial fascia of the scalp towards the frontal tuberosity, lying at first upon the temporal fascia, and then upon the galea aponeurotica. It supplies the frontalis and the orbicularis oculi, and anastomoses with the lacrimal and supra-orbital branches of the ophthalmic artery, with the parietal terminal branch of the superficial temporal, and with its fellow of the opposite side.

(*h*) The **parietal branch**, less tortuous than the frontal, runs upwards and posteriorly in the superficial fascia of the scalp. It anastomoses, anteriorly, with the frontal terminal branch, posteriorly with the posterior auricular and occipital arteries, and, across the

median line, with its fellow of the opposite side. It supplies the skin and fascia, and the anterior and superior muscles of the auricle.

(8) **Arteria Maxillaris Interna.**—The **internal maxillary artery** commences between the antero-medial surface of the parotid gland and the neck of the mandible, and terminates in the pterygo-palatine fossa.

Course and Relations.—Although the internal maxillary artery is only a short trunk it has many important relations, in the consideration of which it is convenient to divide the vessel into three parts. The **first part** extends from the back of the neck of the mandible into the infratemporal fossa, as far as the lower border of the external pterygoid muscle. It lies between the spheno-mandibular ligament and the neck of the mandible, along with the auriculo-temporal nerve and the internal maxillary vein. The **second part** is in the infratemporal fossa, and runs upwards and anteriorly. It may lie on the lateral or the medial side of the lower head of the external pterygoid muscle. In the former case it is situated between the temporal and external pterygoid muscles, and in the latter between the external pterygoid muscle and the branches of the mandibular division of the trigeminal nerve. The **third part** passes between the upper and the lower heads of the external pterygoid, through the pterygo-maxillary fissure and into the pterygo-palatine fossa.

Branches.—*From the first part.*—(a) **Deep auricular.** A small branch which arises from the commencement of the artery and passes upwards to the external acoustic meatus. It supplies the mandibular joint, the parotid gland, the external acoustic meatus, and the superficial surface of the tympanic membrane. It anastomoses with branches of the superficial temporal and posterior auricular arteries.

(b) The **anterior tympanic**, a variable and small branch. It runs upwards and posteriorly, traverses the petro-tympanic fissure (Glaserian), and enters the tympanum through its lateral wall. In the tympanic cavity it anastomoses with tympanic branches from the internal carotid and ascending pharyngeal arteries, and with the stylo-mastoid branch of the posterior auricular, forming with the latter, in young subjects, a circular anastomosis around the tympanic membrane.

(c) **Middle Meningeal.**—The largest branch of the internal maxillary. It ascends between the external pterygoid muscle laterally and the spheno-mandibular ligament and the tensor veli palatini medially; passes between the two roots of the auriculo-temporal nerve and through the foramen spinosum, and enters the middle fossa of the cranial cavity. Before it enters the skull it lies posterior to the third division of the trigeminal nerve, and is accompanied by a vein which also passes through the foramen spinosum. In the middle cranial fossa it passes for a short distance anteriorly, in a groove on the great wing of the sphenoid, between the dura mater and the bone, and divides into anterior and posterior terminal branches.

Branches.—(i.) **Superficial Petrosal.**—A small branch which arises from the middle meningeal soon after it enters the cranium. It passes through the hiatus canalis facialis and anastomoses with the stylo-mastoid branch of the posterior auricular artery; it also sends some small branches into the tympanic cavity.

(ii.) **Ganglionic.**—Minute branches which supply the semilunar ganglion and the roots of the fifth cerebral nerve.

(iii.) **Superior Tympanic.**—A small twig which reaches the tympanic cavity through the canal for the tensor tympani muscle, or through the petro-squamous suture.

(iv.) **Orbital.**—An anastomosing branch which arises occasionally from the anterior terminal branch. It passes through the superior orbital fissure into the orbit, and anastomoses with the lacrimal artery.

(v.) **Anterior terminal**, the larger of the two terminal branches, passes upwards along the great wing of the sphenoid to the sphenoidal angle of the parietal bone, where it is sometimes enclosed in a distinct bony canal; it is continued upwards, a short distance behind the anterior border of the parietal bone, almost to the vertex of the skull, sending branches forwards into the anterior, and backwards towards the posterior cranial fossa.

(vi.) The **posterior terminal branch** passes posteriorly from the great wing of the sphenoid to the squamous part of the temporal bone, beyond which it ascends to the middle of the inner surface of the parietal bone. It sends branches upwards to the vertex, and backwards towards the posterior cranial fossa.

By means of its various branches the middle meningeal artery anastomoses with its fellow of the opposite side, with meningeal branches from the occipital, ascending pharyngeal, ophthalmic, and lacrimal arteries; also with the stylo-mastoid branch of the posterior auricular, the accessory meningeal artery, through the substance of the temporal bone, and with the deep temporal

arteries. The anterior and posterior branches of the middle meningeal arteries and their ramifications are separated from the bone by corresponding veins.

(d) An **accessory meningeal branch** may arise either directly from the first part of the internal maxillary or from its middle meningeal branch. It passes upwards, on the medial side of the external pterygoid muscle, enters the middle fossa of the skull through the foramen ovale, supplies the semilunar ganglion and the dura mater, and terminates by anastomosing with branches of the middle meningeal and internal carotid arteries.

(e) The **inferior alveolar** is a branch of moderate size which passes downwards, between the sphenomandibular ligament and the mandible, to the mandibular foramen. It is accompanied by the inferior alveolar nerve, which lies in front of it. After entering the foramen it descends in the mandibular canal, and terminates at the mental foramen by dividing into mental and incisive branches.

Branches.—Before it enters the mandibular foramen it gives off two branches.

(i.) The **lingual**, a small twig, to the buccal mucous membrane, which accompanies the lingual nerve. (ii.) The **mylo-hyoid**, a small branch which is given off immediately above the mandibular foramen. It pierces the sphenomandibular ligament, and descends in the mylo-hyoid groove, in company with the mylo-hyoid nerve, to the floor of the mouth, where it anastomoses, on the superficial surface of the mylo-hyoid muscle, with the submental branch of the external maxillary artery.

In the mandibular canal the following branches are given off:—

(i.) **Molar branches** to the molar teeth. (ii.) **Premolar branches** to the premolar teeth. (iii.) The **incisive terminal branch**, which supplies the incisor and canine teeth and anastomoses with its fellow of the opposite side. (iv.) The **mental terminal branch**, which passes through the mental foramen, emerges beneath the quadratus labii inferioris, and anastomoses with its fellow of the opposite side, with the inferior labial, and with the submental arteries.

From the second part.—(a) The **masseteric**, a small branch which passes laterally, through the mandibular notch, to the deep surface of the masseter muscle. It anastomoses in the substance of the muscle with branches of the transverse facial and with the masseteric branches of the external maxillary artery.

(b) **Deep Temporal.**—Two in number, anterior and posterior. They ascend, in the temporal fossa, between the temporal muscle and the squamous portion of the temporal bone, supplying the muscle and anastomosing with the temporal and lacrimal arteries, and, through the substance of the temporal bone, with the middle meningeal artery.

(c) Small **pterygoid branches** supply the internal and external pterygoid muscles.

(d) The **buccinator branch**, a long, slender branch which passes obliquely forwards and downwards with the buccinator nerve. It supplies the buccinator muscle, the skin and mucous membrane of the cheek, and anastomoses with the buccal branches of the external maxillary artery.

From the third part.—(a) A **posterior superior alveolar branch** descends in the infratemporal fossa, on the posterior surface of the maxilla, and ends in branches which supply the molar and premolar teeth and the mucous membrane of the maxillary sinus; they also give twigs to the gums and to the buccinator muscle.

(b) An **infra-orbital branch** commences in the pterygo-palatine fossa. It enters the orbit through the inferior orbital fissure, and runs forwards in the infra-orbital groove and canal to the infra-orbital foramen, through which it emerges on the face beneath the quadratus labii superioris. Whilst in the infra-orbital groove it gives branches to the inferior rectus and the inferior oblique muscles and the lacrimal gland. In the infra-orbital canal it gives small twigs to the incisor and canine teeth (aa. alveolares superiores anteriores) and to the maxillary sinus. In the face it sends branches upwards to the lower eyelid, to the lacrimal sac, and to the frontal process of the maxilla; these anastomose with branches of the ophthalmic and external maxillary arteries; other branches run downwards to the upper lip, where they anastomose with the superior labial artery; lastly, some branches run laterally into the cheek to unite with the transverse facial and the buccinator arteries.

(c) The **descending palatine** runs downwards through the pterygo-palatine fossa, enters the pterygo-palatine canal, and becomes the great palatine artery, which supplies the mucous membrane of the roof of the mouth. As it descends it gives off the artery of the pterygoid canal several small twigs which pass through the accessory palatine canals to supply the soft palate, and to anastomose with the ascending palatine and tonsillar branches of the external maxillary and with the ascending pharyngeal artery. The great palatine artery, which is the continuation of the descending palatine, runs forwards in the roof of the mouth, medial to the alveolar process, to terminate in a small branch which ascends through the incisive foramen and anastomoses with the posterior artery of the

septum nasi, which is a branch of the sphenopalatine artery; in its course forwards in the roof of the mouth it supplies the gums and the mucous membrane of the hard palate, and also the palatine and maxillary bones.

(*d*) The **artery of the pterygoid canal** is a long, slender branch, usually given off from the descending palatine; it runs backwards through the pterygoid canal with the corresponding nerve (Vidian), and supplies branches to the upper part of the pharynx, to the levator and tensor veli palatini muscles, and to the auditory tube. One of the latter branches passes along the wall of the auditory tube to the tympanic cavity, where it anastomoses with the other tympanic arteries.

(*e*) The **pharyngeal** is a small artery which runs backwards, with the pharyngeal branch of sphenopalatine ganglion, through the pharyngeal canal to the roof of the pharynx. It supplies the upper and posterior part of the roof of the nose, the roof of the pharynx, the sphenoidal sinus, and the lower part of the auditory (Eustachian) tube, and anastomoses with the pterygoid branch of the internal carotid.

(*f*) The **sphenopalatine branch** springs from the termination of the internal maxillary artery. It passes medially through the sphenopalatine foramen into the nasal cavity, where it gives off (*a*) a branch to the sphenoidal sinus, and (*b*) a branch which replaces the pharyngeal artery and has a similar course and distribution. Then it divides into lateral and septal posterior nasal branches. The **lateral posterior nasal branches** supply the lateral wall of the nasal cavity and the sinuses which open through it, and they anastomose with the posterior and anterior ethmoidal arteries and the lateral nasal branch of the external maxillary. The **septal posterior nasal branch** accompanies the posterior septal nerve across the roof of the nasal cavity and then anteriorly and downwards in the groove on the vomer, and it anastomoses with the great palatine artery and the septal branch of the superior labial.

ARTERIA CAROTIS INTERNA.

The **internal carotid artery** (Figs. 759, 761, and 764) commences at the termination of the common carotid, opposite the upper border of the thyroid cartilage, and terminates in the middle fossa of the skull, close to the commencement of the stem of the lateral fissure (Sylvius), where it divides into the middle and anterior cerebral arteries.

Course.—From its origin in the carotid triangle it ascends to the base of the skull, lying first in the carotid triangle, medial to the anterior border of the sterno-mastoid, and then between the areolar tissue behind the lateral border of the pharynx medially and the posterior belly of the digastric and the styloid process and its muscles laterally. At its commencement it lies postero-lateral to the external carotid, but as it ascends it gradually passes to the medial side of the external carotid, from which it is separated by the styloid process, the stylo-pharyngeus muscle, the glosso-pharyngeal nerve, and the pharyngeal branch of the vagus.

At the base of the skull it enters the carotid canal, in which it ascends, anterior to the tympanum and the cochlea, and then turns antero-medially to the apex of the bone where it enters the foramen lacerum, through which it ascends, along the side of the body of the sphenoid, to the middle fossa of the cranium.

In the middle fossa it runs forwards, in the lateral wall of the cavernous sinus, to the small wing of the sphenoid; there it turns backwards along the medial border of the anterior clinoid process, which it grooves. At the posterior extremity of the process it turns upwards to its termination at the medial end of the stem of the lateral fissure (Sylvius), below the medial part of the anterior perforated substance.

Relations.—The relations of the various parts of the artery require separate consideration.

In the Neck.—**Posterior.**—The longus capitis (O.T. rectus capitis anticus major), the prevertebral fascia, and the sympathetic trunk separate it from the transverse processes of the cervical vertebræ, and postero-lateral to it are the internal jugular vein and the vagus nerve. The accessory and the glossopharyngeal nerves are also postero-lateral to the artery for a short distance, in the upper part of the neck, and intervene between it and the internal jugular vein. *Medial* or deep to the internal carotid is the external

carotid artery for a short distance below, and afterwards the wall of the pharynx, the areolar tissue posterior to the wall of the pharynx, the ascending pharyngeal artery, the pharyngeal plexus of veins, and the external and internal laryngeal nerves. Just before it enters the temporal bone the levator palati muscle is to its medial side. *Lateral* or superficial to it are the sterno-mastoid, skin, and fasciæ, and it is crossed under cover of the sterno-mastoid, from below upwards, by the hypoglossal nerve, the occipital artery, and the posterior auricular artery. It is also crossed superficially, between the last-mentioned arteries, by the digastric and stylo-hyoid muscles, which separate it from the parotid gland, and below the digastric it is covered by the lower part of the postero-medial surface of the gland. Passing obliquely across its anterior lateral surface, and separating

FIG. 761.—THE CAROTID, SUBCLAVIAN, AND VERTEBRAL ARTERIES AND THEIR MAIN BRANCHES.

it from the external carotid artery, are the following structures, viz., the stylo-pharyngeus the styloid process, or the styloglossus muscle, and the glossopharyngeal nerve, the pharyngeal branch of the vagus, and some sympathetic twigs.

In the Carotid Canal.—The artery, as it passes upwards, is antero-inferior to the cochlea and the tympanum; postero-medial to the auditory (Eustachian) tube and the canal for the tensor tympani; and below the semilunar ganglion. The thin lamina of bone which separates it from the tympanum is frequently perforated, and that between it and the semilunar ganglion is frequently absent. In its course through the canal it is accompanied by small veins and sympathetic nerves. The veins receive tributaries from the tympanum, and communicate above with the cavernous sinus and below with the internal jugular vein. The nerves are branches of the nervus caroticus internus, which is the upward continuation of the sympathetic trunk; they form a plexus, called the internal carotid plexus, around the artery.

As it enters the cavity of the cranium the internal carotid artery pierces the external layer of the dura mater and passes between the lingula and the sixth cerebral nerve laterally, and the posterior petrosal process of the body of the sphenoid medially.

In the Cranial Cavity.—The artery runs forwards, in the lateral wall of the cavernous

sinus, in relation with the oculo-motor, trochlear, the ophthalmic division of the trigeminal, and the abducens nerves laterally, and with the endothelial wall of the sinus medially. When it reaches the lower root of the small wing of the sphenoid it turns upwards to the medial side of the anterior clinoid process, pierces the inner layer of the dura mater, and comes into close relation with the inferior surface of the optic nerve immediately posterior to the optic foramen. It then turns abruptly backwards below the optic nerve, and on the medial side of the anterior clinoid process which it frequently grooves; inclining laterally, it runs between the optic and oculo-motor nerves, and below the anterior perforated substance, to the medial end of the stem of the lateral fissure (Sylvius), where it turns upwards, at some distance from the lateral side of the optic chiasma, and, after piercing the arachnoid, divides into its two terminal branches, the anterior and middle cerebral arteries.

BRANCHES OF THE INTERNAL CAROTID ARTERY.

Branches are given off from the internal carotid in the temporal bone and in the cranium, but, as a rule, no regular branches are given off in the neck.

In the Temporal Bone.—(1) A **carotico-tympanic branch**, very small, perforates the posterior wall of the carotid canal, and anastomoses in the tympanum with the stylo-mastoid artery and with the tympanic branches of the internal maxillary and ascending pharyngeal arteries.

(2) A small and inconstant branch which accompanies the nerve of the pterygoid canal (Vidian); it anastomoses with a branch of the descending palatine artery.

In the Cranium.—(1) **Cavernous**, small branches to the walls of the cavernous sinus and to the third, fourth, fifth, and sixth cerebral nerves.

(2) Minute twigs which supply the semilunar ganglion.

(3) **Hypophyseal branches** pass to the hypophysis (O.T. pituitary body).

(4) **Meningeal branches** ramify in the dura mater of the middle cranial fossa, anastomosing with the branches of the middle and accessory meningeal arteries.

(5) **Arteria Ophthalmica.**—The **ophthalmic artery** (Fig. 761) springs from

FIG. 762.—DISTRIBUTION OF THE CEREBRAL ARTERIES ON THE MEDIAL AND INFERIOR SURFACES OF THE CEREBRAL HEMISPHERES.

The anterior cerebral artery is coloured green, the middle cerebral artery red, and the posterior cerebral artery orange.

the antero-medial side of the internal carotid as it turns upwards on the medial side of the anterior clinoid process. It passes forwards and laterally, below the optic nerve and through the optic foramen into the orbital cavity. In the orbit it runs forwards, for a short distance, on the lateral side of the optic nerve, and it is in relation laterally with the ciliary ganglion and the lateral rectus

muscle; turning upwards and medially, it crosses, between the optic nerve and the superior rectus, to the medial wall of the orbit, where it turns forwards to terminate at the anterior boundary of the cavity by dividing into frontal and dorsal nasal branches. It is accompanied at first by the naso-ciliary nerve, and in the terminal part of its course by the infra-trochlear nerve.

Branches.—The branches of the ophthalmic artery are numerous. (a) The **posterior ciliary**, usually six to eight in number, run forwards at the sides of the optic nerve; they soon divide into numerous branches which pierce the posterior part of the sclera; the majority terminate in the choroid coat of the eye as the *short posterior ciliary arteries*, but two of larger size, the *long posterior ciliary arteries*, run forwards, one on each side of the eyeball, almost in the horizontal plane, between the sclera and the choroid coat, to the periphery of the iris, where they divide. The resulting branches anastomose together and form a circle at the periphery of the iris, from which secondary branches run inwards and anastomose together in a second circle near the papillary margin of the iris.

(b) The **central artery of the retina** arises near to, or in common with, the preceding vessels. It pierces the infero-medial aspect of the optic nerve, about 12 mm. (half an inch) posterior to the sclera, and runs in its centre to the retina, where it breaks up into terminal branches.

(c) **Anterior meningeal.**—A small branch which passes backwards through the superior orbital

FIG. 763.—DISTRIBUTION OF CEREBRAL ARTERIES ON THE CONVEX SURFACE OF THE CEREBRUM.

Anterior cerebral artery is coloured green, the middle cerebral red, and the posterior cerebral orange.

fissure into the middle fossa of the cranium, where it anastomoses with the middle and accessory meningeal arteries, and with the meningeal branches of the internal carotid and lacrimal arteries.

(d) The **lacrimal artery** arises from the ophthalmic on the lateral side of the optic nerve. It runs forwards, along the upper border of the lateral rectus, to the upper lateral angle of the orbit, and in its course gives off *glandular branches* to the lacrimal gland, *muscular branches* to the lateral and superior recti, *palpebral branches* to the upper eyelid and the upper and lateral part of the forehead, *temporal* and *zygomatic branches*, which accompany the zygomatico-temporal and zygomatico-facial branches of the zygomatic (temporo-malar) nerve, to the face and the infra-temporal fossa respectively; *anterior ciliary branches*, which perforate the sclera behind the corneo-scleral junction and anastomose with the posterior ciliary arteries; and a *recurrent meningeal branch*, which passes backwards, through the lateral part of the superior orbital fissure, to anastomose, in the middle fossa of the skull, with the middle meningeal artery.

(e) **Muscular.**—These branches are usually arranged in two sets, lateral and medial. The former supply the upper and lateral, and the latter the lower and medial orbital muscles. They anastomose with muscular branches from the lacrimal and the supra-orbital vessels, and they give off *anterior ciliary branches*.

(f) The **supra-orbital branch** is given off as the ophthalmic artery crosses above the optic nerve. It passes round the medial borders of the superior rectus and levator palpebrae muscles, and runs forwards, between the levator and the periosteum, to the supra-orbital notch, accompanying the frontal nerve and its supra-orbital branch. Passing through the notch it reaches the scalp, and, perforating the frontalis muscle, anastomoses with the frontal branches of the superficial temporal and ophthalmic arteries.

(g) **Anterior and posterior ethmoidal branches** arise from the ophthalmic as it runs forwards along the medial boundary of the orbit. They pass medially, between the superior oblique and the medial rectus. The posterior, which is much the smaller of the two, traverses the posterior ethmoidal canal, and supplies the posterior ethmoidal cells and the posterior and upper part of

the lateral wall of the nasal cavity. The anterior ethmoidal artery passes through the anterior ethmoidal canal with the anterior ethmoidal nerve, enters the anterior fossa of the skull, and crosses the lamina cribrosa of the ethmoid to the nasal slit, through which it reaches the nasal cavity, where it descends, with the external branch of the nasal nerve, in a groove on the posterior surface of the nasal bone, and, finally, passes between the lateral cartilage and the lower border of the nasal bone to the tip of the nose. It supplies branches to the membranes of the brain in the anterior cranial fossa as well as to the anterior ethmoidal cells, the frontal sinus, the anterior and upper part of the nasal muco-periosteum, and the skin on the dorsum of the nose.

(*h*) **Palpebral branches**, upper and lower, are given off near the termination of the ophthalmic. They are distributed to the upper and lower eyelids, and they anastomose with the lacrimal, supra-orbital, and infra-orbital arteries.

(*i*) The **dorsal nasal terminal branch** passes out of the orbit above the medial tarsal ligament. It pierces the palpebral fascia, and terminates on the side of the nose by anastomosing with the angular branch of the external maxillary artery.

(*j*) The **frontal terminal branch** pierces the palpebral fascia at the upper and medial part of the orbit, and ascends, with the supra-trochlear nerve, in the superficial fascia of the anterior and medial part of the scalp, anastomosing with its fellow of the opposite side and with the supra-orbital artery.

(6) The **posterior communicating artery** arises from the internal carotid near its termination. It runs backwards, below the optic tract and anterior to the pedunculus cerebri, and, passing above the oculomotor nerve, joins the posterior cerebral artery forming part of the circulus arteriosus (Willis). It gives branches to the optic chiasma, the optic tract, the pedunculus cerebri, the interpeduncular region, the internal capsule, and the optic thalamus. The posterior communicating artery varies much in size; it may be small on one or both sides, sometimes it is very large on one side; occasionally it replaces the posterior cerebral artery, and it sometimes arises from the middle cerebral artery.

(7) The **chorioidal** is a small branch, which also arises near the termination of the internal carotid; it passes backwards and laterally, between the pedunculus cerebri and the uncus, to the lower and anterior part of the chorioidal fissure which it enters, and it terminates in the chorioidal plexus in the inferior cornu of the lateral ventricle. It supplies the optic tract, the pedunculus cerebri, the uncus, the posterior part of the internal capsule, the tail of the caudate nucleus, part of the lentiform nucleus, and the amygdaloid nucleus.

(8) **Arteria Cerebri Anterior.**—The **anterior cerebral artery** is the smaller of the two terminal branches of the internal carotid. It passes forwards and medially, above the optic chiasma and immediately in front of the lamina terminalis, to the commencement of the longitudinal fissure, where it turns round the genu of the corpus callosum, and runs backwards to the parietal lobe of the brain. At the commencement of the longitudinal fissure it is closely connected with its fellow of the opposite side by a wide but short **anterior communicating artery**, and in the remainder of its course it is closely accompanied by its fellow artery of the opposite side.

Branches.—Branches of all the cerebral arteries are distributed both to the basal ganglionic masses of the brain and to the cerebral cortex; they therefore form two distinct groups which do not communicate with one another—(*a*) **central or basal**; (*b*) **cortical**.

The branches of the anterior cerebral include:

(*a*) **Central or basal branches.**—The **antero-medial basal arteries**, a small group of vessels, constitute the basal branches of the anterior cerebral artery; they pass upwards into the base of the brain in front of the optic chiasma, and supply the rostrum of the corpus callosum, the lamina terminalis, the head of the caudate nucleus, the anterior part of the lentiform nucleus and internal capsule, the columns of the fornix, the septum pellucidum, and the anterior commissure.

(*b*) **Cortical branches.**—(*b*¹) **Medial orbital**, one or more small branches which supply the medial orbital convolution, the gyrus rectus, and the olfactory lobe.

(*b*²) **Anterior medial frontal**, one or more branches which are distributed to the anterior and lower part of the medial surface of the superior frontal gyrus, and to the anterior portions of the superior and middle frontal gyri on the lateral surface of the hemisphere.

(*b*³) An **intermediate medial frontal** is distributed to the posterior part of the medial lateral surfaces of the superior frontal gyrus and to the upper parts of the anterior and posterior central gyri.

(*b*⁴) The **posterior medial frontal** runs backwards to the præcuneus. It supplies the corpus callosum, the præcuneus, and the upper part of the superior parietal lobule.

(9) **Arteria Cerebri Media.**—The middle cerebral artery is the larger of the two terminal branches, and the more direct continuation of the internal carotid artery. It passes laterally, in the stem of the lateral fissure (Sylvius), to the surface of the insula, and it divides, in the posterior part of the circular sulcus (Reil), into parieto-temporal and temporal terminal branches.

Branches.—(a) The central or basal, which constitute the antero-lateral basal arteries, are numerous and very variable in size. These arise at the base of the brain, in the region of the anterior perforated substance. Two sets, known as the medial and the lateral striate arteries, are distinguishable.

(a¹) The **medial striate arteries** pass upwards through the two medial segments of the lentiform nucleus (globus pallidus) and the internal capsule to terminate in the caudate nucleus. They supply the anterior portions of the lentiform and caudate nuclei and of the internal capsule.

(a²) The **lateral striate arteries** pass upwards through the lateral segment (putamen) of the lentiform nucleus, or between it and the external capsule, and they form two sets: an anterior, the lenticulo-striate, and a posterior, the lenticulo-optic; both sets traverse the lentiform nucleus and the internal capsule, but the *lenticulo-striate arteries* terminate in the caudate nucleus, and the *lenticulo-optic* in the thalamus. One of the lenticulo-striate arteries, which passes in the first instance round the lateral side of the lentiform nucleus, and afterwards through its substance, is larger than its companions; it frequently ruptures, and is known as the “artery of cerebral hæmorrhage.”

(b) *Cortical branches* are given off as the middle cerebral artery passes over the surface of the insula at the bottom of the lateral fissure, as follows:—

(b¹) The **lateral orbital** runs forwards and laterally, and is distributed to the lateral part of the orbital surface of the frontal lobe and to the inferior frontal gyrus.

(b²) The **inferior lateral frontal**, which supplies the inferior and middle frontal gyri.

(b³) The **ascending frontal**, which turns round the upper margin of the lateral fissure, and is distributed to the anterior central gyrus and to the posterior part of the middle frontal gyrus.

(b⁴) The **ascending parietal branch** emerges from the lateral fissure (Sylvius) and passes upwards along the posterior border of the posterior central gyrus, supplying that gyrus and the superior parietal lobule.

(b⁵) The **temporal branch** passes out of the lateral fissure, and turns downwards to supply the superior and middle temporal gyri.

(b⁶) The **parieto-temporal branch** continues backwards, in the direction of the main stem of the middle cerebral artery, and emerges from the posterior end of the lateral fissure; it supplies the inferior parietal lobule, part of the lateral surface of the occipital lobe, and the posterior part of the temporal lobe.

ARTERIA VERTEBRALIS.

The **vertebral artery** (Figs. 757 and 761) is the first branch given off from the subclavian trunk; it arises from the upper and posterior part of the parent stem, opposite the interval between the anterior scalene and the longus colli muscles, and terminates at the lower border of the pons (Varolii) by uniting with its fellow of the opposite side to form the basilar artery.

Course and Relations.—The vertebral artery is divisible into four parts.

The **first part** runs upwards and backwards, between the scalenus anterior and the lateral border of the longus colli, to the foramen in the transverse process of the sixth cervical vertebra. It is surrounded by a plexus of sympathetic nerve fibres, is covered anteriorly by the vertebral and internal jugular veins, and it may be crossed anteriorly by the inferior thyreoid artery. On the left side the terminal part of the thoracic duct also passes anterior to it. The **second part** runs upwards through the foramina in the transverse processes of the upper six cervical vertebræ. As far as the second cervical vertebra its course is almost vertical; as it passes through the transverse process of the epistropheus, however, it is directed obliquely upwards and laterally to the atlas. It is surrounded by a plexus of sympathetic nerve fibres, and also by a plexus of veins. The artery lies anterior to the trunks of the cervical nerves, and medial to the intertransverse muscles. The **third part**

emerges from the foramen in the transverse process of the atlas, between the anterior division of the sub-occipital nerve medially and the rectus capitis lateralis laterally, and runs almost horizontally backwards and medially, round the lateral and posterior aspects of the superior articular process of the atlas. In this course it enters the sub-occipital triangle, where it lies in the groove on the upper surface of the posterior arch of the atlas (sulcus arteriæ vertebralis). It is separated from the bone by the sub-occipital nerve, and is overlapped superficially by the adjacent borders of the superior and inferior oblique muscles. Finally, this part of the

FIG. 764.—THE ARTERIES OF THE BASE OF THE BRAIN. THE CIRCULUS ARTERIOSUS (WILLIS).

artery passes anterior to the oblique ligament of the atlas and enters the vertebral canal.

The **fourth part** pierces the spinal dura mater and runs upwards into the cranial cavity. It passes between the roots of the hypoglossal nerve posteriorly and the first dentation of the ligamentum denticulatum anteriorly, pierces the arachnoid, and, gradually inclining to the front of the medulla oblongata, reaches the lower border of the pons, where it unites with its fellow of the opposite side to form the basilar artery.

Branches.—*From the first part.*—As a rule there are only a few small **muscular twigs** from this portion of the artery.

From the second part.—(1) **Muscular branches** which vary in number and size. They supply the deep muscles of the neck, and anastomose with the profunda cervicis, the ascending cervical, and the occipital arteries.

(2) **Spinal branches** pass from the medial side of the second part of the vertebral artery through the intervertebral foramina into the vertebral canal, where they give off twigs which pass along the roots of the spinal nerves to reinforce the anterior and posterior spinal arteries; they supply the bodies of the vertebrae and the intervertebral fibrocartilages, and they anastomose with corresponding arteries above and below.

From the third part.—(1) **Muscular branches** to the sub-occipital muscles.

(2) **Anastomotic branches** which unite with the descending branch (O.T. princeps cervicis) of the occipital and with the profunda cervicis artery.

From the fourth part.—(1) **Meningeal.**—One or two small branches given off before the vertebral artery pierces the dura mater. They ascend into the posterior fossa of the skull, where they anastomose with meningeal branches of the occipital and ascending pharyngeal arteries, and occasionally with branches of the middle meningeal artery.

(2) **Posterior Spinal.**—The posterior spinal branch springs from the vertebral directly after it has pierced the dura mater. It runs downwards upon the side of the medulla oblongata and the spinal medulla, either in front of or behind the posterior nerve-roots. It is a slender artery, which is continued to the lower part of the spinal medulla by means of reinforcements from the spinal branches of the vertebral and intercostal arteries. It gives off branches to the pia mater, which form more or less regular anastomoses on the medial and lateral sides of the posterior nerve-roots, and it terminates below by joining the anterior spinal artery.

(3) The **anterior spinal branch** arises near the termination of the vertebral. It runs obliquely downwards and medially, in front of the medulla oblongata, and unites with its fellow of the opposite side to form a single anterior spinal artery, which descends along the anterior median fissure of the spinal medulla, and is continued as a fine vessel along the filum terminale. The anterior spinal artery is reinforced as it descends by anastomosing twigs from the spinal branches of the vertebral, intercostal, and lumbar arteries. It gives off branches which pierce the pia mater and supply the spinal medulla, and it unites below with the posterior spinal arteries.

(4) The **posterior inferior cerebellar** is the largest branch of the vertebral artery. It arises a short distance below the pons and passes obliquely backwards round the medulla oblongata, at first between the fila of the hypoglossal nerve, and then between the fila of the accessory and vagus nerves, into the vallecule of the cerebellum, where it divides into lateral and medial terminal branches.

The trunk of the artery gives branches to the medulla oblongata and to the choroid plexus of the fourth ventricle. The medial terminal runs backwards between the inferior vermis and the lateral lobe of the cerebellum; it supplies principally the former structure, and anastomoses with its fellow of the opposite side. The lateral branch passes laterally on the lower surface of the hemisphere and anastomoses with the superior cerebellar artery.

Arteria Basilaris.—The basilar artery is formed by the junction of the two vertebral arteries; it commences at the lower border and terminates at the upper border of the pons (Varolii), bifurcating at its termination into the two posterior cerebral arteries.

Course and Relations.—It runs upwards, in the median part of the cisterna pontis, in a shallow groove on the front of the pons, behind the sphenoidal section of the basi-cranial axis and between the two abducent nerves.

Branches.—(1) **Pontine**, a series of small arteries which pass across the front and round the sides of the pons, supplying it, the brachia pontis (O.T. middle peduncles of the cerebellum), and the roots of the trigeminal nerve.

(2) The **internal auditory**, a pair of long but slender branches which accompany the acoustic nerve. Each enters the corresponding internal acoustic meatus with the facial and acoustic nerves, and, passing through the lamina cribrosa, is distributed to the internal ear.

(3) The **anterior inferior cerebellar**, two branches which arise, one on each side, from the middle of the basilar artery. They pass backwards on the anterior parts of the lower surfaces of the lateral lobes of the cerebellum, and anastomose with the posterior inferior cerebellar branches of the vertebral arteries.

(4) The **superior cerebellar** branches, two in number, arise near the termination of the basilar. Each passes laterally at the upper border of the pons, directly below the oculo-motor nerve of the same side, and, turning round the lateral side of the pedunculus cerebri, below the trochlear nerve, reaches the upper surface of the cerebellum, where it

divides into a medial and a lateral branch. The medial branch supplies the upper surface of the vermis and the anterior medullary velum. The lateral branch is distributed over the upper surface of the lateral lobe, anastomosing at its margin with the inferior cerebellar arteries.

(5) *Arteriæ Cerebri Posteriores*.—The posterior cerebral arteries (Figs. 762 and 764) are the two terminal branches of the basilar. They run backwards and upwards, between the peduncles of the cerebrum and the uncinate gyri and parallel to the superior cerebellar arteries, from which they are separated by the oculomotor and trochlear nerves. Each posterior cerebral artery is connected with the internal carotid by the posterior communicating artery; it gives branches to the inferior surface of the cerebrum, and is continued backwards, beneath the splenium of the corpus callosum, to the calcarine fissure, where it divides into calcarine and parieto-occipital branches, which pass to the lateral surface of the occipital lobe. It supplies the medial and tentorial surfaces of the occipital lobe and the posterior part of its lateral surface.

Branches.—(A) *Central or basal*.—This group includes (*a*¹) A **postero-medial** set of small vessels which pass on the medial side of the corresponding cerebral peduncle to the posterior perforated substance. They supply the peduncle, the posterior part of the thalamus, the corpora mamillaria, and the walls of the third ventricle.

(*a*²) A **postero-lateral** set of small vessels which pass round the lateral side of the peduncle. They supply the corpora quadrigemina, the brachia, the pineal body, the peduncle, the posterior part of the thalamus, and the corpora geniculata.

(*a*³) A **posterior chorioidal** set of small branches which pass through the upper part of the chorioidal fissure, and, after entering the posterior part of the tela chorioidea of the third ventricle, end in the chorioid plexus in the body of the lateral ventricle and the upper part of its inferior cornu. They also supply the body and corresponding crus of the fornix.

(B) *Cortical*.—(*b*¹) The **anterior temporal**, frequently a single branch of variable size, but not uncommonly replaced by several small branches. It supplies the anterior parts of the uncus and the fusiform gyrus.

(*b*²) The **posterior temporal** is a larger branch than the anterior. It supplies the posterior part of the uncinate gyrus, the greater part of the fusiform gyrus, and the lingual gyrus.

(*b*³) The **calcarine branch** is the continuation of the posterior cerebral artery along the calcarine fissure, it is especially associated with the supply of the visual area of the cortex of the brain. It supplies the cuneus, the lingual gyrus, and the posterior part of the lateral surface of the occipital lobe.

(*b*⁴) The **parieto-occipital branch**, smaller than the calcarine, passes along the corresponding fissure to the cuneus and præcuneus.

Circulus Arteriosus (Willis) (Fig. 764).—The cerebral arteries of opposite sides are intimately connected together at the base of the brain by anastomosing channels. Thus, the two anterior cerebral arteries are connected with one another by the anterior communicating artery, whilst the two posterior cerebrals are in continuity through the basilar artery from which they arise. There is also a free anastomosis on each side between the carotid system of cerebral arteries and the vertebral system by means of the posterior communicating arteries, which connect the internal carotid trunks and posterior cerebral arteries.

The vessels referred to form the so-called **circulus arteriosus** (O.T. circle of Willis) which is situated at the base of the brain, in the interpeduncular and chiasmatic subarachnoid cisterns. It encloses the following structures: the posterior perforated substance, the corpora mamillaria, the tuber cinereum, the infundibulum, and the optic chiasma. The "circle" is irregularly polygonal in outline, and is formed posteriorly by the termination of the basilar and by the two posterior cerebral arteries, postero-laterally by the posterior communicating arteries and the internal carotids, antero-laterally by the anterior cerebral arteries, and in front by the anterior communicating artery.

It is stated that this free anastomosis equalises the flow of blood to the various parts of the cerebrum, and provides for the continuation of a regular blood-supply if one or more of the main trunks should be obstructed.

ARTERIES OF THE UPPER EXTREMITY.

The main arterial stem of each upper extremity passes through the root of the neck, traverses the axillary space, and is continued through the arm to the forearm. In the forearm it runs only a short distance, terminating opposite the neck of the radius by bifurcating into the radial and ulnar arteries, which run through the forearm to the hand. That portion of the common trunk which lies in the root of the neck is known as the **subclavian artery**, the part in the axillary space is termed the **axillary artery**, whilst the remaining part is called the **brachial artery**.

ARTERIE SUBCLAVIÆ.

On the right side the subclavian artery (Figs. 759 and 761) commences at the termination of the innominate artery, posterior to the sterno-clavicular articulation, whilst that on the left side arises from the arch of the aorta, behind the upper half of the manubrium sterni.

The right artery is about 75 mm. (3 inches) long, and it lies in the root of the neck. The left artery is about 100 mm. (4 inches) long, and is situated not only in the root of the neck, but also in the superior mediastinal part of the thorax. In the root of the neck each artery arches laterally, across the apex of the lung and behind the anterior scalene muscle, and is divided into three parts, which lie respectively to the medial side, posterior, and to the lateral side of the muscle. The extent to which the arch rises above the level of the clavicle varies considerably, and not uncommonly it reaches the level of the lower part of the thyreoid body. The first parts of the subclavian arteries differ materially from each other both in extent and relations. The relations of the second and third parts are similar on the two sides.

The **first part of the left subclavian artery** springs from the arch of the aorta, posterior to the commencement of the left common carotid and on the left side of the trachea. It ascends almost vertically, in the superior mediastinum, to the root of the neck, where it arches upwards and laterally to the medial border of the scalenus anterior muscle.

Relations.—*Posterior.*—In the superior mediastinum it is in relation with the lung and pleura.

Anterior.—In front are the left vagus, the left superior cardiac branch of the sympathetic, the left inferior cardiac branch of the vagus, the left phrenic nerve, and the left common carotid artery. It is also crossed obliquely by the left vagus nerve, and it is overlapped on the left side by the left lung and pleura.

Medial.—Medially it is in relation, from below upwards, with the trachea, the left recurrent nerve, the œsophagus, and the thoracic duct, the latter lying in a posterior plane.

Laterally it is closely invested by the left pleura, and it ascends in a groove on the medial aspect of the left lung.

As it turns laterally, at the root of the neck, it lies behind the commencement of the left innominate vein, and the termination of the left vertebral vein, the phrenic nerve, the sterno-thyreoid and sterno-hyoid muscles, the anterior jugular vein, and, more superficially, the sterno-mastoid muscle and the deep cervical fascia; the thoracic duct arches obliquely over it; and it lies in front of the apex of the pleural sac and lung.

The **first part of the right subclavian artery** (Fig. 761) extends from the back of the right sterno-clavicular articulation to the medial border of the scalenus anterior. It is thus limited to the root of the neck.

Relations.—*Posterior.*—Behind this part of the artery, and intervening between it and the upper two thoracic vertebræ, are the recurrent nerve, the posterior part of the ansa subclavia, and the apex of the right pleural sac. *Anterior.*—In front it is in relation with the right vagus, the cardiac branches of the vagus and the sympathetic, the anterior portion of the ansa subclavia, the internal jugular and vertebral veins, and more superficially the sterno-hyoid and sterno-thyreoid muscles, the anterior jugular vein, the sternal end of the clavicle, the sterno-clavicular ligaments, and the sterno-mastoid muscle. The recurrent nerve passes *below* it and intervenes between it and the apex of the pleural sac.

The **second part of the subclavian artery**, on *each side*, extends from the medial to the lateral border of the scalenus anterior, behind which it lies.

Relations.—Posteriorly and *below* it is in relation with the pleural sac. Anteriorly it is covered by the anterior scalene and the sterno-mastoid muscles. The anterior scalene separates it from the subclavian vein, which lies at a slightly lower level, from the transverse cervical and transverse scapular arteries, from the anterior jugular vein, and, on the right side, from the phrenic nerve.

The **third part of the subclavian artery** is the most superficial portion. It extends from the lateral border of the anterior scalene to the outer border of the first rib, lying partly in the clavicular portion of the posterior triangle of the neck and partly behind the clavicle and the subclavius muscle.

Relations.—It rests upon the upper surface of the first rib. Immediately *posterior* to it is the lowest trunk of the brachial plexus, which separates it from the middle scalene muscle. *Anterior* to it, and at a slightly lower level, lies the subclavian vein. The external jugular vein crosses the medial part of this portion of the artery in its course to join the subclavian vein, and just before its termination it receives the transverse cervical and transverse scapular veins; these vessels also pass superficial to the artery, which is thus covered superficially by venous trunks; it is also crossed vertically, behind the veins, by the nerve to the subclavius muscle. The lateral section of this part of the artery lies posterior to the clavicle and the subclavius muscle. It is crossed anteriorly by the transverse scapular artery, but the layer of deep cervical fascia which binds the posterior belly of the omo-hyoid to the posterior border of the subclavian groove intervenes between the two vessels. More superficially the third part of the artery is covered by the superficial layer of the deep fascia, the supra-clavicular branches of the cervical nerves, the platysma, and the skin.

BRANCHES OF THE SUBCLAVIAN ARTERY.

(1) The **vertebral artery** is distributed almost entirely to the head and neck, and its chief function is to supply the posterior part of the brain. Its description has therefore been given with that of the other cerebral arteries (see p. 905).

(2) **Truncus Thyreocervicalis.**—The **thyreo-cervical trunk** (Figs. 758 and 759) arises close to the medial border of the scalenus anterior, from the upper and front part of the subclavian artery, directly above the origin of the internal mammary artery. After a short upward course of about 4 mm. (two lines), it ends, under cover of the internal jugular vein, by dividing into three branches—viz., the inferior thyreoid, the transverse cervical, and the transverse scapular.

(A) **Arteria Thyreoidea Inferior.**—The **inferior thyreoid artery** (Fig. 759) ascends along the anterior border of the scalenus anterior, and turns medially, opposite the cricoid cartilage, to the middle of the posterior border of the lateral lobe of the thyreoid gland; it then curves medially and downwards, and descends to the lower end of the lobe, where it divides into ascending and inferior terminal branches.

Relations.—*Posterior* are the vertebral artery, and the longus colli muscle; the recurrent nerve passes either anterior or posterior to the vessel, opposite the lower border of the thyreoid gland. It is covered *anteriorly* by the carotid sheath, which contains the common carotid artery, the internal jugular vein, and the vagus nerve; the middle cervical ganglion of the sympathetic lies in front of the artery as it bends medially; and on the left side the thoracic duct also passes in front of it.

Branches.—It gives off the following branches:—

(a) **Muscular.**—Numerous small branches pass to the scalenus anterior, the longus colli, the infra-hyoid muscles, and the inferior constrictor of the pharynx.

(b) The **ascending cervical** usually springs from the inferior thyreoid near its origin, though not uncommonly it arises separately from the thyreo-cervical trunk. It ascends, parallel with and medial to the phrenic nerve, in the angle between the longus capitis and the scalenus anterior, to both of which it gives branches. It also gives off spinal branches which pass through the intervertebral foramina to the vertebral canal, and it anastomoses with branches of the vertebral, occipital, ascending pharyngeal, and deep cervical arteries.

(c) **Œsophageal.**—Small branches given to the walls of the œsophagus, which anastomose with the œsophageal branches of the thoracic aorta.

(d) **Tracheal branches** are distributed to the trachea; they anastomose with branches of the superior thyreoid and with the bronchial arteries.

(e) An **inferior laryngeal branch** accompanies the recurrent nerve to the lower part of the larynx. It enters the larynx, at the lower border of the inferior constrictor, gives branches to its muscles and mucous membrane, and anastomoses with the laryngeal branch of the superior thyreoid artery.

(f) The **ascending terminal branch** supplies the posterior and lower part of the thyreoid gland, and anastomoses with branches of the superior thyreoid artery.

(g) The **inferior terminal branch** is distributed to the lower and medial part of the thyreoid gland. It anastomoses with its fellow of the opposite side and with branches of the superior thyreoid artery.

(B) **Arteria Transversa Colli.**—The **transverse cervical artery** (Figs. 759 and 761) runs upwards and posteriorly, from the thyreo-cervical trunk, across the posterior triangle of the neck to the anterior border of the trapezius, where it divides into a ramus ascendens (O.T. superficial cervical) and a ramus descendens (O.T. posterior scapular). It is very variable in size, and not infrequently the ramus descendens arises separately from the third part of the subclavian.

Immediately after its origin, under cover of the internal jugular vein, it crosses the scalenus anterior, lying superficial to the phrenic nerve and under cover of the sterno-mastoid muscle; on the left side it is also crossed, superficially, by the terminal part of the thoracic duct. Passing from beneath the sterno-mastoid, it enters the lower part of the posterior triangle of the neck, where it lies upon the trunks of the brachial plexus, and, as it runs upwards and backwards to its termination, it passes medial to the posterior belly of the omo-hyoid.

Not uncommonly the ascending branch forms a separate vessel which springs from the thyreo-cervical trunk and takes the course described, whilst the descending branch arises from the third part of the subclavian artery and lies at a lower level. In such cases the upper of the two vessels is called the **superficial cervical artery** and the lower the **transverse cervical artery**. If the superficial cervical artery is absent it is replaced by the ascending branch of the transverse cervical.

Branches.—(a) **Small muscular branches** to the surrounding muscles.

(b) The **ascending branch**, usually a slender branch, passes beneath the trapezius; it runs upwards, superficial to the levator scapulæ and upon the splenius, and anastomoses with the descending branch of the occipital artery, and it sends branches downwards which accompany the accessory nerve and anastomose with the descending branch and transverse scapular arteries.

(c) The **descending branch** runs downwards, deep to the levator scapulæ and the rhomboid muscles, close to the vertebral border of the scapula. It runs parallel with, and a short distance away from, the dorsal scapular nerve (O.T. nerve to the rhomboid muscles), and it sends branches into the supraspinous, the infraspinous, and the subscapular fossæ, which anastomose with branches of the transverse scapular and subscapular arteries. It also sends branches backwards, through and between the rhomboid muscles, which anastomose with the ascending branch of the transverse cervical and with the posterior branches of the intercostal arteries.

(C) **Arteria Transversa Scapulæ.**—The **transverse scapular artery** (O.T. **supra-scapular**) springs from the thyreo-cervical trunk and terminates in the infraspinous fossa of the scapula. As a rule it is smaller than the transverse cervical artery.

Commencing behind the internal jugular vein, it crosses the scalenus anterior and phrenic nerve, and is covered superficially by the sterno-mastoid and the anterior jugular vein; on the left side it lies behind the termination of the thoracic duct also. Continuing behind the clavicle, and crossing superficial to the third part of the subclavian artery and the cords of the brachial plexus, it reaches the scapular notch and passes over the superior transverse ligament. Then it descends, with the suprascapular nerve, through the supraspinous fossa and beneath the supraspinatus muscle, and passing through the great scapular notch, deep to the inferior transverse ligament, enters the infraspinous fossa, where it anastomoses with the circumflex scapular branch of the subscapular artery and with branches of the descending branch of the transverse cervical artery.

Branches.—(a) **Muscular**, to the sterno-mastoid, the subclavius, and the muscles on the dorsum of the scapula.

(b) The **medullary**, a small branch to the clavicle.

FIG. 765.—DISSECTION OF THE BACK OF THE SHOULDER AND ARM, showing the anastomosing vessels on the dorsum of the scapula, and the posterior humeral circumflex and the profunda arteries.

(c) The **suprasternal**, to the sternal end of the clavicle and the sterno-clavicular joint.

(d) **Acromial branches**, which ramify over the acromion, anastomosing with the acromial branches of the thoraco-acromial and the posterior circumflex arteries.

(e) **Articular**, to the acromio-clavicular and shoulder-joints.

(f) The **subscapular**, which is given off as the artery passes over the superior transverse ligament. It passes down into the subscapular fossa, gives branches to the subscapularis, and anastomoses with the branches of the subscapular artery and the descending branch of the transverse cervical artery.

(g) **Supraspinous**, which ramify in the supraspinous fossa, supplying the muscle, and anastomosing with the descending branch of the transverse cervical.

(h) **Terminal branches** ramify in the infraspinous fossa, and anastomose with the circumflex scapular and with branches of the descending branch of the transverse cervical artery.

(3) **Arteria Mammaria Interna**.—The **internal mammary artery** (Fig. 761) arises from the lower and anterior part of the subclavian, at the medial border of the scalenus anterior and immediately below the origin of the thyreo-cervical trunk. It terminates behind the medial extremity of the sixth intercostal space by dividing into the musculo-phrenic and the superior epigastric arteries.

The artery passes at first downwards, forwards, and medially, lying upon the pleura, and behind the innominate vein, the sternal extremity of the clavicle, and the cartilage of the first rib; it is crossed obliquely, from the lateral to the medial side, by the phrenic nerve, which usually passes anterior to it. From the cartilage of the first rib it descends vertically, about 12 mm. (half an inch) from the border of the sternum, and lies, in the upper part of its course, in front of the pleura, and, in the lower part, in front of the transversus thoracis. It is covered anteriorly by the cartilages of the upper six ribs, the intervening intercostal muscles, and the terminal portions of the intercostal nerves; and it is accompanied by two venæ comites, which unite together above, and on its medial side, to form a single trunk which terminates in the innominate vein.

Branches.—(a) The **pericardiaco-phrenic** (O.T. *comes nervi phrenici*) is a long slender branch which is given off from the upper part of the internal mammary. It accompanies the phrenic nerve, through the superior and middle mediastina, to the diaphragm, where it anastomoses with the inferior phrenic and musculo-phrenic arteries. In its course downwards the artery gives off numerous small branches to the pleura and pericardium, which anastomose with offsets of the mediastinal and pericardial branches of the aorta and internal mammary arteries, and also with the bronchial arteries, forming the wide-meshed *subpleural plexus* of Turner.

(b) **Anterior mediastinal branches**, small and numerous, pass to the areolar tissue of the anterior mediastinum and supply the areolar tissue and the sternum.

(c) **Thymic**.—Small twigs which supply the thymus.

(d) **Bronchial**.—One or several small branches which pass to the lower end of the trachea and to the bronchi.

(e) The **intercostal** are two in number in each of the upper six intercostal spaces. They pass laterally for a short distance either between the pleura and the internal intercostal muscles or between the transversus thoracis and the internal intercostal muscles; they then pierce the internal intercostal muscles, and ramify between them and the external intercostal muscles, anastomosing with the aortic and superior intercostal arteries and their collateral branches.

(f) The **perforating branches**, one in each of the upper six intercostal spaces, are small vessels which pass forwards, with the anterior branches of the thoracic nerves, piercing the internal intercostal muscle, the anterior intercostal membrane, and the pectoralis major, to terminate in the skin and subcutaneous tissue. They supply twigs to the sternum, and those in the third and fourth spaces, usually the largest of the series, give off branches to the mammary gland.

(g) The **musculo-phrenic**, or lateral terminal branch of the internal mammary artery, runs downwards and laterally from the sixth intercostal space to the tenth costal cartilage. In the upper part of its course it lies upon the thoracic surface of the diaphragm, but it pierces the muscle about the level of the eighth costal cartilage, and terminates on its abdominal surface. Its branches are :—

(i) **Muscular**, which supply the diaphragm and anastomose with the superior and inferior phrenic arteries.

(ii) **Intercostal branches**, two in each of the seventh, eighth, and ninth intercostal spaces; they are distributed in the same manner as the corresponding branches of the internal mammary artery, and terminate by anastomosing with the aortic intercostals and their collateral branches.

(h) The **superior epigastric**, or medial terminal branch of the internal mammary artery, descends into the anterior wall of the abdomen. It leaves the thorax, between the sternal and costal origins of the diaphragm, and enters the sheath of the rectus, lying first behind, and then in the substance of the rectus muscle. It terminates by anastomosing with branches of the inferior epigastric artery. Its branches are :—

- (i.) **Muscular**, to the rectus, to the flat muscles of the abdominal wall, and to the diaphragm.
- (ii.) **Anterior Cutaneous**.—These branches pierce the rectus and the anterior portion of its sheath. They accompany the anterior terminal branches of the lower thoracic nerves, and terminate in the subcutaneous tissues and skin of the middle portion of the anterior abdominal wall.
- (iii.) **Xiphoid**, a small branch which crosses the front of the xiphoid process to anastomose with its fellow of the opposite side. It supplies the adjacent muscles and skin.
- (iv.) **Hepatic branches** of small size pass backwards in the falciform ligament to the liver, where they anastomose with branches of the hepatic artery.

(4) **Truncus Costocervicalis**.—The costo-cervical trunk (Fig. 761) springs from the posterior aspect of the second part of the subclavian artery on the right side and from the first part on the left side. It runs upwards and backwards, over the apex of the pleural sac, to the neck of the first rib, where it divides into superior intercostal and deep cervical branches.

Branches—(a) **Arteria Cervicalis Profunda**.—The deep cervical branch sometimes arises from the subclavian artery directly; but more commonly it springs from the costo-cervical trunk at the upper border of the neck of the first rib. It runs backwards, like the posterior branch of an intercostal artery, passes between the first thoracic and last cervical nerves, and between the transverse process of the last cervical vertebra and the neck of the first rib, to the back of the neck; there it ascends, between the semispinalis capitis (O.T. complexus) and the semispinalis cervicis muscle, to terminate by anastomosing with the descending branch of the occipital artery. It anastomoses also with branches of the ascending cervical and vertebral arteries, supplies the adjacent muscles, and sends a spinal branch, through the intervertebral foramen between the last cervical and the first thoracic vertebrae, into the vertebral canal, where it anastomoses with the spinal branches of the vertebral and intercostal arteries.

(b) **Arteria Intercostalis Suprema**.—The superior intercostal branch descends, anterior to the neck of the first rib, between the first thoracic nerve laterally and the first thoracic ganglion of the sympathetic trunk medially and, at the lower border of the neck of the rib, it gives off the intercostal artery of the first space; then, crossing anterior to the neck of the second rib, it becomes the posterior intercostal artery of the second intercostal space. The first two posterior intercostal arteries run laterally, each in its own space, lying first between the pleura and the posterior intercostal membrane, and then between the internal and external intercostal muscles. The branches terminate by anastomosing with anterior intercostal branches of the internal mammary artery. Each gives off *muscular* branches to the intercostal muscles, a *nutrient branch* to the rib below which it lies, and a *collateral branch* which runs along the lower border of the space and terminates by anastomosing with an anterior intercostal branch of the internal mammary artery.

ARTERIA AXILLARIS.

The **axillary artery**, which lies in the axillary space, is the direct continuation of the subclavian artery, and it becomes the brachial artery.

It commences at the external border of the first rib, at the apex of the axillary space. It passes distally, with a lateral inclination, along the lateral wall of the space, *i.e.* to the medial side of the shoulder-joint and the humerus, to the lower border of the teres major, where it becomes the brachial artery. A line drawn from the middle of the clavicle to the medial border of the prominence of the coracobrachialis and biceps muscles, when the arm is abducted until it is at right angles with the side, indicates the position and direction of the artery.

The position and direction, however, and to a certain extent the relations of the axillary artery, are modified by changes in the position of the upper extremity. With the arm hanging by the side the axillary artery describes a curve with the concavity directed downwards and medially, and the vein is to its medial side. When the arm is at right angles with the side, the axillary artery is almost straight; it lies closer to the lateral wall of the axilla, and the vein overlaps it antero-medially. When the arm is raised above the level of the shoulder the axillary artery is curved over the head of the humerus, and the vein lies still more in front of it.

For descriptive purposes the artery is divided into three parts: the first part

lies above, the second behind, and the third part below the pectoralis minor muscle.

Though it is the usual custom to describe three parts of the axillary artery, —a division which is perhaps of practical interest in so far as it emphasises the fact that the axillary artery is surgically accessible above the pectoralis minor,— it is to be noted that the upper border of the pectoralis minor is frequently exactly opposite the external border of the first rib, at the point where the axillary artery

FIG. 766.—THE AXILLARY ARTERY AND ITS BRANCHES AND RELATIONS.

begins. In the strict sense, therefore, no part of the artery is above the pectoralis minor.

Relations of the First Part—Posterior.—The first part of the artery is enclosed, together with the vein and the cords of the brachial plexus, in a prolongation of the cervical fascia known as the axillary sheath, posterior to which are the upper serration of the serratus anterior muscle, the contents of the first intercostal space, the medial cord of the brachial plexus, the medial anterior thoracic and the long thoracic nerves, the latter descending vertically between the artery and the serratus anterior. *Anterior.*—It is covered in front by the costo-coracoid membrane. The membrane intervenes between the artery and the cephalic vein, the branches of the lateral anterior thoracic nerve, the branches of the thoraco-acromial artery with their accompanying veins, and the clavicular part of the pectoralis major muscle, superficial to which are the deep fascia, the platysma, the supra-clavicular branches of the cervical plexus, and the superficial fascia and the skin. Posterior to the costo-coracoid membrane the artery is crossed by a loop of communication between the lateral and medial anterior thoracic nerves. *Lateral.*—Above and to the lateral side are the lateral and posterior cords of the brachial plexus and the lateral

anterior thoracic nerve. Below and to the medial side is the axillary vein, the medial anterior thoracic nerve intervening.

Relations of the Second Part—Posterior.—Behind this portion of the artery are the posterior cord of the brachial plexus and a layer of fascia which separates it from the subscapularis muscle. *Anterior.*—In front is the pectoralis minor, and, more superficially, the pectoralis major, the fasciæ and skin. *Lateral.*—To the lateral side lies the lateral cord of the brachial plexus. *Medial.*—On the medial side the medial cord of the plexus lies in close relation to the artery, and intervenes between it and the axillary vein.

Relations of the Third Part—Posterior.—The third part of the artery rests posteriorly upon the lower border of the subscapularis, the latissimus dorsi, and the teres major. It is separated from the fibres of the subscapularis by the axillary (O.T. circumflex) and radial (O.T. musculo-spiral) nerves, and from the latissimus dorsi and teres major by the radial nerve alone. *Anterior.*—It is crossed in front by the medial head of the median nerve. In its upper half it lies under cover of the lower part of the pectoralis major, the fasciæ and skin, whilst its lower part, which is superficial, is covered by skin and fasciæ only. *Lateral.*—To the lateral side lie the median and musculo-cutaneous nerves and the coraco-brachialis muscle. *Medial.*—To the medial side is the axillary vein. The two vessels are, however, separated by two of the chief branches of the medial cord of the brachial plexus. In the angle between the vein and the artery, and somewhat in front of the latter, lies the medial cutaneous nerve of the forearm (O.T. internal cutaneous nerve); in the angle behind is the ulnar nerve. The medial cutaneous nerve of the arm (O.T. lesser internal cutaneous) lies medial to the vein, and the venæ comites of the brachial artery ascend along the medial side, to terminate in the axillary vein at the lower border of the subscapularis muscle.

BRANCHES OF THE AXILLARY ARTERY.

(1) **Arteria Thoracalis Suprema.**—The supreme thoracic artery (Fig. 760) is a small branch which arises from the first part of the axillary at the lower border of the subclavius. It runs downwards and medially, across the first intercostal space, pierces the medial part of the costo-coracoid membrane, and supplies branches to the subclavius, the pectoralis major and minor, and to the serratus anterior (O.T. magnus) and the intercostal muscles; it anastomoses with branches of the transverse scapular, the internal mammary, and the thoraco-acromial arteries.

(2) **Arteria Thoracoacromialis.**—The thoraco-acromial artery (Fig. 766) arises near the upper border of the pectoralis minor, from the second part of the axillary artery. It is a very short trunk, of considerable size, which passes forwards, pierces the costo-coracoid membrane, and terminates, deep to the clavicular portion of the pectoralis major, by dividing into four terminal branches—clavicular, pectoral, deltoid, and acromial.

(a) The **clavicular branch** is a long slender artery which runs upwards and medially to the sterno-clavicular joint, anastomosing with the supreme thoracic, with branches of the transverse scapular, and with the first perforating branch of the internal mammary artery. It supplies the adjacent muscles and the sterno-clavicular articulation.

(b) The **pectoral** is a large branch which descends between the two pectoral muscles, to both of which it gives branches, and it anastomoses with the intercostal and lateral thoracic arteries.

(c) The **deltoid branch** runs distally in the groove between the pectoralis major and the deltoid, where it lies by the side of the cephalic vein, as far as the insertion of the deltoid. It anastomoses with the acromial branch and with the anterior circumflex artery, and it gives branches to the pectoralis major and deltoid muscles and to the skin.

(d) The **acromial branch** runs upwards and laterally, across the tip of the coracoid process, to the acromion, where it anastomoses with the deltoid branch, with the acromial branches of the transverse scapular, and with the posterior circumflex arteries. It gives branches to the deltoid.

(3) **Arteria Thoracalis Lateralis.**—The lateral thoracic artery arises from the second part of the axillary, and descends, along the lower border of the pectoralis minor, to anastomose with the intercostal and subscapular arteries and with the pectoral branch of the thoraco-acromial. It supplies the adjacent muscles, and sends mammary branches to the lateral part of the mammary gland.

(4) **Arteria Subscapularis.**—The **subscapular artery** is the largest branch of the axillary artery. It arises from the third part of the artery, opposite the lower border of the subscapularis, along which it descends, giving branches to the muscle and to the medial wall of the axillary space. After a short course it divides into two terminal branches, the *circumflexa scapulæ* and the *thoraco-dorsalis*.

(1) The **circumflex scapulæ** is frequently the larger branch. It arises about 37 mm. (one and a half inches) from the commencement of the subscapular trunk, and passes backwards into the triangular space between the subscapularis above, the *teres major* below, and the long head of the *triceps* laterally. Turning round, and usually grooving, the axillary border of the scapula, under cover of the *teres minor*, it enters the *infraspinous fossa*, where it breaks up into branches which anastomose with branches of the descending branch of the transverse cervical artery and the transverse scapular arteries. Whilst it is in the triangular space the artery gives off an *infrascapular branch* which passes into the subscapular fossa and terminates by anastomosing with the branches of the descending branch of the transverse cervical and the transverse scapular arteries. It gives off, in the same situation, a descending branch also, which runs downwards, to the lower angle of the scapula, between the *teres major* and *minor* muscles, and small branches are given to the deltoid and long head of *triceps*.

(2) The thoraco-dorsal continuation of the subscapular trunk accompanies the thoraco-dorsal nerve (O.T. long subscapular) along the axillary border of the scapula to the wall of the thorax, where it anastomoses with the lateral thoracic artery and with branches of the intercostal arteries.

(5) **Arteria Circumflexa Humeri Posterior.**—The **posterior circumflex artery** arises from the third part of the axillary artery and passes backwards, accompanied by the axillary nerve, through an intermuscular cleft, the so-called quadrilateral space, which is bounded by the *teres minor* and *subscapularis* above, the *teres major* below, the long head of the *triceps* medially, and the humerus laterally. It turns round the surgical neck of the humerus, under cover of the deltoid muscle, and terminates in numerous branches which supply the deltoid. As a rule it is an artery of large size, only slightly smaller than the subscapular.

Branches.—(a) **Muscular** to the *teres major* and *minor*, the long and lateral heads of the *triceps*, and the deltoid; (b) An **acromial branch**, which ascends to the acromial process, where it anastomoses with the acromial branches of the transverse scapular and the thoraco-acromial arteries; (c) A **descending branch**, which runs distally, along the lateral head of the *triceps*, to anastomose with the profunda artery; (d) **Articular** to the shoulder-joint; (e) **Nutrient** to the head of the humerus; (f) **Terminal**, which supply a large portion of the deltoid, and anastomose with the anterior circumflex and thoraco-acromial arteries.

(6) **Arteria Circumflexa Humeri Anterior.**—The **anterior circumflex artery** is a small branch which is given off from the third part of the axillary close to, or in common with, the posterior circumflex. It passes laterally, posterior to the *coraco-brachialis* and the two heads of the *biceps*, round the front of the surgical neck of the humerus, and terminates by anastomosing with the posterior circumflex. At the intertubercular groove it gives a well-marked branch which accompanies the long head of the *biceps*, supplying the sheath of the tendon, and giving branches to the shoulder-joint. It also gives muscular branches to the adjacent muscles, one of which runs distally along the tendon of insertion of the *pectoralis major*.

ARTERIA BRACHIALIS.

The **brachial artery** is the direct continuation of the axillary. It commences at the lower border of the *teres major*, and terminates in the cubital fossa, at the level of the neck of the radius, by dividing into the radial and ulnar arteries.

The general course of the brachial artery is distally and laterally, along the *medial* side of the arm. Its position and that of the axillary artery may be

indicated on the surface, when the arm is abducted, by a line drawn from the middle of the clavicle to the centre of the bend of the elbow.

Relations—Posterior.—It lies, successively, anterior to the long head of the triceps, the radial (O.T. musculo-spiral) nerve and the profunda vessels intervening; the medial head of the triceps; the insertion of the coraco-brachialis; and the brachialis. **Anterior.**—It is overlapped *anteriorly* by the medial border of the biceps, is crossed at the middle of the arm by the median nerve, and, in addition, it is covered by deep and superficial fascia and by skin. In the cubital fossa a thickened portion of the deep fascia, the lacertus fibrosus (O.T. semilunar or bicipital fascia), separates it from the median basilic vein and the volar branch of the medial cutaneous nerve of the forearm, both of which lie in the superficial fascia. **Lateral.**—To the *lateral side* it is in relation proximally with the median nerve, and distally with the biceps. **Medial.**—To the *medial side* it is in relation, in the proximal part of its extent, with the basilic vein, the medial cutaneous nerve of the forearm, the medial cutaneous nerve of the arm, and the ulnar nerve, and in the distal part with the median nerve. Two venæ comites, a medial and a lateral, accompany the artery, and communications between these pass across the vessel.

FIG. 767.—THE BRACHIAL ARTERY AND ITS BRANCHES.

BRANCHES OF THE BRACHIAL ARTERY.

(1) *Arteria Profunda Brachii.*—The **profunda artery** of the arm (O.T. superior profunda) is a large branch which arises from the postero-medial aspect of the brachial soon after its commencement. It runs distally and laterally, with the radial (O.T. musculo-spiral) nerve, in the radial sulcus (O.T. musculo-spiral groove), and divides, at the back of the humerus, into two terminal branches, anterior and posterior. Not infrequently this division takes place at a higher level, and the artery appears double. The anterior terminal branch accompanies the radial nerve through the lateral intermuscular septum, and passes distally, between the brachio-radialis and the brachialis, to the front of the lateral epicondyle, where it anastomoses with the radial recurrent artery. The posterior terminal branch continues distally, behind the lateral intermuscular septum, and anastomoses, posterior to the lateral epicondyle,

with the interosseous recurrent artery and with the inferior ulnar collateral artery.

Whilst they are posterior to the humerus one of the terminal branches gives off—(a) a slender *medial collateral twig*, which descends in the substance of the medial head of the triceps to the back of the elbow, where it anastomoses with the inferior ulnar collateral artery; (b) a *nutrient branch*, which enters a foramen on the posterior surface of the humerus; and (c) an *ascending branch*, which anastomoses with the descending branch of the posterior circumflex artery.

(2) **Muscular branches** are given to the biceps, coraco-brachialis, brachialis, triceps, and pronator teres.

(3) **Nutrient.**—A small artery which arises from the middle of the brachial and enters the nutrient foramen on the antero-medial surface of the body of the humerus.

(4) **Arteria Collateralis Ulnaris Superior.**—The **superior ulnar collateral artery** (O.T. **inferior profunda**) is smaller than the profunda, with which it sometimes arises by a common trunk; usually, however, it springs from the postero-medial aspect of the middle of the brachial. It runs distally and posteriorly, with the ulnar nerve, through the medial intermuscular septum, and then, passing more vertically, reaches the back of the medial epicondyle of the humerus, where it terminates by anastomosing with the dorsal and volar ulnar recurrent and inferior ulnar collateral arteries.

(5) **Arteria Collateralis Ulnaris Inferior.**—The **inferior ulnar collateral artery** (O.T. **anastomotica**) arises from the medial side of the brachial artery about 50 mm. (2 inches) above its termination. It runs medially, posterior to the median nerve and anterior to the brachialis. Then it pierces the medial intermuscular septum, and turns laterally, between the medial head of the triceps and the posterior surface of the bone, to the lateral epicondyle. It supplies the adjacent muscles and anastomoses, anterior to the medial epicondyle, with the volar ulnar recurrent, behind the medial epicondyle with the dorsal ulnar recurrent and the superior ulnar collateral, at the middle of the back of the humerus with the medial collateral branch of the profunda, and posterior to the lateral epicondyle with the posterior terminal branch of the profunda and the interosseous recurrent artery.

ARTERIA RADIALIS.

The **radial artery** (Figs. 768, 769, and 770) is the smaller of the two terminal branches of the brachial artery, but it is the more direct continuation of the parent trunk. It commences in the cubital fossa, opposite the neck of the radius, and terminates in the palm of the hand, by anastomosing with the deep branch of the ulnar artery, and thus completing the deep volar arch (O.T. palmar).

The trunk is divisible into **three parts**.

The *first part* lies in the volar part of the forearm. It runs distally and somewhat laterally to the apex of the styloid process of the radius. The *second part* curves round the lateral side of the wrist and across the back of the os multangulum majus to reach the proximal end of the first interosseous space. The *third part* passes forwards, through the first interosseous space, to the palm of the hand, where it joins the deep branch of the ulnar artery.

Relations of the First Part.—*Dorsal.*—It passes successively across the volar aspects of the following structures: the tendon of insertion of the biceps, the supinator, the pronator teres, the radial portion of the flexor digitorum sublimis, the flexor pollicis longus, the pronator quadratus, and the volar ligament of the wrist-joint.

Volar.—The artery is covered superficially, in the proximal half, by the volar border of the brachio-radialis; in the remainder of its extent it is covered only by skin and fasciæ.

To the *radial side* are the brachio-radialis, and the superficial branch of the radial nerve (O.T. radial nerve). The nerve lies quite near to the artery in its middle third. To the *ulnar side* are the pronator teres proximally and the flexor carpi radialis distally. Two venæ comites, one on each side, accompany the artery.

Branches of the First Part.—(1) The **radial recurrent** arises in the cubital fossa. It springs from the lateral side of the radial on the volar surface of the supinator. It runs towards the radial border of the forearm, passes between the superficial and deep divisions of the radial (musculo-spiral) nerve, and then runs proximally to the lateral epicondyle of the humerus, where it anastomoses with the anterior terminal branch of the profunda. The radial recurrent supplies numerous muscular branches to the brachio-radialis, the supinator, the extensor carpi radialis longus, and the extensor carpi radialis brevis.

(2) **Muscular branches** to the muscles on the radial side of the volar aspect of the forearm.

(3) The **superficial volar branch** (Fig. 768) is a slender vessel which arises a short distance proximal to the wrist and runs distally across the ball of the thumb. It usually pierces the superficial muscles of the thenar eminence, and terminates either in their substance or by uniting with the ulnar artery and completing the superficial arch of the palm of the hand.

(4) A **volar carpal branch** passes ulnarwards, between the flexor tendons and their synovial sheaths, and the radial attachments of the volar carpal ligaments. It anastomoses with the volar carpal branch of the ulnar artery to form the volar carpal arch, and it receives communications from the volar interosseous artery and from the deep volar arch.

FIG. 768.—SUPERFICIAL DISSECTION OF THE VOLAR ASPECT OF THE FOREARM AND HAND, showing the radial and ulnar arteries and the superficial volar arch with its branches.

Each dorsal metacarpal artery is connected with the deep volar (palmar) arch by a **proximal perforating branch** which passes through the proximal part of the corresponding interosseous space, and with a digital branch from the superficial volar (palmar) arch by a **distal perforating branch** which passes through the distal part of the space.

Relations of the Second Part.

As it curves round the radial side and the dorsum of the wrist, the radial artery lies upon the radial collateral ligament of the intercarpal joint and upon the back of the os multangulum majus. It is crossed by the abductor pollicis longus, the extensor pollicis brevis, and the extensor pollicis longus; more superficially it is covered by skin and fascia, in which are the cephalic vein and some filaments of the superficial branch of the radial nerve.

Branches of the Second Part.

(1) **Dorsales Pollicis.**—Two small arteries which run along the borders of the dorsal aspect of the thumb; they supply the skin, tendons, and joints, and anastomose with the volar digital arteries.

(2) **Dorsalis Indicis Radialis.**—A slender artery which runs distally, on the ulnar head of the first dorsal interosseous muscle and along the dorsal aspect of the radial border of the index-finger.

(3) and (4) The **first dorsal metacarpal** and the **dorsal radial carpal** arise by a common trunk which crosses deep to the extensor pollicis longus.

(a) The metacarpal branch passes distally, on the dorsal aspect of the second dorsal interosseous muscle, and divides, opposite the heads of the metacarpal bones, into two dorsal digital branches which supply the adjacent sides of the index and middle fingers. (b) The dorsal carpal branch runs ulnarwards on the dorsal carpal ligaments, deep to the extensor tendons, to anastomose with the dorsal carpal branch of the ulnar artery, and to complete the **dorsal carpal arch** which receives the terminations of the volar and dorsal interosseous arteries. The dorsal carpal arch gives off the **second and third dorsal metacarpal arteries**, which run distally, on the dorsal aspects of the third and fourth dorsal interosseous muscles, as far as the heads of the metacarpal bones, where each divides into two dorsal digital branches for the adjacent sides of the third and fourth and the fourth and fifth digits, respectively.

Relations of the third part.—The third part of the radial artery passes volarwards, between the two heads of the first dorsal interosseous muscle, to reach the palm, where it turns ulnarwards, deep to the proximal oblique part of the adductor muscle of the thumb, and, after passing through the proximal fibres of the transverse part of the adductor pollicis, or between the adjacent borders of the oblique and transverse parts of the muscle, it unites with the deep branch of the ulnar artery, completing the deep volar (palmar) arch.

Branches of the third part.—

(1) The **princeps pollicis** branch is given off as soon as the radial artery enters the palm. It runs distally, on the volar aspect of the first metacarpal bone, between the adductor and the opponens pollicis, and under cover of the long flexor tendon, and divides, near the distal end of the bone, into collateral branches which run along the sides of the thumb and anastomose with the dorsales pollicis arteries.

(2) The **volaris indicis radialis** is a branch which runs distally between the ulnar head of the first dorsal interosseous muscle and the adductor of the thumb and along the radial side of the index-finger to its tip, supplying the adjacent tissues; not uncommonly it anastomoses with the superficial volar (palmar) arch.

ARTERIA ULNARIS.

The **ulnar artery** (Figs. 768 and 769) is the larger terminal branch, but the less direct continuation of the brachial artery. It commences in the cubital fossa, opposite the neck of the radius, and terminates in the palm of the hand, where it anastomoses with the superficial volar artery to form the superficial volar (palmar) arch.

From its origin it runs obliquely, distally, and ulnarwards, deep to the muscles arising from the medial epicondyle, to the junction of the proximal and middle thirds of the forearm, where it comes into relation with the ulnar nerve; it then passes directly distally, on the radial side of the ulnar nerve, to the wrist; crosses anterior to the main part of the transverse carpal ligament, on the radial side of the pisiform bone, and enters the palm of the hand to form the main part of the superficial volar (palmar) arch.

FIG. 769.—DEEP DISSECTION OF THE FRONT OF THE FOREARM AND HAND, showing the radial and ulnar arteries and their branches and the deep volar arch and its branches.

Relations—Dorsal.—Proximo-distally it lies volar to the distal part of the brachialis,

the flexor digitorum profundus, and the transverse carpal ligament (O.T. anterior annular). *Volar*.—On its volar aspect it is crossed, in the oblique part of its course, by the pronator teres, the median nerve, which is separated from the artery by the deep head of the pronator teres, the flexor digitorum sublimis, the flexor carpi radialis, and the palmaris longus. In the middle third of the forearm it is overlapped by the volar border of the flexor carpi ulnaris, and in the distal third it is covered by skin and fasciæ only. A short distance proximal to the wrist the palmar cutaneous branch of the ulnar nerve lies volar to it, and as it crosses the transverse carpal ligament, it is bound down by a fascial expansion from the tendon of the flexor carpi ulnaris. Two venæ comites, which frequently communicate with one another, lie one on each side of the artery. On the *radial side* there is also, in its distal two-thirds, the flexor digitorum sublimis. On its *ulnar side* are the flexor carpi ulnaris and the ulnar nerve.

Branches.—(1) The **volar ulnar recurrent** is a small branch which arises in the cubital fossa, frequently in common with the dorsal ulnar recurrent. It passes proximally, to the anterior aspect of the medial epicondyle, under cover of the pronator teres, and anastomoses with branches of the superior and inferior ulnar collateral arteries.

(2) The **dorsal ulnar recurrent branch**, larger than the volar, arises in the cubital fossa, from the ulnar side of the ulnar artery, and ascends on the brachialis and under cover of the muscles which arise from the medial epicondyle, to the posterior aspect of that prominence, where it passes between the humeral and olecranon heads of the flexor carpi ulnaris, and anastomoses with the superior and inferior ulnar collateral arteries. It gives branches to the adjacent muscles and to the elbow-joint.

(3) The **common interosseous artery**, a short trunk which springs from the radial and dorsal aspect of the ulnar artery in the distal part of the cubital fossa. It passes dorsally, towards the proximal border of the interosseous membrane, and divides into volar and dorsal interosseous branches.

(3a) The **volar interosseous artery** runs distally, on the volar surface of the interosseous membrane, between the adjacent borders of the flexor pollicis longus and the flexor digitorum profundus, to the proximal border of the pronator quadratus, where it pierces the interosseous membrane, and runs distally, first on the dorsal surface of the membrane, deep to the extensor pollicis longus and extensor indicis proprius, and then on the dorsal surface of the radius, in the groove for the extensor digitorum communis; and it terminates, on the dorsum of the carpus, by joining the dorsal carpal arch. It is accompanied on the volar aspect of the interosseous membrane by the volar interosseous nerve, and, after it has pierced the membrane, by the dorsal interosseous nerve.

Branches.—(a) **Nutrient** to the radius and ulna; (b) **Muscular** to the adjacent muscles; (c) **The volar communicating**, a slender branch which passes distally, deep to the pronator quadratus and on the volar surface of the interosseous membrane, to anastomose with the volar carpal arch; (d) **Small anastomotic branches** are given on the dorsum of the forearm to anastomose with the dorsal interosseous artery; (e) **The median artery** (O.T. comes nervi mediani) is a long slender branch which arises from the proximal part of the volar interosseous artery and runs with the median nerve to the palm, where it anastomoses with recurrent branches of the superficial volar arch.

(3b) The **dorsal interosseous artery** is usually smaller than the volar interosseous. It passes dorsally between the proximal border of the interosseous membrane and the oblique cord, and then between the supinator and abductor pollicis longus (O.T. ext. oss. met. poll.), after which it runs distally, between the superficial and deep muscles on the dorsum of the forearm, to the wrist, where it anastomoses with the volar interosseous artery and with the dorsal carpal arch. As it crosses the abductor pollicis longus it is accompanied by the dorsal interosseous nerve, but in the remainder of its course it is separated from the nerve by the deep muscles.

Branches.—(a) An **interosseous recurrent** branch is given off at the dorsal margin of the distal border of the supinator. It runs proximally, on the dorsal surface of the supinator, under cover of the anconeus, to the back of the lateral epicondyle of the humerus, where it anastomoses with the posterior terminal branch of the profunda and with branches of the inferior ulnar collateral artery. (b) **Muscular branches** to both superficial and deep muscles on the dorsum of the forearm. (c) **Cutaneous branches** to the skin on the dorsum of the forearm and the wrist.

(4) The **volar carpal** branch of the ulnar artery is a small branch given off proximal to the transverse carpal ligament; it passes towards the radial side, deep to the flexor tendons and their sheaths, on the volar surface of the proximal attachments of the volar radio-carpal ligament, and anastomoses with the volar carpal branch of the radial to form the volar carpal arch.

(5) The **dorsal carpal branch** of the ulnar artery arises from the ulnar side of the ulnar artery immediately proximal to the pisiform bone. It passes dorsally, deep to the ulnar flexor and extensor of the carpus, to the dorsum of the carpus, where it unites with the dorsal carpal branch of the radial to form the dorsal carpal arch.

(6) **Profunda.**—This branch passes distally between the abductor and flexor brevis digiti quinti, and, turning towards the radial side, deep to the flexor brevis, the opponens digiti quinti, and the flexor tendons and their sheaths, joins the termination of the radial artery to complete the deep volar (palmar) arch.

THE ARTERIAL ARCHES OF THE WRIST AND HAND.

Arcus Carpeus Volaris

—**The Volar Carpal Arch** (Figs. 768 and 769).—The volar carpal arch lies on the volar aspect of the volar carpal ligaments deep to the flexor tendons and their synovial sheaths. It is formed by the union of the volar carpal branches of the radial and ulnar arteries, and it receives the communicating branch from the volar interosseous artery and recurrent branches from the deep volar arch. The branches of distribution which pass from it supply the ligaments and synovial membrane of the radio-carpal and inter-carpal joints.

Arcus Carpeus Dorsalis.

—**The Dorsal Carpal Arch.** (Fig. 770).—This arch lies on the dorsal carpal ligaments deep to the extensor tendons and their sheaths. It is formed by the union of the dorsal carpal branches of the radial and ulnar arteries, and receives the terminations of the volar and dorsal interosseous arteries.

Branches.—(a) **Articular** to the adjacent articulations.

(b) **Dorsal metacarpal**, two slender branches which run distally, along the third and fourth dorsal interosseous muscles, to the clefts of the fingers, where each divides into dorsal digital branches. They communicate near their origins with the deep volar arch by the proximal perforating arteries, and near their terminations with the volar digital vessels through the distal perforating arteries. Their digital terminal branches run

FIG. 770.—THE DORSAL INTEROSSEOUS ARTERY AND THE SECOND PART OF THE RADIAL ARTERY, WITH THEIR BRANCHES.

distally, on the dorso-lateral aspects of the fingers which bound the third and fourth interosseous spaces, and they anastomose with the proper volar digital branches of the volar digital arteries.

Arcus Volaris Superficialis.—The **superficial volar arch** (Fig. 768) includes the terminal portion of the ulnar artery, and is usually completed on the radial side by the superficial volar, or by the volaris indicis radialis or the princeps pollicis branches of the radial artery. It extends from the ball of the little finger to the ulnar border of the superficial head of the flexor pollicis brevis, and reaches distally to a line drawn across the palm at the level of the distal border of the fully abducted thumb. It is covered by the integuments and the central portion of the palmar aponeurosis, and, on the ulnar side of the palm, by the palmaris brevis. It is accompanied by venæ comites. It is in contact dorsally with the flexor brevis and opponens digiti quinti, and with the common digital branches of the ulnar and median nerves, as well as with the flexor tendons and the lumbrical muscles.

Branches.—Four **volar common digital arteries** arise from the convexity of the arch. The most ulnar of the four passes along the ulnar border of the little finger, accompanied by the common digital branch of the ulnar nerve; the other three pass distally superficial to the common digital nerves, one along the middle of each of the ulnar three interosseous spaces towards the interdigital clefts, just proximal to which each common digital artery divides into two **proper digital arteries** which supply the contiguous sides of the fingers bounding the cleft. As the proper digital branches pass along the sides of the fingers they lie superficial to the corresponding proper digital nerves, and supply branches to the joints, to the flexor tendons and their sheaths, and to the skin and subcutaneous tissues on the volar surface; they give off dorsal branches also which anastomose with the dorsal digital arteries and supply the tissues on the dorsal aspects of the second and terminal phalanges. Some of the dorsally directed branches form a plexus in the matrix of the nail. In the pulp of the finger-tips anastomosing twigs join to form arches from which numerous branches are given off to the skin and subcutaneous fat.

Each of the three most radial proper digital arteries is joined, immediately proximal to its division, by a volar metacarpal artery from the deep volar arch and a distal perforating artery from a dorsal metacarpal artery. The most ulnar digital artery is joined by a branch which comes either from the most ulnar volar metacarpal artery or from the deep volar arch.

Arcus Volaris Profundus.—The **deep volar arch** (O.T. **deep palmar**) (Fig. 769) extends from the base of the metacarpal bone of the little finger to the proximal end of the first interosseous space, and is formed by the terminal part of the radial artery anastomosing with the profunda branch of the ulnar. It is from 12 to 18 mm. (half to three-quarters of an inch) proximal to the level of the superficial volar arch. It lies deeply in the palm, in contact with the proximal ends of the metacarpal bones and their ligaments and on the origin of the interossei muscles, and deep to the flexor tendons and their synovial sheaths.

Branches.—(a) The **proximal perforating**: three small arteries which pass dorsally through the ulnar three interosseous spaces, and between the origins of the dorsal interosseous muscles. They anastomose on the dorsum of the hand with the dorsal metacarpal arteries.

(b) Small irregular **recurrent branches** pass proximally and unite with the volar carpal arch.

(c) The **articular** to the adjacent articulations.

(d) The **volar metacarpal arteries** are three vessels which pass distally, on the interosseous muscles of the three ulnar interosseous spaces, deep to the flexor tendons. They terminate by anastomosing with the volar digital arteries just before the latter vessels divide into proper volar digital branches.

(e) The **communicating**, a small irregular branch which passes ulnarwards between the flexor tendons and the short muscles of the little finger to anastomose with the ulnar proper volar digital artery.

BRANCHES OF THE DESCENDING THORACIC AORTA.

The branches given off from the thoracic portion of the descending aorta are distributed chiefly to the walls of the thorax and to the thoracic viscera. They

contribute also to the supply of the spinal medulla and its membranes, and to that of the vertebral column and of the upper part of the abdominal wall. The branches, which are numerous and for the most part arranged in pairs, are as follows:—

Visceral. { <ul style="list-style-type: none"> Bronchial. Œsophageal. Pericardial. Mediastinal. 	Parietal. { <ul style="list-style-type: none"> Intercostal. Subcostal. Superior phrenic. The vas aberrans.
--	---

VISCERAL BRANCHES OF THE DESCENDING THORACIC AORTA.

1. **Arteriæ Bronchiales.**—The bronchial branches of the thoracic aorta are usually two in number—an upper and a lower—and both pass to the left lung. The *upper left bronchial artery* arises from the front of the aorta opposite the fifth thoracic vertebra; the *inferior left bronchial artery* usually takes origin near the lower border of the left bronchus. Both vessels are directed downwards and laterally to the back of the bronchus which they accompany, and, dividing similarly, they follow its ramifications in the lung. They not only supply the walls of the bronchial tubes and the substance of the lungs, but also give branches to the bronchial glands, the pulmonary vessels, the pericardium, and the œsophagus.

As a rule there is only one *right bronchial artery*. It arises either from the first right aortic intercostal artery or from the upper left bronchial artery. More rarely it springs directly from the aorta. In its course and distribution it corresponds to the bronchial arteries of the left side.

2. **Arteriæ Œsophageæ.**—The œsophageal branches are variable; usually four or five small branches spring from the front of the aorta and pass forwards to the œsophagus, in the walls of which they ramify, anastomosing above with branches of the left bronchial and inferior thyreoid arteries, and below with œsophageal branches of the left gastric and the phrenic arteries.

3. The **pericardial branches** are three or four small irregular vessels which are distributed on the surface of the pericardium.

4. Small **mediastinal branches** pass to the areolar tissue and glands in the posterior mediastinum, and to the posterior part of the diaphragm.

PARIETAL BRANCHES OF THE DESCENDING THORACIC AORTA.

1. **Arteriæ Intercostales**—The **Intercostal Arteries.**—There are nine pairs of aortic intercostal arteries which usually arise separately, though not uncommonly a pair may take origin by a common trunk from the back of the aorta. They are distributed to the lower nine intercostal spaces, to the vertebral column, to the contents of the vertebral canal, and to the muscles and skin of the back. The first three on each side give branches to the mammary gland also. The arteries of opposite sides closely correspond, but, since the aorta in the thoracic region lies on the left of the vertebral column, the right intercostal arteries cross the front of the column, posterior to the œsophagus, the thoracic duct, and the vena azygos, and are longer than the left arteries. In other respects the courses of all the aortic intercostal arteries are almost identical. As each artery runs postero-laterally, across the side of the vertebral column, to an intercostal space, it passes posterior to the pleura, and is crossed, opposite the head of a rib, by the sympathetic trunk. The lower arteries are crossed by the splanchnic nerves also, and those on the left side are crossed by the hemiazygos or accessory hemiazygos veins.

As each artery passes laterally between the neck of two adjacent ribs, it gives off a posterior branch. Then it ascends to the upper border of the space, and, passing either behind or in front of the corresponding intercostal nerve, is continued along the space, in the costal groove. In the space, as far as the angle of the rib, it lies between the pleura and the posterior intercostal membrane, and, in this part of its course, it is embedded in the endothoracic fascia. Then it is continued forward between the internal and external intercostal muscles. In the

costal groove the artery lies between the corresponding vein above and the intercostal nerve below, and it terminates anteriorly by anastomosing with an anterior intercostal branch of the internal mammary or of the musculo-phrenic artery. The lower two intercostal arteries, on each side, extend beyond their spaces into the abdominal wall, and anastomose with branches of the superior epigastric, subcostal, and lumbar arteries. The first right aortic intercostal artery frequently gives off the right bronchial artery.

Branches.—(a) The **posterior branch** passes backwards, accompanied by the posterior branch of a spinal nerve, medial to the anterior superior costo-transverse ligament, between the necks of the ribs which bound the space, and between the adjacent transverse processes, to the vertebral groove, where it divides into a medial and a lateral cutaneous terminal branch. The *medial cutaneous branch* passes backwards and medially either over or through the multifidus, giving branches to the muscles between which it passes and to the vertebral column. The *lateral branch* runs laterally under cover of the longissimus dorsi to the interval between it and the iliocostalis dorsi. It terminates in the skin of the back, after giving branches to the adjacent muscles. Before it divides, each posterior branch gives off muscular branches, and a *spinal branch* which passes through the corresponding intervertebral foramen, and enters the vertebral canal, to the contents and walls of which it is distributed. It divides into three branches—neural, post-central, and pre-laminar. The *neural branch* divides into two branches which run medially, on the roots of the spinal nerve, pierce the dura mater and arachnoid, and divide into branches some of which pass to the membranes of the spinal medulla, whilst others are continued on to reinforce the posterior and anterior spinal arteries. The *post-central branch* divides into ascending and descending branches which, anastomosing with similar branches above and below, form a series of vertical arches on the backs of the bodies of the vertebrae. The arches of opposite sides are connected by short transverse anastomoses. The *pre-laminar branch* is small, and its ascending and descending branches are distributed in a similar though less regular manner on the posterior wall of the vertebral canal.

(b) A **collateral branch** which arises near the angle of the rib. It descends to the lower border of the intercostal space, along which it runs forward to anastomose in front, like the termination of the trunk, with a separate anterior intercostal branch of the internal mammary or musculo-phrenic artery. The collateral branches of the lower two intercostal arteries on each side are inconstant; when present they are small, and terminate in the abdominal wall.

(c) **Muscular branches** to the adjacent muscles are given off both by the main trunk and its collateral branch.

(d) A **lateral cutaneous** offset accompanies the lateral cutaneous branch of the intercostal nerve.

In addition to the secondary branches above-named, the trunk of the first aortic intercostal on each side anastomoses with the superior intercostal, and may supply the whole or the greater part of the second intercostal space. The upper three or four aortic intercostals on each side give branches to the mammary gland which anastomose with branches of the lateral thoracic and internal mammary arteries. Longitudinal anastomoses between adjacent trunks and also between adjacent posterior branches of intercostal arteries sometimes exist near the necks of the ribs, or near the transverse processes. These longitudinal anastomoses are of considerable morphological interest.

2. The **subcostal arteries** are the last pair of parietal branches given off from the thoracic aorta. They are in series with and are very similar to the aortic intercostal arteries, but are situated below the last ribs. Each gives off a posterior branch which behaves in the same manner as the posterior branch of an ordinary aortic intercostal artery. The trunk runs along the lower border of the twelfth rib in company with the last thoracic nerve. It passes below the arcus lumbocostalis lateralis (O.T. ligamentum arcuatum externum) to the abdomen, and there crosses anterior to the quadratus lumborum, and posterior to the kidney and the adjacent part of the colon. It next pierces the aponeurosis of origin of the transversus abdominis, and runs between the transversus and the internal oblique muscles, anastomosing with the lower intercostal arteries, with the lumbar arteries, and with branches of the superior epigastric artery.

3. **Superior phrenic branches** are given off from the lower part of the thoracic aorta. They are small vessels which ramify on the upper and posterior surfaces of

the diaphragm, and anastomose with branches of the pericardiaco-phrenic and musculo-phrenic arteries.

4. The **vas aberrans** is a variable and inconstant branch of the thoracic aorta; it represents the dorsal roots of the fourth and sixth right aortic arches of the embryo. When present it arises from the front and right side of the upper part of the descending aorta near the upper left bronchial artery, and passes upwards and to the right behind the cesophagus; it frequently anastomoses with the right superior intercostal artery, and it may be enlarged and form the first part of the right subclavian artery.

BRANCHES OF THE ABDOMINAL AORTA.

The branches of the abdominal portion of the aorta are distributed almost entirely to the walls and contents of the abdominal cavity, but some supply small branches to the vertebral column, and to the contents of the vertebral canal, and others are prolonged into the pelvis minor. They are divisible into visceral and parietal groups, both of which include paired and single (unpaired) vessels.

Visceral.	Paired.	Suprarenal.	Parietal.	Paired.	Inferior phrenic.
		Renal.			Lumbar.
		Spermatic or ovarian.			Common iliac.
	Single.	Coeliac axis.		Single.	Middle sacral.
		Superior mesenteric.			
		Inferior mesenteric.			

THE PAIRED VISCERAL BRANCHES OF THE ABDOMINAL AORTA.

1. **Arteriæ Suprarenales** (Fig. 773).—There are three pairs of **suprarenal arteries**—the superior, middle, and inferior. Of these the middle only arise directly from the aorta; the superior spring from the inferior phrenic, and the inferior from the renal arteries.

The *middle suprarenal arteries* are two small branches which arise, posterior to the pancreas, from the sides of the aorta, close to the origin of the superior mesenteric artery. They run, one on each side, laterally and upwards, upon the crura of the diaphragm and just above the renal arteries, to the suprarenal glands, to which they are distributed, and they anastomose with the superior and inferior suprarenal arteries.

2. **Arteriæ Renales**.—The **renal arteries** (Fig. 773) arise, one on each side, from the aorta, about 12 mm. (half an inch) below the origin of the superior mesenteric artery and opposite the second lumbar vertebra.

Both arteries are of large size, and the right is frequently slightly lower in position than the left. Each artery runs almost transversely to the hilus of the corresponding kidney. It passes anterior to the crus of the diaphragm and the upper part of the psoas muscle. The left artery lies posterior to the pancreas; the right vessel passes behind the inferior vena cava, the head of the pancreas, and the descending part of the duodenum. The renal vein usually lies below and anterior to the artery, but near the kidney the vein not infrequently occupies a posterior position.

On reaching the hilus of the kidney each artery divides into three branches, two of which pass anterior to the pelvis renalis, and between it and the renal vein, and the third posterior to the pelvis. In the renal sinus these primary branches break up into numerous secondary branches which enter the kidney substance between the pyramids.

Branches.—The following branches are given off by each renal artery, in addition to the terminal branches :—

- (a) **Inferior suprarenal**, which passes upwards to the lower part of the suprarenal gland.
- (b) **Ureteral**.—Small branches to the upper part of the ureter, which anastomose with branches of the internal spermatic or ovarian arteries.
- (c) **Peri-nephric**.—Small branches to the fatty capsule of the kidney, which anastomose with the lumbar arteries.
- (d) **Glandular offsets**, either from the main trunk or from some of its branches, pass to the lumbar lymph glands.

3. *Arteriæ Spermaticæ Internæ*.—The internal spermatic arteries are present in both sexes; in the male they are called the **testicular arteries** and in the female **ovarian arteries**. In each sex they are long slender vessels which spring from the front of the aorta a short distance below the origins of the renal arteries.

3*a*. *The Testicular Arteries*.—Each testicular artery runs downwards and forwards on the anterior surface of the psoas major to the abdominal inguinal ring, where it comes into relation with the ductus deferens. It accompanies the ductus deferens through the inguinal canal to the testis, to which it is distributed.

Relations—*Posterior*.—The right artery passes in front of the inferior vena cava, and as each artery descends, on the anterior surface of the psoas major, it passes in front of the corresponding genito-femoral nerve and the ureter.

Anterior.—Each artery is in relation anteriorly with the peritoneum to which it is attached; but crossing in front of the right artery and intervening between it and the peritoneum are the third part of the duodenum, the right colic and the ileo-colic arteries, the terminal part of the superior mesenteric artery, and the cæcum. Crossing anterior to the left artery are the left colic and sigmoid branches of the inferior mesenteric artery and the iliac colon.

In the lower part of the abdominal portion of its course each testicular artery is accompanied by two veins, which issue from the pampiniform plexus in the inguinal canal and enter the abdomen through the abdominal inguinal ring, but at a higher level the two veins usually fuse into a single stem.

As it enters the inguinal canal each spermatic artery passes in front of the inferior epigastric artery, and the lower end of the external iliac artery; and as it runs downwards and medially, in the canal, it is accompanied by the ductus deferens, and is more or less enclosed in the meshes of the pampiniform venous plexus. At the lower end of the canal it passes through the subcutaneous inguinal ring and descends through the scrotum, lying antero-lateral to the ductus deferens in close association with the anterior group of testicular veins. At the upper end of the testis it breaks up into branches, some of which are distributed to the testis and others to the epididymis.

Branches.—In the abdominal part of its course each testicular artery gives off:—

- (*a*) **Ureteral branches**, to the abdominal part of the ureter.
- (*b*) **Peri-nephric twigs**, to the peri-nephric fat.
- (*c*) **Peritoneal branches**, which are distributed to the peritoneum.
- (*d*) **Glandular branches**, which supply blood to the lumbar lymph glands.

Its terminal branches are the **testicular** and **epididymal** twigs already mentioned.

3*b*. *Ovarian Arteries*.—The course and the relations of each ovarian artery, as far as the level of the brim of the pelvis minor, are the same as the relations of the corresponding testicular artery; but at the level of the upper end of the external iliac artery each ovarian artery turns medially, crosses anterior to the upper ends of the external iliac artery and vein, and enters the upper part of the broad ligament of the uterus. In the broad ligament it runs medially, below the uterine tube, to the level of the ovary. There it turns backwards and passes between the layers of the mesovarium, where it breaks up into terminal branches which enter the ovary through the hilus in its anterior border. As it lies in the broad ligament each ovarian artery is accompanied by the pampiniform plexus of ovarian veins. In the lower portion of the abdominal part of its course it is accompanied by two veins, which issue from the pampiniform plexus at the brim of the pelvis minor, and unite at a higher level into a single trunk.

Branches.—(*a*) In the abdominal part of its course the branches of the ovarian artery are the same as those of the testicular artery.

In the pelvic part of its course it gives off:—

- (*a*) **Tubal branches**, to the walls of the uterine tube.
- (*b*) **Branches** to the round ligament of the uterus.

(*c*) **Uterine branches**, which pass towards the uterus to anastomose with the branches of the uterine artery.

THE UNPAIRED OR SINGLE VISCERAL BRANCHES OF THE ABDOMINAL AORTA.

1. *Arteria Cœliaca*.—The celiac artery (Figs. 771 and 773) arises from the front of the abdominal aorta, immediately below the aortic orifice of the diaphragm and between its crura. It is a short but wide vessel which runs almost horizontally

forwards for a distance of about 12 mm. (half an inch), and terminates by dividing into three large branches—the left gastric, the hepatic, and the splenic.

Relations.—The short trunk lies behind the omental bursa, and runs forwards below the caudate lobe of the liver and above the upper border of the pancreas and the splenic vein. It is surrounded by the celiac plexus of the sympathetic, and has the right celiac ganglion to its right side and the left celiac ganglion to its left side.

Branches.—(a) The **left gastric** (O.T. coronary) is the smallest branch of the celiac artery. It runs obliquely upwards and to the left, and reaches the lesser curvature of the stomach close to the œsophagus. It then turns sharply forwards, downwards, and to the right, and runs towards the pyloric end of the stomach to anastomose with the right gastric branch of the hepatic artery. In the first part of its course the artery lies posterior to the omental bursa; it then

FIG. 771.—THE CELIAC ARTERY AND ITS BRANCHES.

passes into the left gastro-pancreatic fold, and is continued between the layers of the lesser omentum.

Branches.—(i.) **Œsophageal.**—When the left gastric artery reaches the stomach it gives off an œsophageal branch which passes upwards, on the œsophagus, and breaks up into branches which anastomose with œsophageal branches of the thoracic aorta and with branches of the inferior phrenic. (ii.) **Gastric branches** are distributed to both surfaces of the stomach. They anastomose with branches of the short gastric of the splenic, and with branches of the gastro-epiploic arterial arch on the greater curvature of the stomach.

(b) **Arteria Lienalis.**—The **splenic artery** (Fig. 771) is the largest branch of the celiac artery. It runs a more or less tortuous course behind the stomach and the omental bursa, and along the upper border of the pancreas. It lies anterior to the left suprarenal gland and the upper end of the left kidney, and passes forwards between the two layers of the lienorenal ligament, in which it divides into from five to eight terminal branches which enter the hilus of the spleen and supply the splenic substance. It is accompanied by the splenic vein, which lies below it.

Branches.—(i.) **Pancreatic.**—Numerous small branches are given off to the pancreas. A larger branch (pancreatica magna), occasionally present, enters the upper border of the pancreas, about the junction of its middle and left thirds, and runs from left to right in

the substance of the pancreas, a little above and posterior to the pancreatic duct. Both the small and large arteries supply the substance of the pancreas, and anastomose with one another and with branches of the pancreatico-duodenal arteries.

(ii.) The **short gastric branches** (O.T. *vasa brevia*), four or five in number, are given off either from the terminal part of the splenic artery or, more commonly, from some of its terminal branches. They pass between the layers of the gastro-splenic ligament to the left part of greater curvature of the stomach, and anastomose with the œsophageal, the left gastric, and the left gastro-epiploic arteries.

(iii.) The **left gastro-epiploic branch** arises from the front of the splenic, close to its termination, and passes forwards, between the layers of the gastro-splenic ligament, to the left end of the lower part of the greater curvature of the stomach, along which it is continued, from left to right, between the layers of the greater omentum. It ends by anastomosing with the right gastro-epiploic artery, and it gives off numerous *gastric* branches to both surfaces of the stomach, which anastomose with the short gastric and with branches of the left and right gastric arteries. Long slender *omental* branches pass to the omentum and anastomose with branches of the colic arteries.

(c) **Arteria Hepatica.**—The **hepatic artery** (Fig. 771) runs along the upper border of the head of the pancreas to the right gastro-pancreatic fold of peritoneum, in which it turns forwards to the upper border of the first part of the duodenum. It then passes upwards, between the layers of the hepato-duodenal ligament, anterior to the portal vein and to the left of the bile duct, and reaches the porta hepatis (O.T. *transverse fissure*), where it divides into right and left branches.

Branches.—(i.) The **right gastric artery** is a small branch which arises opposite the upper border of the first part of the duodenum. It runs to the pylorus, between the layers of the lesser omentum, and then turns to the left along the smaller curvature of the stomach. It gives branches to both surfaces of the stomach, and terminates by anastomosing with the left gastric artery.

(ii.) The **gastro-duodenal artery**.—This branch of the hepatic arises just above the upper border of the first part of the duodenum, descends behind it and terminates opposite its lower border. In its course it lies between the neck of the pancreas and the first part of the duodenum, and anterior to the portal vein. The bile duct is on its right side. The vessel ends by dividing into the right gastro-epiploic and the superior pancreatico-duodenal arteries. The **right gastro-epiploic artery** is the larger of the two terminal branches of the gastro-duodenal; it passes from right to left, along the greater curvature of the stomach, between the layers of the greater omentum, and unites with the left gastro-epiploic branch of the splenic artery. From the arterial arch so formed branches pass upwards on both surfaces of the stomach, to anastomose with branches of the right and left gastric arteries. Other branches pass downwards in the greater omentum, and anastomose with branches of the colic arteries. The **superior pancreatico-duodenal artery** runs a short course to the right, between the duodenum and the head of the pancreas, and divides into anterior and posterior terminal branches, which descend, the former in front of and the latter behind the head of the pancreas, to anastomose with similar branches of the inferior pancreatico-duodenal artery. They supply the head of the pancreas, anastomosing in it with the pancreatic branches of the splenic artery; branches are given also to the second part of the duodenum and to the bile duct.

(iii.) **Terminal branches.**—The **right hepatic artery** passes either in front of or behind the hepatic duct and behind the cystic duct, to the right end of the porta hepatis, where it divides into two or more branches which enter the substance of the liver and accompany the branches of the portal vein and the hepatic duct. As it crosses above the junction of the hepatic and cystic ducts, the right hepatic artery gives off a cystic branch. The *cystic artery* runs downwards and anteriorly, along the cystic duct, to the gall-bladder, where it divides into anterior and posterior branches; the anterior passes downwards between the gall-bladder and the visceral surface of the liver, to both of which it gives offsets; the posterior branch is distributed on the posterior surface of the gall-bladder, between it and the peritoneum. The **left hepatic artery** is longer and narrower than the right. It runs to the left end of the porta hepatis, gives one or two branches to the caudate lobe, crosses the fossa of the umbilical vein, and breaks up into branches which terminate in the substance of the left lobe of the liver.

2. *Arteria Mesenterica Superior*.—The superior mesenteric artery (Figs. 772 and 773) springs from the front of the aorta, about 12 mm. (half an inch) below the origin of the coeliac artery and opposite the first lumbar vertebra.

It passes obliquely downwards and forwards, crossing anterior to the left renal vein, the uncinate process of the head of the pancreas, and the third part of the duodenum; opposite the latter it enters the root of the mesentery, in which it

FIG. 772.—THE SUPERIOR MESENTERIC ARTERY AND ITS BRANCHES.

continues to descend, curving obliquely from above downwards and to the right, to the right iliac fossa, and crossing, in this part of its course, obliquely in front of the aorta, the lower part of the inferior vena cava, the right ureter, and the right psoas major muscle. At its origin it lies posterior to the neck of the pancreas and the splenic vein; where it passes in front of the duodenum it is crossed anteriorly by the transverse colon, and in the lower part of its extent it is behind the coils of small intestine.

Branches.—It gives off numerous branches which supply the duodenum and the pancreas in part, the whole of the small intestine below the duodenum, and the large intestine nearly as far as the left colic flexure.

The branches are as follows :—

(a) The **intestinal** branches to the small intestine, varying from ten to sixteen in number, are separable into two groups, *jejunal* and *ileal*; they spring from the convexity of the superior mesenteric artery, and pass obliquely forwards and downwards, between the layers of the mesentery, each dividing into two branches which anastomose with adjacent branches to form a series of arcades, from which secondary branches are given off. This process of division and union is repeated three or four times; thus four or five tiers of arches are formed, from the most distal of which terminal branches are given off to the walls of the jejunum and ileum. Branches from the successive arcades are also given off to the mesenteric lymph glands. The terminal branches anastomose together in the walls of the gut, forming a vascular network, which communicates above with the inferior pancreatico-duodenal artery and below with the terminal branch of the superior mesenteric trunk. The arterial loops and branches are accompanied by corresponding veins, lymphatics, and nerves.

(b) The **inferior pancreatico-duodenal artery**. This branch arises either from the trunk of the superior mesenteric, at the upper border of the third part of the duodenum, or from the first jejunal branch. It runs to the right, between the head of the pancreas and the third part of the duodenum, and terminates by dividing into two branches, anterior and posterior, which ascend, the former in front, and the latter behind the head of the pancreas; they supply the head of the pancreas, the second and third parts of the duodenum, and they anastomose with the similar branches of the superior pancreatico-duodenal artery.

(c) The **middle colic artery** is a large branch which springs from the front of the superior mesenteric as it enters the root of the mesentery. It runs downwards and forwards, in the transverse mesocolon, and terminates by dividing into two branches, right and left, which anastomose respectively with the right and left colic arteries, forming arcades from which secondary and tertiary loops are derived, the terminal branches being distributed to the walls of the transverse colon.

(d) The **right colic artery** springs from the right or concave side of the superior mesenteric, either alone or in the form of a common trunk which divides into right colic and ileo-colic branches. It runs to the right, posterior to the peritoneum on the posterior wall of the abdomen, and in front of the right psoas major, the ureter, and the internal spermatic vessels, towards the ascending colon, near which it divides into an ascending and a descending branch. The former passes upwards, and anastomoses, in the transverse mesocolon, with the middle colic artery. The latter descends to anastomose with the upper branch of the ileo-colic, and from the loops thus formed branches are distributed to the walls of the ascending colon and the beginning of the transverse colon.

(e) The **ileo-colic artery** arises by a common trunk with the right colic, or separately from the right side of the superior mesenteric, and passes downwards and to the right, behind the peritoneum, towards the lower part of the ascending colon, where it terminates by dividing into an ascending branch which anastomoses with the lower branch of the right colic, and a descending branch which communicates with the colic terminal branches of the superior mesenteric trunk.

(f) **Terminal**.—The lower end of the superior mesenteric artery divides into five branches—(i.) ileal, (ii.) appendicular, (iii.) anterior ileo-cæcal, (iv.) posterior ileo-cæcal, and (v.) colic.

The **ileal branch** turns upwards and to the left in the lowest part of the mesentery, and anastomoses with the intestinal arteries. The **appendicular branch** passes behind the terminal portion of the ileum, and through the mesentery of the vermiform process to the vermiform process, upon which it ends. The **anterior ileo-cæcal** crosses the front of the ileo-cæcal junction in a fold of peritoneum; the **posterior ileo-cæcal** crosses the ileo-cæcal junction posteriorly, and the **colic** runs upwards to the ascending colon. The ileo-cæcal branches supply the walls of the cæcum, and, like the colic branch, anastomose with branches of the ileo-colic artery. In some cases the majority or all of the above terminal branches spring from the ileo-colic.

3. **Arteria Mesenterica Inferior**.—The **inferior mesenteric artery** (Fig. 773) arises from the front of the aorta towards the left side, 37 mm. (an inch and a half) above the bifurcation; it passes downwards and slightly to the left, lying posterior to the peritoneum and anterior to the left psoas major muscle, to the upper and left border of the left common iliac artery, where it becomes the superior hæmorrhoidal.

Branches.—(a) The **left colic artery** arises from the left side of the inferior mesenteric near its origin, and almost immediately divides into an upper and a lower

branch. The *upper branch* runs upwards and to the left towards the left colic flexure, and to the lower pole of the left kidney, where it divides into (i.) a branch which enters the transverse mesocolon, and, turning medially, terminates by joining the left branch of the middle colic artery, and (ii.) a descending branch to the upper part of the descending colon. The *lower branch* passes to the left, behind the peritoneum, and divides into upper and lower divisions; the upper anastomoses with the descending division of the upper branch and supplies the lower part of the descending colon. The lower division supplies the iliac colon, and its branches anastomose with the branches of the upper division and with the branches of the sigmoid arteries. Both branches of the left colic artery lie immediately behind the peritoneum, and each branch crosses anterior to the ureter and the internal spermatic vessels.

(b) The **sigmoid branches**, usually two in number, arise from the convexity of the inferior mesenteric, and pass downwards and to the left to the lower part of the iliac colon and to the pelvic colon. They lie posterior to the peritoneum, and anterior to the psoas major, the ureter, and the upper part of the iliacus. They terminate by dividing into branches which anastomose with the terminal twigs of the lower branch of left colic above and with branches of the superior hæmorrhoidal below, forming a series of arches from which branches are distributed to the lower part of the iliac colon and the pelvic colon.

(c) The **superior hæmorrhoidal artery** is the direct continuation of the inferior mesenteric. It enters the mesentery of the pelvic colon, crosses the front of the left common iliac artery, descends into the pelvis minor as far as the third piece of the sacrum, or, in other words, the junction between the pelvic colon and the rectum, and divides into two branches which pass downwards on the sides of the rectum. Half-way down the rectum each of the two terminal branches of the superior hæmorrhoidal artery divides into two or more branches which pass through the muscular coats and terminate in the submucous tissue, where they divide into numerous small branches which pass vertically downwards, anastomosing with one another, with offsets from the middle hæmorrhoidal branches of the internal iliac arteries, the inferior hæmorrhoidal branches of the internal pudic arteries, and with branches from the middle sacral artery.

The superior hæmorrhoidal artery supplies the mucous membrane of the pelvic colon and the rectum and the muscular coats of the pelvic colon.

PARIETAL BRANCHES OF THE ABDOMINAL AORTA.

1. **Arteriæ Phrenicæ Inferiores.**—The **inferior phrenic arteries** (Fig. 773), right and left, are of small size; they arise, either separately or by a common trunk, from the aorta, immediately below the diaphragm, to the abdominal surface of which they are distributed. Diverging from its fellow, each artery runs upwards and laterally on the corresponding crus of the diaphragm—that on the right side passing posterior to the inferior vena cava, that on the left side posterior to the œsophagus—and just before reaching the central tendon of the diaphragm each divides into medial and lateral terminal branches. The *medial branch* runs forwards and anastomoses with its fellow of the opposite side, forming an arch, convex forwards, along the anterior border of the central tendon of the diaphragm. Offsets from this arch anastomose with the pericardio-phrenic, musculo-phrenic, and internal mammary arteries. The *lateral branch* passes laterally towards the lower ribs, and anastomoses with the musculo-phrenic and lower intercostal arteries.

In addition to supplying the diaphragm each inferior phrenic artery frequently gives a **superior suprarenal branch** to the suprarenal gland of its own side, and occasionally small hepatic branches which pass through the coronary ligament to the liver. Further, the left artery gives branches to the œsophagus which anastomose with œsophageal branches of the aorta and of the left gastric artery, whilst from the artery of the right side, minute branches pass to the inferior vena cava.

2. **Arteriæ Lumbales.**—The **lumbar arteries** correspond to the intercostal branches of the thoracic aorta. They are in series with them, their distribution is very similar, and, like the intercostals, they arise, either separately or by common trunks, from the posterior aspect of the aorta.

There are usually four pairs of lumbar arteries, but occasionally a fifth pair arises from or in common with the middle sacral artery.

From their origins the lumbar arteries pass laterally and posteriorly, on the front and sides of the bodies of the upper four lumbar vertebræ, to the intervals between the adjacent transverse processes, beyond which they are continued into the lateral part of the abdominal wall.

Each artery lies on the body of the corresponding lumbar vertebra. In its back-

FIG. 773.—THE ABDOMINAL AORTA AND ITS BRANCHES.

ward course, and while still in relation with the vertebral body, it is crossed by the sympathetic trunk, and then, after passing medial to and being protected by the fibrous arches from which the psoas major muscle arises, it runs behind the muscle and the lumbar plexus. The upper two arteries, on each side, also pass posterior to the crura of the diaphragm. Beyond the interval between the transverse processes of the vertebræ each artery turns laterally and crosses the quadratus lumborum—the last usually passing anterior to, and the others posterior to the muscle; it then pierces the aponeurosis of origin of the transversus, and proceeds forwards in the lateral abdominal wall, in the interval between the transversus and internal oblique muscles. The lumbar arteries anastomose with one another, with the lower intercostal and subcostal arteries, and

with branches of the superior and inferior epigastric and of the deep circumflex iliac and ilio-lumbar arteries.

Fine twigs also pass from the lumbar arteries to the extra-peritoneal fat; these anastomose with corresponding branches from the inferior phrenic and ilio-lumbar arteries, and with small branches from the hepatic, renal, and colic arteries, to form the *subperitoneal plexus* of Turner.

The abdominal aorta lies but little to the left of the median plane, and consequently the right lumbar arteries are scarcely longer than the left. On the right side the arteries pass behind the inferior vena cava, the upper two arteries being separated from that vessel by the right crus of the diaphragm. The upper two right arteries also pass posterior to the cisterna chyli and the lower end of the azygos vein.

Branches.—Dorsal.—Each lumbar artery gives off, opposite the interval between the vertebral transverse processes, a dorsal branch of considerable size. It is analogous with and is distributed like the posterior branch of an aortic intercostal artery (p. 925). **Muscular branches** are given off, both from the main trunk and its dorsal branch, to the adjacent muscles.

3. **Arteria Sacralis Media.**—The middle sacral artery (Fig. 773) is a single median vessel. It is commonly regarded as a caudal aorta and as the direct continuation of the abdominal aorta. It is, however, of small size, and almost invariably arises from the back of the aorta, about 12 mm. (half an inch) above its bifurcation. It descends anterior to the lower two lumbar vertebræ and to the sacrum and coccyx, and ends, opposite the tip of the last-named bone, by anastomosing with the lateral sacral arteries to form a loop from which branches pass to the coccygeal glomus. Opposite the fifth lumbar vertebra it is crossed anteriorly by the left common iliac vein, below which it is covered by peritoneum and coils of small intestine as far as the third segment of the sacrum, and in the rest of its extent it is posterior to the rectum. It is accompanied below by venæ comites, which, however, unite above to form a single middle sacral vein.

As it lies anterior to the last lumbar vertebra it gives off on each side a lumbar branch, the *arteria lumbalis ima*, which is distributed like an ordinary lumbar artery, and as it descends in front of the sacrum it distributes small parietal branches laterally which anastomose with the lateral sacral arteries. These usually give off small spinal offsets which enter the anterior sacral foramina. Small and irregular visceral branches pass to the rectum and anastomose with the superior and middle hæmorrhoidal arteries.

ARTERIE ILIACÆ COMMUNES.

4. The **common iliac arteries** (Figs. 773 and 774) are the terminal branches of the abdominal aorta. They commence opposite the middle of the body of the fourth lumbar vertebra a little to the left of the median plane. Each artery passes downwards and laterally, across the bodies of the fourth and fifth lumbar vertebræ and the intervening intervertebral fibro-cartilage, and it terminates, at the level of the lumbo-sacral articulation and anterior to the corresponding sacro-iliac joint, by dividing into external iliac and hypogastric (O.T. internal iliac) branches.

The direction of each common iliac is indicated by a line drawn from the bifurcation of the aorta to a point midway between the symphysis pubis and the anterior superior spine of the ilium.

The angle included between the two diverging trunks is about 60° in the male and about 68° in the female.

The right artery is, for obvious reasons, a little longer than the left; the former being about 50 mm. (two inches) and the latter 43 mm. (one and three-quarter inches) in length.

Relations.—Anterior.—Both arteries are covered anteriorly by peritoneum, and are separated by it from coils of the small intestine. Communicating branches between the

aortic and hypogastric plexuses of the sympathetic pass in front of the arteries, each of which is often crossed, anteriorly, near its termination by the corresponding ureter.

The left artery is crossed, in addition, by the superior hæmorrhoidal vessels.

Posterior.—Behind the artery, of each side, are the bodies of the fourth and fifth lumbar vertebræ, and the intervening intervertebral fibro-cartilage, the sympathetic trunk, and the psoas major muscle. These relationships, however, are much closer on the left side than on the right. The right common iliac, except at its lower end, where it is in contact with the psoas major, is separated from the structures named by the terminations of the right and left common iliac veins and the commencement of the inferior vena cava. The left common iliac, which is not so separated, lies on the medial border of the psoas major. Somewhat deeply placed, in the areolar tissue between the psoas major and the lumbar vertebræ, are the obturator nerve, the lumbo-sacral trunk, and the ilio-lumbar artery, which form posterior relations to the common iliac artery of the corresponding side.

Lateral.—The lateral relations of each artery are coils of small intestine, and the commencement of the inferior vena cava lies to the lateral side of the upper part of the right artery.

Medial.—On the medial side of the right common iliac artery are the right common iliac vein below, and the left common iliac vein above. The last-named vein lies on the medial side of the left common iliac artery.

Branches.—The external iliac and the hypogastric are the only branches.

ARTERIA HYPOGASTRICA.

The **hypogastric artery** (O.T. **internal iliac**) (Figs. 773, 774, and 777) in the fœtus is the direct continuation of the common iliac trunk. It supplies numerous branches to the pelvis, runs upwards on the anterior abdominal wall to the umbilicus as the umbilical artery, and is prolonged through the umbilical cord to the placenta. One of its pelvic branches—the inferior glutæal (O.T. sciatic)—is at first the main artery of the inferior extremity, but subsequently another branch is given off which becomes the chief arterial trunk of the lower limb. This branch is the external iliac artery; it soon equals and ultimately exceeds the hypogastric in size, and it is into these two vessels that the common iliac appears to bifurcate.

When the placental circulation ceases and the umbilical cord is severed, the umbilical part of the hypogastric trunk which extends from the pelvis minor to the umbilicus atrophies, and is afterwards represented almost entirely by a fibrous cord, known as the obliterated umbilical artery. It is only at its proximal end that the atrophied part remains pervious, and there it forms the commencement of the superior vesical artery. The permanent hypogastric is a comparatively short vessel. Owing to the arrangement of some of its branches it appears to end in an anterior and a posterior division, the former of which is to be regarded as the continuation of the vessel, whilst the latter is simply a common stem of origin for some of the branches.

With this explanation the artery may be described in the usual manner.

It arises from the common iliac opposite the sacro-iliac and at the level of the lumbo-sacral articulation, and descends into the pelvis minor, to terminate, as a rule, opposite the upper border of the greater sciatic notch, in two divisions—anterior and posterior—from each of which branches of distribution are given off. The artery measures about 37 mm. (one and a half inches) in length, and is the medial of the two terminal branches of the common iliac artery.

Relations.—*Anterior.*—Each hypogastric artery is covered antero-medially by peritoneum, behind which the corresponding ureter descends along the anterior border of the artery. The pelvic colon crosses from the front to the medial side of the left artery, and the terminal part of the ileum bears the same relation to the right artery.

Posterior to it are the hypogastric vein and the commencement of the common iliac vein; still more posteriorly are the lumbo-sacral trunk and the sacro-iliac joint.

Lateral.—On its lateral side the external iliac vein separates it from the psoas major muscle above. At a lower level the obturator nerve, embedded in a mass of fat, intervenes between the hypogastric artery and the lateral wall of the pelvis. On its medial side it is crossed by some of the tributaries of the hypogastric vein, and it is covered by peritoneum.

Branches.—The hypogastric artery supplies the greater part of the pelvic wall and viscera, and its branches are distributed also to the buttock and thigh and to the external organs of generation.

All the branches may be given off separately from a single undivided parent

FIG. 774.—HYPOGASTRIC ARTERY AND ITS BRANCHES IN THE FEMALE.

				Middle hæmorrhoidal.

In the female two additional branches are present—a *uterine* and a *vaginal*.

BRANCHES OF THE POSTERIOR DIVISION.

The posterior terminal division gives off the ilio-lumbar and lateral sacral arteries, and is continued as the superior glutæal artery. No visceral branches are derived from this division.

1. *Arteria Ilio-lumbalis*.—The **ilio-lumbar artery** runs upwards and laterally across the upper margin of the pelvis minor to the iliac fossa. It passes anterior to the sacro-iliac articulation, between the lumbo-sacral trunk and the obturator nerve, and posterior to either the lower part of the common or the upper part of the external iliac vessels, and the psoas and iliacus muscles.

In the iliac fossa it divides into an iliac and a lumbar branch. The **iliac branch** anastomoses with branches of the deep circumflex iliac and obturator arteries. It also gives off offsets to the iliacus, and supplies a large nutrient branch to the ilium. A **lumbar branch** ascends behind the psoas major to the crest of the ilium. It supplies the psoas and quadratus lumborum, and anastomoses with the lumbar and deep circumflex iliac arteries; it also gives off a *spinal branch*, which enters the intervertebral foramen between the fifth lumbar vertebra and the sacrum, and is distributed like the spinal branches of the lumbar and the aortic intercostal arteries.

2. *Arteriæ Sacrales Laterales*.—There is sometimes only a single **lateral sacral artery** on each side; more commonly there are two, **superior** and **inferior**.

Both branches run downwards and medially, on the front of the sacrum. The inferior passes anterior to the piriformis and the sacral nerves, and descends, on the lateral side of the sympathetic trunk, to the coccyx, where it terminates by anastomosing with the middle sacral. The superior branch reaches only as far as the first or the second anterior sacral foramen; then it enters the sacral canal. It anastomoses with the lower branch and with the middle sacral artery. Transverse branches are given off by the lateral sacral arteries to the piriformis, and to the sacral nerves. Spinal offsets are also given off, which pass through the anterior sacral foramina to the sacral canal; they supply the membranes of the spinal medulla, the roots of the sacral nerves, and the filum terminale, and anastomose with other spinal arteries. They then pass backwards through the posterior sacral foramina, and anastomose on the back of the sacrum with branches of the superior and inferior glutæal arteries.

3. *Arteria Glutæa Superior*—(Figs. 774 and 776).—After giving off the ilio-lumbar and lateral sacral branches, the posterior division of the hypogastric artery is continued as the **superior glutæal artery**. This is a large vessel which pierces the pelvic fascia, and passes backwards, between the lumbo-sacral trunk and the first sacral nerve. It leaves the pelvis through the upper part of the greater sciatic foramen, above the piriformis muscle, and enters the buttock, where it divides, under cover of the glutæus maximus and between the adjacent borders of the piriformis and glutæus medius muscles, into superficial and deep branches.

(a) The **superficial branch** divides at once into numerous rami, some of which supply the glutæus maximus, whilst others pass through it, near its origin, to the overlying skin. The branches freely anastomose with branches of the inferior glutæal, internal pudendal, medial circumflex, deep circumflex iliac, and lateral sacral arteries.

(b) The **deep terminal branch**, accompanied by the superior glutæal nerve, runs forwards between the glutæus medius and minimus, and, after giving a nutrient branch to the ilium, subdivides into upper and lower branches. The *upper branch*, runs forwards along the origin of the glutæus minimus from the anterior curved line of the ilium, and passes beyond the anterior margins of the glutæus medius and minimus to anastomose, under cover of the tensor fasciæ latæ, with the ascending branch of the lateral circumflex artery. It anastomoses with the deep circumflex iliac artery also, and it supplies muscular branches to the adjacent muscles. The *lower branch* passes more directly forwards, across the glutæus minimus, towards the trochanter major, along with the branch of the superior glutæal nerve which supplies the tensor fasciæ latæ. It supplies the glutæal muscles, and anastomoses with the ascending branch of the lateral circumflex artery.

Before leaving the pelvis the glutæal artery gives **muscular branches** to the pelvic diaphragm and the obturator internus, small **neural branches** to the roots of the sacral plexus, and **nutrient branches** to the hip-bone.

BRANCHES OF THE ANTERIOR DIVISION.

The anterior division gives off both parietal and visceral branches, and is continued as the umbilical artery, which for the greater part of its extent is completely obliterated. The parietal branches are the obturator, the internal pudendal, and the inferior glutæal. The visceral branches include the superior and inferior vesical, and the middle hæmorrhoidal arteries in the male. In the female the anterior division of the hypogastric artery gives off similar visceral branches, and, in addition, a uterine and a vaginal branch.

VISCERAL BRANCHES.

1. *Arteria Vesicalis Superior*.—The superior vesical artery arises from the incompletely obliterated posterior part of the umbilical artery, as it lies at the side of the bladder. It passes medially to the upper part of the urinary bladder and divides into numerous branches which anastomose with the other vesical arteries, and it also gives small branches to the urachus, and often to the lower part of the ureter. It may in addition give off a middle vesical branch, and not infrequently the long slender artery to the *ductus deferens* arises from it.

2. *Arteria Umbilicalis*.—Atrophy of that portion of the umbilical artery which extends from the anterior division of the hypogastric to the umbilicus has already been referred to. The atrophy is complete between the umbilicus and the origin of the superior vesical artery, but between that origin and the apparent ending of the hypogastric in its two divisions it is incomplete, and the lumen of the vessel, though greatly diminished in size, remains patent. It is from this incompletely obliterated portion that the superior vesical artery arises. The completely obliterated part of the umbilical artery is reduced to a fibrous cord which runs along the side of the bladder to its apex, and then ascends, on the posterior surface of the anterior abdominal wall, to the umbilicus. In the latter part of its course it is known as the *ligamentum umbilicale laterale*. As it passes along the wall of the pelvis it is external to the peritoneum, and it is crossed by the *ductus deferens* in the male, and by the round ligament in the female.

3. *Arteria Vesicalis Inferior*.—The inferior vesical artery is a very constant branch which runs medially, upon the upper surface of the levator ani, to the base of the bladder. It also gives branches to the seminal vesicles, the *ductus deferens*, the lower part of the ureter and the prostate, and it anastomoses with its fellow of the opposite side, with the other vesical arteries, and with the middle hæmorrhoidal artery.

4. *Arteria Deferentialis*.—The artery to the *ductus deferens* may arise from either the superior vesical or the inferior. It is a long slender vessel which accompanies the *ductus deferens* to the testis, where it anastomoses with the testicular artery. It also anastomoses with the external spermatic branch of the inferior epigastric artery.

5. *Arteria Hæmorrhoidalis Media*.—The middle hæmorrhoidal artery is an irregular branch which arises either directly from the anterior division of the internal iliac or from the inferior vesical branch; more rarely it springs from the internal pudendal artery. It runs medially, and is distributed to the muscular coats of the rectum; it also gives branches to the prostate, the seminal vesicle, and the *ductus deferens*, and it anastomoses with its fellow of the opposite side, with the inferior vesical, and with the superior and inferior hæmorrhoidal arteries.

6. *Arteria Vaginalis*.—The vaginal artery may arise either directly from the anterior division of the hypogastric or from a stem common to it and the uterine artery, and it may be represented by several branches.

It runs downwards and medially, on the floor of the pelvis, to the sides of the vagina, and divides into numerous branches which ramify on the anterior and posterior walls of the passage. The corresponding branches of opposite sides anastomose and form anterior and posterior longitudinal vessels, the so-called *azygos arteries*. They also anastomose above with the cervical branches of the uterine artery, and below with the perineal branches of the internal pudendal.

In addition to supplying the vagina, small branches are given to the bulb of the vestibule, to the base of the bladder, and to the rectum.

7. *Arteria Uterina*.—The **uterine artery** arises from the anterior division of the internal iliac, either separately or in common with the vaginal or middle hæmorrhoidal arteries. It runs medially and slightly forwards, upon the upper surface of the levator ani, to the lower border of the broad ligament, between the two layers of which it passes medially, and arches above the ureter about three-quarters of an inch from the uterus. It passes above the lateral fornix of the vagina to the side of the neck of the uterus, and then ascends towards the fundus, but at the level of the uterine tube it turns laterally, below the tube and between the layers of the broad ligament, and anastomoses with the ovarian artery. It supplies the uterus, the upper part of the vagina, the medial part of the uterine tube, and gives branches to the round ligament of the uterus. It anastomoses with its fellow of the opposite side, and with the vaginal, the ovarian, and the inferior epigastric arteries, along the round ligament of the uterus.

PARIETAL BRANCHES OF THE ANTERIOR DIVISION.

1. *Arteria Obturatoria*.—The **obturator artery** (Figs. 774 and 777) runs anteriorly and downwards along the lateral wall of the pelvis minor, just below its upper margin, to the obturator foramen, through the upper part of which it passes. It terminates, immediately on entering the thigh, by dividing into anterior and posterior terminal branches, which skirt round the margin of the obturator foramen deep to the obturator externus muscle. It is accompanied, in the whole of its course, by the obturator nerve and vein, the nerve being above the artery and the vein below it.

To its lateral side is the pelvic fascia, which intervenes between it and the upper part of the obturator internus muscle, whilst on its medial side it is covered by peritoneum. The ureter intervenes between the posterior part of the artery and the peritoneum. When the bladder is distended it also comes into close relation with the lower and anterior part of the artery. In the female the ovarian vessels and the broad ligament are on the medial side of the obturator artery.

Branches.—All the branches except the terminal are given off before the artery leaves the pelvis. They include:—(a) **Muscular branches** to the obturator internus, levator ani and ilio-psoas muscles. (b) A **nutrient branch** to the ilium, which passes deep to the ilio-psoas muscle, supplies the bone, and anastomoses with the ilio-lumbar artery. (c) A **vesical branch** or branches pass medially to the bladder beneath the lateral false ligament. (d) A **pubic branch** ascends on the posterior surface of the pubis, and anastomoses with its fellow of the opposite side and with the pubic branch of the inferior epigastric. It is given off just before the artery leaves the pelvis, and in its upward course it may pass either on the lateral or medial side of the external iliac vein, whilst not infrequently it runs on the medial side of the femoral ring. In the latter case it is important in relation to femoral hernia; this importance is emphasised when, as sometimes happens, the obturator artery arises as an enlarged pubic branch of the inferior epigastric artery instead of from the hypogastric. (e) **Terminal**.—The *anterior terminal branch* runs forwards, and the *posterior* backwards around the margin of the obturator foramen. They lie on the obturator membrane, under cover of the obturator externus, and they anastomose together at the lower margin of the foramen. Both give off offsets which anastomose with the medial circumflex artery, and twigs of supply to the adjacent muscles. The posterior branch also gives an acetabular branch to the hip-joint, which passes upwards, through the acetabular notch on the medial side of the transverse ligament, to supply the ligamentum teres and the head of the femur.

2. *Arteria Pudenda Interna*.—The **internal pudendal artery** (Figs. 774 and 775) arises from the anterior division of the hypogastric, close to the origin of the inferior gluteal artery, which slightly exceeds it in size. It runs downwards and backwards, to the lower part of the greater sciatic foramen, lying anterior to the piriformis muscle and the sacral plexus, from both of which it is separated by the pelvic fascia. At the lower border of the piriformis it pierces the pelvic

fascia, passes between the piriformis and coccygeus muscles, and leaves the pelvis to enter the buttock. It is accompanied by venæ comites, the inferior glutæal vessels and nerves, the pudendal nerve, and the nerve to the obturator internus. In the buttock it lies on the spine of the ischium, under cover of the glutæus maximus, and between the pudendal nerve and the nerve to the obturator internus, the former being medial to it. It next passes through the lesser sciatic foramen and enters the perineum, in the anterior part of which it terminates by dividing into the profunda artery of the penis and the dorsal artery of the penis.

In the first part of its course *in the perineum* the artery lies in the lateral fascial wall of the ischio-rectal fossa, where it is enclosed in a canal in the fascia

FIG. 775.—THE PERINEAL DISTRIBUTION OF THE INTERNAL PUDENDAL ARTERY IN THE MALE.

(Alcock's canal). This canal, which is situated about one and a half inches above the lower margin of the tuberosity of the ischium, contains also the pudendal veins and the terminal parts of the pudendal nerve, viz., the dorsal nerve of the penis, which lies above the artery, and the perineal division, which lies below the vessel. From the ischio-rectal fossa the internal pudendal artery is continued forwards between the two layers of the fascia of the urogenital diaphragm (O.T. triangular ligament of the urethra), and close to the ramus of the pubis. About half-an-inch below the arcuate ligament it turns somewhat abruptly forwards, pierces the inferior fascia of the urogenital diaphragm, and immediately divides into its terminal branches, viz., the profunda artery and the dorsal artery of the penis. The division sometimes takes place whilst the artery is still between the layers of the urogenital diaphragm.

Branches.—*In the pelvis* it gives small branches to the neighbouring muscles and to the roots of the sacral plexus.

In the buttock.—(a) **Muscular branches** are distributed to the adjacent muscles. (b) **Anastomotic branches** unite with branches of the superior and inferior glutæal, and medial circumflex arteries.

In the ischio-rectal fossa.—(c) The **inferior hæmorrhoidal artery** pierces the wall of the fascial canal, and runs obliquely forwards and medially. It soon divides into two or three main branches, which may arise separately from the pudendal; they pass across the space to the anal passage. The artery anastomoses in the walls of the anal passage with its fellow of the opposite side, and with the middle and superior hæmorrhoidal arteries; it anastomoses with the transverse perineal arteries also; and it supplies cutaneous twigs to the region of the anus, and others, which turn round the lower border of the glutæus maximus, to supply the lower part of the buttock.

(d) The **perineal artery** arises in the anterior part of the ischio-rectal fossa, pierces the base of the fascia of the urogenital diaphragm, and divides into long slender *posterior scrotal branches* in the male, and *posterior labial branches* in the female. These branches are continued forwards, in the urethral triangle, to the scrotum, deep to the superficial perineal fascia. They anastomose with their fellows of the opposite side, with the transverse perineal and the external pudendal arteries, and supply the muscles and subcutaneous structures of the urethral triangle.

(e) The **transverse perineal artery** is a small branch which arises either directly from the internal pudendal or from its perineal branch. It runs medially along the base of the fascia of the urogenital diaphragm (O.T. triangular lig.) to the central point of the perineum, where it anastomoses with its fellow of the opposite side, with the perineal artery, and with the inferior hæmorrhoidal arteries. It supplies the sphincter ani, the bulbo-cavernosus or sphincter vaginae, and the anterior fibres of the levator ani.

In the urethral triangle.—(f) The **artery to the bulb**, a branch which is usually of relatively large size, is given off between the fascial layers of the urogenital diaphragm. It runs transversely along the posterior border of the sphincter of the membranous urethra, and then, turning forwards a short distance from the side of the urethra, it pierces the inferior fascia of the urogenital diaphragm and enters the substance of the bulb. It passes onwards in the corpus cavernosum urethrae to the glans, where it anastomoses with its fellow and with the dorsal arteries of the penis.

It supplies the sphincter of the membranous urethrae, bulbo-urethral gland (Cowper), the corpus cavernosum urethrae, and the penile part of the urethra. In the female this artery supplies the bulb of the vestibule.

(g) The **profunda artery of the penis** (O.T. **artery of the corpus cavernosum**) in the male, and **of the clitoris** in the female, is usually the larger of the two terminal branches. Immediately after its origin it enters the crus penis, and runs forwards in the corpus cavernosum penis, which it supplies.

(h) The **dorsal artery of the penis** in the male, and **of the clitoris** in the female, passes forwards between the layers of the suspensory ligament, and runs along the dorsal surface of the penis, with the dorsal nerve immediately to its lateral side, whilst it is separated from its fellow of the opposite side by the deep dorsal vein, which lies in the median plane. It supplies the superficial tissues on the dorsal aspect of the penis, sends branches into the corpus cavernosum penis to anastomose with the profunda artery of the penis, and its terminal branches enter the glans penis, where they anastomose with the arteries to the bulb. It anastomoses also with the external pudendal branches of the femoral.

3. Arteria Glutæal Inferior.—The **inferior glutæal artery** (O.T. **sciatic**), (Figs. 774 and 776) arises from the hypogastric artery, either separately or by a common trunk with the internal pudendal artery. It descends a little postero-lateral to the internal pudendal vessels, pierces the pelvic fascia, runs backwards between the first and second, or second and third sacral nerves, and, passing between the piriformis and coccygeus muscles, leaves the pelvis through the lower part of the greater sciatic foramen, and enters the buttock just below the piriformis. In the buttock it descends posterior and to the medial side of the sciatic nerve beneath the glutæus maximus, and posterior to the obturator internus, the two gemelli, the quadratus femoris, and upper part of the adductor magnus muscles, to the proximal part of the thigh.

Below the lower border of the glutæus maximus the artery is comparatively superficial, and having given off its largest branches, it runs distally as a long slender vessel with the posterior femoral cutaneous nerve.

Branches—*In the pelvis.*—Small and irregular branches supply the adjacent viscera and muscles and the sacral nerves; they anastomose with branches of the internal pudendal and lateral sacral arteries.

In the buttock.—(a) **Muscular branches** are given off to the muscles of the buttock and to the proximal parts of the hamstring muscles. They anastomose with the internal pudendal, medial circumflex, and obturator arteries. (b) The **coccygeal branch** arises immediately after the artery leaves the pelvis. It runs medially, pierces the sacro-tuberous ligament and the glutæus maximus, and ends in the soft tissues over the posterior aspect of the lower part of the sacrum and of the coccyx. It gives several branches to the glutæus maximus, and anastomoses with branches of the glutæal and lateral sacral arteries. (c) An **anastomotic branch** passes laterally, superficial or deep to the sciatic nerve, towards the greater trochanter of the femur. It anastomoses with branches of the glutæal, internal pudendal, medial and lateral circumflex, and the first perforating arteries, taking part in the formation of the so-called "crucial anastomosis." (d) **Cutaneous branches**, accompanying twigs of the posterior cutaneous nerve of the thigh, pass round the lower border of the glutæus maximus muscle to the integument. (e) The **a. comitans n. ischiadici** is a long slender branch which runs distally on the surface, or in the substance of the sciatic nerve. It supplies the nerve, and anastomoses with the perforating arteries and with the termination of the profunda femoris artery.

FIG. 776.—THE ARTERIES OF THE BUTTOCK AND THE BACK OF THE THIGH AND KNEE.

ARTERIES OF THE INFERIOR EXTREMITY.

The main artery of each lower limb is continued from the corresponding common iliac artery. It descends as a single trunk as far as the lower border of the popliteus, and ends there by dividing into the anterior and posterior tibial arteries. Distinctive names are, however, applied to different parts of the artery, corresponding to the several regions through which it passes. Thus in the abdomen it is called the **external iliac artery**, in the proximal two-thirds of the thigh it receives the name of the **femoral artery**, whilst its distal part, which is situated on the flexor aspect of the knee, is termed the **popliteal artery**.

ARTERIA ILIACA EXTERNA.

The **external iliac artery** extends from a point opposite the sacro-iliac joint, at the level of the lumbo-sacral articulation, to a point below the inguinal ligament (Poupart's), midway between the anterior superior spine of the ilium and the symphysis pubis, where it becomes the femoral artery. Its length is about 87 to 100 mm. (three and a half to four inches), and in the adult it is usually somewhat larger than the hypogastric artery.

It runs forwards and laterally, along the superior aperture of the minor pelvis, resting upon the fascia iliaca, which separates it above from the medial border, and below from the anterior surface of the psoas major muscle; and it is enclosed with its accompanying vein in a thin fascial sheath.

Relations.—*Anterior.*—It is covered in front by peritoneum, which separates it on the left side from the iliac colon, and coils of small intestine, and on the right side from the terminal portion of the ileum, and sometimes from the vermiform process. The ureter, descending behind the peritoneum, sometimes crosses the front of the artery near its origin, and in the female the ovarian vessels cross the upper part of the artery. Near its lower end the artery is crossed anteriorly by the external spermatic branch of the genito-femoral nerve and by the deep circumflex iliac vein. In the male this part of the artery is crossed also by the ductus deferens, and in the female by the round ligament of the uterus. Several iliac lymph glands lie in front and at the sides of the external iliac artery, and almost invariably one of these is directly anterior to its termination.

Posterior.—The fascia iliaca and psoas major muscle lie behind the artery. Near its upper end the obturator nerve and the external iliac vein are posterior to the vessel.

Lateral.—On its lateral side is the genito-femoral nerve. *Medial.*—To the medial side of its lower part is the external iliac vein.

Branches.—In addition to small branches to the psoas major muscle and to the lymph glands, two named branches of considerable size spring from the external iliac artery, viz., the inferior epigastric and the deep circumflex iliac.

(1) **Arteria Epigastrica Inferior.**—The **inferior epigastric artery** (Figs. 774 and 777) arises, immediately above the inguinal ligament, from the front of the external iliac. It lies in the extra-peritoneal fat, it curves forward from its origin, turns round the lower border of the peritoneal sac, and runs upwards and medially, along the medial side of the abdominal inguinal ring and along the lateral border of the medial inguinal fossa; it then pierces the transversalis fascia, passes over the semi-circular fold (Douglas) and enters the sheath of the rectus abdominis muscle. For a short distance it ascends posterior to the rectus, but it soon penetrates the substance of the muscle, and breaks up into branches which anastomose with terminal offsets of the superior epigastric branch of the internal mammary artery and with the lower intercostal arteries. At the abdominal inguinal ring, in the male, the ductus deferens, the testicular vessels, and the external spermatic branch of the genito-femoral nerve hook round the front and lateral side of the artery, the ductus deferens turning medially behind it; whilst in the female the round ligament of the uterus and the external spermatic branch of the genito-femoral nerve occupy the corresponding positions.

Branches.—(a) **Muscular branches**, which spring mainly from the lateral side of the artery, supply the rectus, the pyramidalis, the transversus, and the oblique muscles of

the abdominal wall, and anastomose with branches of the deep circumflex iliac, the lumbar, and the lower intercostal arteries. (b) **Cutaneous branches**, which pass from the front of the inferior epigastric, pierce the rectus abdominis and the anterior part of its sheath, and terminate in the subcutaneous tissues of the anterior abdominal wall, where they anastomose with corresponding branches of the opposite side and with branches of the superficial epigastric artery. (c) The **external spermatic** in the male (**artery of the round ligament of the uterus** in the female) is small. It descends through the inguinal canal and anastomoses with the external pudendal and the scrotal branches of the perineal artery, and in the male with the internal spermatic artery also. In the male it accompanies the spermatic funiculus, supplying its coverings, including the cremaster. In

FIG. 777.—THE ILIAC AND HYPOGASTRIC ARTERIES AND VEINS IN THE FEMALE.

the female it runs with the round ligament. (d) The **pubic branch** descends, either on the lateral or the medial side of the femoral ring, to anastomose with the pubic branch of the obturator artery; it anastomoses also with its fellow of the opposite side. Sometimes when the obturator branch of the hypogastric artery is absent, the pubic branch of the inferior epigastric artery enlarges and becomes the obturator artery, which descends to the obturator foramen either on the lateral or the medial side of the femoral ring. In the latter case the artery may be injured in the operation for the relief of a strangulated femoral hernia.

(2) **Arteria Circumflexa Ilium Profunda**.—The deep circumflex iliac artery (Figs. 774 and 777) springs from the lateral side of the external iliac artery, usually a little below the inferior epigastric, and immediately above the inguinal ligament. It runs laterally and upwards to the anterior superior spine of the ilium. In this part of its course it lies just above the lower border of the inguinal ligament, and is enclosed in a fibrous canal formed by the union of the transversalis and iliac

fasciæ. A little beyond the anterior superior spine it pierces the transversus abdominis, and is continued backwards, between the transversus and the internal oblique, to terminate by anastomosing with branches of the ilio-lumbar artery.

FIG. 778.—THE FEMORAL ARTERY AND ITS BRANCHES.

Branches.—(a)

Muscular to the upper parts of the sartorius and the tensor fasciæ latæ, and to the muscles of the abdominal wall. One of the latter branches is frequently of considerable size; it pierces the transversus muscle a short distance anterior to the anterior superior spine of the ilium, and ascends vertically, between the transversus and the internal oblique, anastomosing with the lumbar and the epigastric arteries. (b) **Cutaneous branches** pierce the internal and external oblique muscles. They terminate in the skin over the crest of the ilium, and they anastomose with the superior glutæal, the superficial circumflex iliac, and the ilio-lumbar arteries.

ARTERIA FEMORALIS.

The **femoral artery** (Figs. 778 and 779) is the continuation of the external iliac into the thigh. It commences at the lower

border of the inguinal ligament (O.T. Poupart's), passes through the proximal two-thirds of the thigh, and terminates at the opening in the adductor magnus. At one time it was customary to speak of the first one and a half inches, as far as the origin of the profunda branch, as the common femoral, and to say that it divided into the superficial and deep femoral branches, of which the former was the direct continuation of the common trunk. The morphology and development of the vessel gives no support for such terminology.

Course.—Its general direction is indicated by a line drawn from the point of origin, midway between the anterior superior spine of the ilium and the symphysis pubis, to the adductor tubercle, the thigh being flexed, abducted, and rotated laterally.

In its proximal half the femoral artery lies in the femoral trigone (O.T. Scarpa's triangle), and is comparatively superficial; at the apex of the trigone it passes deep to the sartorius, enters the adductor canal (Hunter's), and is thus more deeply placed.

At their entry into the femoral trigone both the artery and its vein are enclosed, for a distance of 31 mm. (one and a quarter inches), in a funnel-shaped fascial sheath formed of the fascia transversalis anteriorly and the fascia iliaca posteriorly. This is called the **femoral sheath**; it is divided, by antero-posterior septa, into three compartments, of which the lateral is occupied by the femoral artery and lumbo-inguinal branch of the genito-femoral nerve; the intermediate compartment contains the femoral vein; and the medial compartment constitutes the femoral canal.

Relations.—*Anterior.*—In the femoral trigone the femoral artery is covered superficially by skin and fasciae, by superficial sub-inguinal lymph glands and small superficial vessels. The anterior part of the femoral sheath and the fascia cribrosa are in front of the proximal part of the artery, and the fascia lata is in front of the distal part. Near the apex of the triangle the artery is crossed by the medial cutaneous nerve, and not infrequently by a tributary of the great saphenous vein. *Posterior.*—It is in relation, posteriorly, proximo-distally, with the posterior part of the femoral sheath, the pubic or pectineal portion of the fascia lata and the psoas major, the pectineus, and the proximal part of the adductor longus muscles. The nerve to the pectineus passes between the artery and the psoas major; the femoral vein and the profunda artery and vein intervene between it and the pectineus, and the femoral vein also separates it from the adductor longus.

The femoral vein, which lies on a plane posterior to the artery in the lower part of the femoral trigone, passes to its medial side above, where it is separated from the artery by the lateral septum of the femoral sheath. On the lateral side of the artery is the femoral nerve (O.T. anterior crural) proximally; more distally the saphenous nerve and the nerve to the vastus medialis are continued on the lateral side. The lumbo-inguinal branch of the genito-femoral nerve is anterior and to the lateral side proximally, as it runs for a short distance in the femoral sheath.

In the *adductor canal* the artery has posterior to it the adductor longus and the adductor magnus, whilst anterior and to the lateral side is the vastus medialis. The femoral vein is also posterior to the artery, but lies to its lateral side distally and to its medial side proximally. Anterior to the artery is the fascial roof of the canal, with the obturator or sub-sartorial plexus of nerves and the sartorius muscle. The saphenous nerve enters the adductor canal with the artery, and runs first on its lateral side, then anterior, and lastly on its medial side.

Branches.—The femoral artery gives off the following branches:—

- (1) Superficial branches.
 - (a) The superficial circumflex iliac.
 - (b) The superficial epigastric.
 - (c) The superficial external pudendal.
- (2) Muscular.
- (3) The deep external pudendal.
- (4) The profunda.
- (5) The arteria genu suprema.

(a) *Arteria Circumflexa Ilium Superficialis.*—The **superficial circumflex iliac** springs from the front of the femoral artery just below the inguinal ligament. It pierces the femoral sheath and the fascia lata, lateral to the fossa ovalis (O.T. saphenous opening), and runs, in the superficial fascia, as far as the anterior superior spine of the ilium. It supplies the lateral set of sub-inguinal glands and the skin of the groin, and it sends branches through the fascia lata which anastomose with the deep circumflex iliac and supply the upper parts of the sartorius and tensor fasciæ latæ muscles.

(b) *Arteria Epigastrica Superficialis.*—The **superficial epigastric artery** arises near the preceding. It pierces the femoral sheath and the fascia cribrosa,

and passes upwards and medially, between the superficial and deep layers of the superficial fascia of the abdominal wall, towards the umbilicus. It supplies the sub-inguinal glands and the integument, and anastomoses with its fellow of the opposite side, with the inferior epigastric, and with the superficial circumflex iliac and superficial external pudendal arteries.

(c) *Arteria Pudenda Externa Superficialis*.—The **superficial external pudendal artery** also springs from the front of the femoral artery, and, after piercing the femoral sheath and the fascia cribrosa, runs upwards and medially towards the

FIG. 779.—THE FEMORAL VESSELS IN FEMORAL TRIGONE.

pubic tubercle, where it crosses superficial to the spermatic cord and divides into terminal *anterior scrotal* or *labial branches* according to the sex. It supplies the integument of the lower part of the abdominal wall, the root of the dorsum of the penis in the male, and the region of the mons Veneris in the female, and it anastomoses with its fellow of the opposite side, the deep external pudendal, the dorsal artery of the penis, and the superficial epigastric artery.

(2) *Rami Musculares*.—The **muscular branches** are distributed to the pectineus and the adductor muscles on the medial side, and to the sartorius and the vastus medialis on the lateral side.

(3) *Arteria Pudenda Externa Profunda*.—The **deep external pudendal artery** arises from the medial side of the femoral. It runs medially, anterior to the pectineus, and either anterior or posterior to the adductor longus, to the medial

side of the thigh; it then pierces the deep fascia, and terminates in the scrotum, where it anastomoses with the posterior scrotal branches of the perineal and the anterior scrotal branches of the superficial external pudendal arteries, and with the external spermatic branch of the inferior epigastric artery. In the female it terminates in the labium majus.

(4) **Arteria Profunda Femoris.**—The profunda artery (Fig. 778) is the largest branch of the femoral artery. It arises about 37 mm. (an inch and a half) distal to the inguinal ligament, from the lateral side of the femoral artery. Curving backwards and medially, it passes posterior to the femoral artery, and runs distally, close to the medial aspect of the femur, to the distal third of the thigh, where it perforates the adductor magnus and passes to the back of the thigh. Its termination is known as the *fourth perforating artery*. As the profunda descends it lies anterior to the iliacus, the pectineus, the adductor brevis, and the adductor magnus. It is separated from the femoral artery by its own vein, by the femoral vein, and by the adductor longus muscle.

Branches.—(a) **Muscular branches** are given off from the profunda, both in the femoral trigone and whilst it lies between the adductor muscles; many of them terminate in the adductors, others pass through the adductor magnus, and terminate in the hamstrings, where they anastomose with the transverse branch of the medial circumflex and with the proximal muscular branches of the popliteal artery.

(b) The **lateral circumflex artery** (Figs. 778 and 779) springs from the lateral side of the profunda, or occasionally from the femoral artery proximal to the origin of the profunda. It runs laterally, anterior to the iliacus and between the superficial and deep branches of the femoral nerve, to the lateral border of the femoral trigone; then, passing posterior to the sartorius and the rectus femoris, it terminates by dividing into three terminal branches—the ascending, the transverse, and the descending. Before its termination it supplies branches to the muscles mentioned and to the upper part of the crureus.

(i.) The **ascending terminal branch** runs proximally and laterally, posterior to the rectus femoris and the tensor fasciæ late, along the linea intertrochanterica, to the anterior borders of the glutæi, medius and minimus, between which it passes to anastomose with the deep branches of the superior glutæal artery. It supplies twigs to the neighbouring muscles, anastomoses with the glutæal, the deep circumflex iliac, and the transverse branch of the lateral circumflex arteries, and, as it ascends along the linea intertrochanterica, it gives off a branch which passes between the two limbs of the ilio-femoral ligament into the hip-joint. (ii.) The **transverse terminal branch** is small; it runs laterally between the vastus intermedius and the rectus femoris, passes into the substance of the vastus lateralis, winds round the femur, and anastomoses with the ascending and descending branches, with the perforating branches of the profunda, and with the inferior glutæal and medial circumflex arteries. (iii.) The **descending terminal branch** runs distally, posterior to the rectus and along the anterior border of the vastus lateralis, accompanied by the nerve to the latter muscle. It anastomoses with the transverse branch, with twigs of the inferior perforating arteries, with the arteria genu suprema of the femoral, and with the superior lateral genicular branch of the popliteal artery.

(c) The **medial circumflex artery** (Fig. 778) springs from the medial and posterior part of the profunda, at the same level as the lateral circumflex, and runs backwards, through the floor of the femoral trigone, passing between the psoas major and the pectineus; crossing the upper border of the adductor brevis it is continued backwards, below the neck of the femur, and passes between the adjacent borders of the obturator externus and the adductor brevis to the upper border of the adductor magnus, where it divides into two terminal branches, a transverse and a profunda branch (O.T. ascending).

Branches.—(i.) An **acetabular branch** is given off as the artery passes below the neck of the femur. It ascends to the acetabular notch where it anastomoses with twigs from the posterior branch of the obturator artery, and it sends branches into the acetabular fossa and along the ligamentum teres to the head of the femur. (ii.) A **superficial branch**, which passes medially, anterior to the pectineus and between the adductors brevis and longus. (iii.) **Muscular branches** are given off to the neighbouring muscles. The largest of these branches usually arises immediately before the termination of the artery; it runs distally, on the anterior aspect of the adductor magnus, and anastomoses with the muscular branches of the profunda artery. (iv.) The **profunda terminal branch** (ascending) passes upwards and laterally, between the obturator externus and the quadratus femoris to the trochanteric fossa of the femur, where it anastomoses with branches of the superior and inferior glutæal arteries. (v.) The **transverse terminal branch** runs backwards, between the lower border of the quadratus femoris and the upper border of the adductor magnus, to the hamstring muscles. It anastomoses, in front of the distal part of the

glutæus maximus, with the inferior gluteal and first perforating arteries and with the transverse branch of the lateral circumflex, and, in the substance of the hamstrings, with the muscular branches of the profunda.

(d) The **perforating arteries** (Fig. 780), including the terminal branch of the profunda, are four in number.

They curve postero-laterally, round the posterior aspect of the femur lying close to the bone, and anterior to the well-marked tendinous arches which interrupt the continuity of muscular attachments; their terminal branches enter the vastus lateralis and anastomose, in its substance, with one another, with the descending branch of the lateral circumflex, with the arteria genu suprema, and with the superior lateral genicular branch of the popliteal.

FIG. 780.—THE ARTERIES OF THE BUTTOCK AND THE POSTERIOR ASPECT OF THE THIGH AND KNEE.

The **third and fourth perforating arteries** pass through the adductor magnus and the short head of the biceps femoris into the vastus lateralis. Their anastomoses are similar to those of the second perforating.

A **nutrient branch** to the femur is given off either from the second or third perforating

The **first perforating artery** pierces the insertions of the adductors brevis and magnus, and some of its branches anastomose, anterior to the glutæus maximus, with the inferior gluteal, with the transverse branch of the medial circumflex, and with the transverse branch of the lateral circumflex, forming what is known as the **crucial anastomosis**.

The **second perforating artery** pierces the adductors brevis and magnus, and then passes between the glutæus maximus and the short head of the biceps femoris into the vastus lateralis. It anastomoses with its proximal and distal fellows, and with the medial circumflex and the proximal muscular branches of the popliteal artery.

artery, usually the former; an additional nutrient branch may also be supplied by the first or fourth perforating arteries.

(5) The **arteria genu suprema** (O.T. **anastomotica**) arises near the termination of the femoral artery, in the distal part of the adductor canal, and divides, almost immediately, into a superficial, saphenous, and a deep (musculo-articular) branch; indeed, very frequently the two branches arise separately from the femoral trunk.

(a) The **saphenous branch** passes through the distal end of the adductor canal with the saphenous nerve, and appears superficially, on the medial side of the knee, between the gracilis and the sartorius. It gives twigs to the integument of the proximal and medial part of the leg, and it anastomoses with the inferior medial genicular artery.

(b) The **musculo-articular branch** runs towards the knee, in the substance of the vastus medialis, along the anterior aspect of the tendon of the adductor magnus. It anastomoses with the superior medial genicular, and it sends branches laterally, one on the surface of the femur and another along the proximal border of the patella, to anastomose with the descending branch of the lateral circumflex, the fourth perforating artery, the superior external genicular, and the anterior tibial recurrent.

ARTERIA POPLITEA.

The **popliteal artery** is the direct continuation of the femoral. It commences at the proximal and medial part of the popliteal fossa, under cover of the semimembranosus, and terminates at the distal border of the popliteus muscle, and on a level with the distal part of the tuberosity of the tibia, by dividing into the anterior and the posterior tibial arteries.

From its origin the artery passes distally, with a lateral inclination, to the interspace between the condyles of the femur, whence it is continued vertically to its termination.

Relations.—*Anterior.*—It is in contact in front and proximo-distally with the popliteal surface of the femur, the posterior part of the capsule of the knee-joint, and the fascia covering the posterior surface of the popliteus.

Posterior.—The artery is overlapped behind by the lateral border of the semimembranosus proximally; it is crossed about its middle by the popliteal vein and the tibial (O.T. internal popliteal) nerve, the vein intervening between the artery and the nerve; whilst in the distal part of its extent it is overlapped by the adjacent borders of the two heads of the gastrocnemius, and is crossed by the nerves to the soleus and popliteus and by the plantaris muscle.

Lateral.—On its lateral side it is in relation proximally with the tibial nerve and the popliteal vein, then with the lateral condyle of the femur, and distally with the lateral head of the gastrocnemius and the plantaris.

Medial.—On the medial side it is in relation proximally with the semimembranosus, in the middle with the medial condyle of the femur, and distally with the tibial nerve, the popliteal vein, and the medial head of the gastrocnemius. Popliteal lymph glands are arranged irregularly around the artery.

Branches.—(1) **Muscular branches** are given off in two sets, proximal and distal.

The *proximal muscular branches* are distributed to the distal parts of the hamstring muscles, in which they anastomose with branches of the profunda artery.

The distal muscular, or *sural*, arteries enter the proximal parts of the gastrocnemius, the plantaris, the soleus, and the popliteus muscles, and they anastomose with branches of the posterior tibial artery and the lower genicular arteries.

(2) The **genicular branches** are five in number—viz., superior and inferior lateral, superior and inferior medial, and a median branch.

(a) The **superior lateral genicular artery** (a. genu superior lateralis) passes laterally, proximal to the lateral condyle, behind the femur and in front of the biceps tendon, into the vastus lateralis, where it anastomoses with the arteria genu suprema, the descending branch of the lateral circumflex, and the fourth perforating artery; it also sends branches distally to anastomose with the inferior lateral genicular and with the anterior tibial recurrent.

(b) The **superior medial genicular artery** passes medially, proximal to the medial condyle, behind the femur, and anterior to the tendon of the adductor magnus, into the vastus medialis. It anastomoses with branches of the arteria genu suprema and of the superior lateral genicular artery.

(c) The **inferior lateral genicular artery** runs laterally, across the popliteus muscle and anterior to the plantaris and the lateral head of the gastrocnemius; then, turning forwards, it is joined by the inferior lateral genicular nerve, and passes to the medial side of the fibular collateral ligament.

It terminates by anastomosing with its fellow of the opposite side and with the superior lateral genicular and anterior tibial recurrent arteries.

(d) The **inferior medial genicular artery** passes medially, distal to the medial condyle of the tibia, along the proximal border of the popliteus and in front of the medial head of the gastrocnemius, to the medial side of the knee, where it turns forwards, between the bone and the tibial collateral ligament, and terminates anteriorly by anastomosing with its fellow of the opposite side, with the recurrent branch of the anterior tibial artery, and with the superior medial genicular artery.

(e) The **arteria genu media** passes directly forwards from the front of the popliteal artery, pierces the central part of the posterior surface of the capsule of the knee-joint, and enters the intercondylar fossa. It supplies branches to the crucial ligaments and to the synovial membrane, and is accompanied by the medial genicular branch of the tibial nerve, and sometimes by the genicular branch of the obturator nerve.

(3) **Cutaneous branches** are distributed to the skin over the popliteal fossa. One of these, the *superficial sural artery*, runs along the middle of the back of the calf with the medial sural nerve.

FIG. 781.—THE POPLITEAL AND POSTERIOR TIBIAL ARTERIES AND THEIR BRANCHES.

terminates midway between the tip of the medial malleolus and the most prominent part of the heel, at the distal border of the lacinate ligament (O.T. internal annular). It ends by dividing into the medial and the lateral plantar arteries, which pass onwards to the sole of the foot.

The posterior tibial artery runs distally and medially in the posterior part of the leg, between the superficial and deep layers of muscles, and covered posteriorly by the deep intermuscular fascia which intervenes between them.

ARTERIA TIBIALIS POSTERIOR.

The **posterior tibial artery**, the larger of the two terminal branches of the popliteal, commences at the distal border of the popliteus and

Relations.—*Anterior.*—It is in contact anteriorly, and proximo-distally, with the tibialis posterior, the flexor digitorum longus, the posterior surface of the tibia, and the posterior ligament of the ankle-joint.

Posterior.—The artery is crossed about 37 mm. (an inch and a half) distal to its origin by the tibial nerve. Elsewhere it is in contact with the intermuscular fascia which binds down the deep layer of muscles. More superficially the proximal half of the artery is covered by the fleshy parts of the soleus and gastrocnemius muscles, between which is the plantaris; the distal half of the artery is much nearer the surface, and is covered only by skin and fasciæ, except at its termination, where it lies deep to the lacinate ligament and the origin of the abductor hallucis.

Lateral and Medial.—The artery is accompanied by two venæ comites, one on each side. The tibial nerve lies at first on the medial side of the vessel, then crosses posterior to it, and is continued distally on its lateral side. In the most distal part of its course the artery is separated from the medial malleolus by the tendons of the tibialis posterior and the flexor digitorum longus, whilst the tendon of the flexor hallucis longus lies postero-lateral to it.

Branches.—The posterior tibial gives off numerous branches, the largest of which, the peronæal, forms one of the chief arteries of the leg. The branches include—

(1) Two large **muscular branches** which are distributed to the soleus, the tibialis posterior, the flexor digitorum longus, and the flexor hallucis longus. They anastomose with the deep sural branches of the popliteal artery and the lower medial genicular artery.

(2) A **fibular branch** passes laterally to the neck of the fibula, where it anastomoses with the inferior lateral genicular and the deep sural arteries, and supplies the adjacent muscles.

(3) The **peronæal artery** (Fig. 781) is the largest branch of the posterior tibial. It arises about 25 mm. (an inch) below the distal border of the popliteus, curves laterally across the proximal part of the tibialis posterior to the medial crest of the fibula, along which it passes to the distal part of the interosseous space. About 25 mm. (an inch) proximal to the ankle-joint it gives off a perforating branch and then passes, posterior to the tibio-fibular syndesmosis and lateral malleolus, to the lateral side of the heel and the foot. It supplies the ankle, the tibio-fibular syndesmosis, and the talo-calcaneal joint, and anastomoses with the medial calcaneal branch of the lateral plantar artery, and with the tarsal and arcuate branches of the dorsalis pedis.

As the peronæal artery passes laterally from its origin it lies posterior to the tibialis posterior, and is covered posteriorly by the deep intermuscular fascia and by the soleus. As it descends along the medial crest of the fibula it lies in a fibrous canal between the tibialis posterior in front and the flexor hallucis longus behind. The peronæal artery is accompanied by two venæ comites, and is crossed anteriorly and posteriorly by communicating branches between them.

Branches.—(a) **Muscular branches** are distributed to the soleus, tibialis posterior, flexor hallucis longus, and the peronæal muscles. Some pass through the interosseous membrane and supply the anterior muscles of the leg.

(b) A **nutrient branch** enters the nutrient foramen of the fibula.

(c) A **communicating branch** passes across the back of the distal end of the shaft of the tibia, about 25 mm. (an inch) above the tibio-fibular syndesmosis, to anastomose with the posterior tibial artery.

(d) The **perforating branch** passes forwards at the junction of the distal border of the interosseous membrane and the interosseous tibio-fibular ligament, and runs, in front of the ankle, to the dorsum of the foot, where it anastomoses with the lateral malleolar branch of the anterior tibial artery and with the tarsal branch of the dorsalis pedis; it also supplies branches to the tibio-fibular syndesmosis, to the ankle-joint, and to the peronæus tertius.

(4) The **nutrient branch**, the largest of the nutrient group of arteries to long bones, springs from the proximal part of the posterior tibial, pierces the tibialis posterior, and enters the nutrient foramen on the posterior surface of the tibia. In the interior of the bone it divides into proximal and distal branches, the former passing towards the proximal extremity of the bone, and the latter towards the distal extremity. Before entering the tibia the nutrient artery gives small muscular branches.

(5) A **communicating branch** unites the posterior tibial to the peronæal artery about 25 mm. (an inch) above the tibio-fibular syndesmosis. It passes posterior to the shaft of the tibia and anterior to the flexor hallucis longus.

(6) **Cutaneous branches** are distributed to the skin of the medial and posterior part of the leg.

(7) A **posterior medial malleolar branch** is distributed to the medial surface of the medial malleolus, anastomosing with a corresponding branch of the anterior tibial artery.

PLANTAR ARTERIES.

(8) The **medial and lateral plantar arteries** are the terminal branches of the posterior tibial artery. They arise, under cover of the origin of the abductor hallucis muscle, midway between the tip of the medial malleolus and the most prominent part of the medial side of the os calcis.

Arteria Plantaris Medialis.—The **medial plantar artery** is the smaller of the two terminal branches of the posterior tibial artery. It passes forwards, along the

FIG. 782.—THE PLANTAR ARTERIES AND THEIR BRANCHES.

medial side of the foot in the interval between the abductor hallucis and the flexor digitorum brevis, to the head of the first metatarsal bone, where it terminates by uniting with the plantar digital branch of the dorsalis pedis, which is distributed to the medial side of the great toe. In its course forwards it gives off a *superficial branch*, which ramifies on the superficial surface of the abductor hallucis, and branches to the adjacent muscles and articulations, and to the subjacent skin; it also gives three *digital branches* which anastomose, at the roots of the medial three interdigital clefts, with the medial plantar metatarsal arteries. Some of the cutaneous branches of the medial plantar artery anastomose, round the medial border of the foot, with the medial cutaneous branches of the dorsalis pedis artery.

Arteria Plantaris Lateralis.—The **lateral plantar artery** is the larger of the two terminal

Branches.—Between its origin and the base of the fifth metatarsal the lateral

plantar artery gives off (*a*) the **medial calcanean branch**, which is distributed to the skin and the subcutaneous tissue of the heel.

(*b*) **Muscular branches** to the abductor hallucis, flexor digitorum brevis, quadratus plantæ, and abductor digiti quinti.

(*c*) **Cutaneous branches** to the skin of the lateral side of the foot.

Between the base of the fifth metatarsal bone and the first interosseous space it forms the **plantar arch**, and gives off (*d*) four **plantar metatarsal branches**; (*e*) three **posterior perforating arteries** to the dorsal metatarsal arteries; and (*f*) **articular branches** to the tarsal joints.

The **fifth** or most lateral **metatarsal branch** runs along the lateral side of the little toe, supplying the skin, joints, and the flexor tendons with their synovial sheaths. The medial three **plantar metatarsal branches**, **second**, **third**, and **fourth**, run forwards on the plantar surfaces of the interossei, the medial two lying dorsal to the oblique head of the adductor of the great toe, and all three passing dorsal to the transverse head of the adductor. At the bases of the interdigital clefts the second, third, and fourth plantar metatarsal arteries divide into plantar digital arteries which run along the plantar aspects of adjacent toes, and supply skin, joints, and the flexor tendons and sheaths. Opposite the last phalanx of each toe the digital arteries of opposite sides of the toe anastomose together.

The **posterior perforating arteries** are three in number; they pass dorsalwards through the three lateral intermetatarsal spaces, between the heads of the dorsal interosseous muscles, and terminate by uniting with the corresponding dorsal metatarsal arteries. **Anterior perforating branches** which communicate with the dorsal metatarsal arteries are given off from two or three of the plantar metatarsal arteries just before they divide.

The **articular branches** are numerous and irregular; they supply the joints and ligaments of the tarsus on its plantar aspect.

ARTERIA TIBIALIS ANTERIOR.

The **anterior tibial artery**, the smaller of the two terminal divisions of the popliteal, commences opposite the distal border of the popliteus muscle, and terminates in front of the ankle, where it is continued into the dorsal artery of the foot.

Course and Relations.—From its origin, at the back of the leg, the artery passes anteriorly between the two slips of the proximal part of the tibialis posterior and above the proximal border of the interosseous membrane. It then runs distally, resting, in the proximal two-thirds of its course, against the anterior surface of the interosseous membrane and, subsequently, on the distal part of the tibia and the anterior ligament of the ankle-joint. In the proximal third of the anterior compartment of the leg it lies between the extensor digitorum longus laterally and the tibialis anterior medially; in the middle third it is between the extensor hallucis longus and the tibialis anterior; in the distal third the extensor hallucis longus crosses in front of the artery and reaches its medial side, and the most distal part of the vessel lies between the tendon of the extensor hallucis longus on the medial side and the most medial tendon of the extensor digitorum longus on the lateral side.

The deep peronæal nerve (O.T. anterior tibial) is at first well to the lateral side of the artery, but it soon passes in front of the vessel, and it lies in front of the middle third of the artery; more distally the nerve is usually found on the lateral side again, and at the ankle it intervenes between the artery and the most medial tendon of the extensor digitorum longus.

Two venæ comites, with numerous intercommunications, accompany the artery.

Obviously the anterior tibial artery is, at least in its proximal part, deeply placed; moreover, its lateral muscular boundaries overlap it. In the greater part of its extent it is, however, easily accessible from the surface; and beyond being crossed by the nerve and tendon, as already described, is only covered, in addition, by skin, fascia, and the transverse crural ligament.

Branches.—Close to its origin the artery gives off fibular and posterior tibial recurrent branches; after it reaches the front of the leg it gives off anterior tibial recurrent, muscular, cutaneous, medial malleolar, and lateral malleolar branches.

(1) The **fibular branch** is a small vessel which may arise separately from the anterior tibial artery, or by a common stem with the posterior tibial recurrent; occasionally it springs from the lower end of the popliteal artery, or from the posterior tibial.

It runs upwards and laterally, behind the neck of the fibula and through the fibres of the soleus, and it terminates in branches which supply the soleus, the peronæus longus, and the skin of the proximal and lateral part of the leg. It anastomoses with the inferior lateral genicular artery.

(2) The **posterior tibial recurrent branch**, also small, and not always present, runs upwards, anterior to the popliteus muscle, to the back of the knee-joint. It anastomoses with the inferior genicular branches of the popliteal, and gives branches to the popliteus muscle and the proximal tibio-fibular articulation.

(3) The **anterior tibial recurrent branch** arises from the anterior tibial artery in front of the interosseous membrane. It runs proximally and medially, between the proximal part of the tibialis anterior and the lateral condyle of the tibia, accompanied by the recurrent articular branch of the common peronæal nerve, and, after supplying the tibialis anterior and the proximal tibio-fibular articulation, it pierces the deep fascia of the leg; it is connected with the anastomoses round the knee-joint, formed by the genicular branches of the popliteal artery, the descending branch of the lateral circumflex artery, and the arteria genu suprema.

(4) The **muscular branches** are distributed to the muscles of the front of the leg, and a few small branches also pass backwards to the deep surface of the tibialis posterior muscle.

(5) The **cutaneous branches** supply the skin of the front of the leg.

(6) The **medial anterior malleolar branch** arises from the lower part of the anterior tibial artery, and is smaller than its companion on the lateral side. It runs medially, posterior to the tibialis anterior tendon, ramifies over the medial malleolus, anastomosing with branches of the posterior tibial artery, and is distributed to the skin and to the ankle-joint.

FIG. 783.—THE ANTERIOR TIBIAL ARTERY AND ITS BRANCHES.

(7) The **lateral anterior malleolar branch**, more constant and larger than the medial, passes laterally, posterior to the extensor digitorum longus and peronæus tertius, towards the lateral malleolus. It anastomoses with the perforating branch of the peronæal artery and with the tarsal artery, and supplies the ankle-joint and the adjacent articulations.

Dorsalis Pedis Artery.—The dorsal artery of the foot is the direct continuation of the anterior tibial; it commences opposite the front of the ankle-joint, and extends to the posterior extremity of the first interosseous space, where it divides into the first dorsal metatarsal and the profunda branch.

It is covered superficially by skin and fascia, including the cruciate ligament, and it is crossed, just before it reaches the first interosseous space, by the most medial tendon of the extensor digitorum brevis. It rests upon the anterior ligament of the ankle, the head of the talus, the talo-navicular ligament, the dorsum of the navicular bone, and the dorsal naviculo-cuneiform and the inter-cuneiform ligaments between the first and second cuneiform bones. On its lateral side is the medial terminal branch of the deep peronæal nerve (O.T. anterior tibial), which intervenes between it and the extensor digitorum brevis and most medial tendon of the extensor digitorum longus. On its medial side it is in relation with the tendon of the extensor hallucis longus. Two venæ comites, one on each side, accompany the artery.

FIG. 784.—THE DORSALIS PEDIS ARTERY AND ITS BRANCHES.

Branches.—On the dorsum of the foot the dorsalis pedis artery gives off cutaneous branches, lateral and medial tarsal branches, the arcuate branch, and the first dorsal metatarsal and the profunda branch.

(1) **Cutaneous branches**, two or three in number, are distributed to the skin on the dorsum and medial side of the foot; they anastomose with branches of the medial plantar artery.

(2) **The tarsal branches, medial and lateral.**—The medial tarsal branches are small vessels given off from the medial side of the artery. They pass to the medial borders of the foot and anastomose with branches of the medial plantar artery. The lateral tarsal branch is given off opposite the head of the talus; it runs laterally, deep to the extensor digitorum brevis, supplying that muscle and the tarsal joints, and it anastomoses with the perforating branch of the peronæal, the arcuate, and lateral plantar arteries, and with the lateral malleolar artery.

(3) The **arcuate artery** arises opposite the first cuneiform bone. It runs laterally, on the bases of the metatarsal bones, deep to the long and short extensor tendons, supplies the extensor brevis, and anastomoses with branches of the lateral tarsal and lateral plantar arteries. It gives off three **dorsal metatarsal arteries**, second, third, and fourth, which run forwards on the muscles which occupy the lateral three interosseous spaces to the clefts of the toes, where each divides into two *dorsal digital branches* for the adjacent sides of the toes bounding the cleft to which it goes. The lateral side of the little toe receives a branch from the most lateral dorsal metatarsal artery. Each dorsal metatarsal artery gives off a *posterior perforating branch*, which passes through the posterior part of the intermetatarsal space, between the heads of the dorsal interosseous muscle, to anastomose with the plantar arch, and an *anterior perforating branch*, which passes through the anterior part of the space to anastomose with the corresponding plantar metatarsal artery.

(4) The **first dorsal metatarsal artery** is continued forwards from the dorsal artery of the foot, and runs on the dorsal surface of the first dorsal interosseous muscle. It ends by dividing into dorsal digital branches for the adjacent sides of the first and second toes. Before it divides it usually gives off a *dorsal digital branch* which passes, deep to the tendon of the extensor hallucis, to the medial side of the great toe.

(5) The **profunda branch** passes through the posterior end of the first intermetatarsal space, between the two heads of the first dorsal interosseous muscle, to the plantar aspect of the foot, where it unites with the lateral plantar artery and completes the plantar arch. As it unites with the lateral plantar artery it gives off the first plantar metatarsal artery (O.T. *arteria magna hallucis*), which passes forwards, along the first intermetatarsal space, to the base of the first interdigital cleft, where it divides into plantar digital arteries for the adjacent sides of the great and second toes; before it divides it gives off a *plantar digital artery* to the medial side of the great toe.

VENÆ.

Veins commence at the terminations of the capillaries. They converge towards the heart, and unite with one another to form larger and still larger vessels, until finally seven large trunks are formed which open into the atria of the heart. Three of these, the **superior vena cava**, the **inferior vena cava**, and the **coronary sinus**, belong to the *systemic circulation*; they contain venous blood, and open into the right atrium. The remaining four belong to the *pulmonary circulation*; they return oxygenated blood from the lungs, and open into the left atrium.

In addition to the systemic and pulmonary veins, there is also a third group of veins, constituting the **portal system**, in which blood from the abdominal part of the alimentary canal, and from the spleen and pancreas, is conveyed to the liver. The portal system is further peculiar in that it both begins and ends in capillaries. From its terminal capillaries in the liver the *hepatic veins* arise, and as these open into the inferior vena cava the blood of the portal system is finally poured into the general systemic circulation. The hepatic veins also receive blood supplied to the liver by the hepatic arteries.

VENÆ PULMONALES.

The terminal **pulmonary veins** (Figs. 750 and 757), two on each side, open into the left atrium of the heart. Their tributaries arise in capillary plexuses in the walls of the pulmonary alveoli. By the union of the smaller veins larger vessels are formed which run along the anterior aspects of the bronchial tubes, and, uniting together, ultimately form a single efferent vessel in each lobe, which passes into the root of the lung. Thus there are five main pulmonary veins, but, immediately after entering the root of the lung, the vessels from the upper and middle lobes of the right lung join together, and so only four terminal pulmonary veins open into the left atrium of the heart. Neither the main stems nor their tributaries possess valves.

Relations.—In the root of the lung the upper pulmonary vein, on each side, lies below and in front of the pulmonary artery. The lower pulmonary vein on each

side is in the lowest part of the root, and it is in a plane posterior to that in which the upper vein lies.

On the right side the upper pulmonary vein passes behind to the superior vena cava, and the lower passes behind the right atrium. They both terminate in the upper and posterior part of the left atrium close to the interatrial septum.

On the left side both upper and lower pulmonary veins cross anterior to the descending aorta, and they terminate in the upper and posterior part of the left atrium near its left border.

All four pulmonary veins perforate the fibrous layer of the pericardium, and receive partial coverings of the serous layer before they enter the atrium.

SYSTEMIC VEINS.

The **systemic veins** return blood to the right atrium of the heart through the superior vena cava, the inferior vena cava, and the coronary sinus. The two first-named receive blood from the veins of the body and limbs and from most of the abdominal and pelvic viscera. The coronary sinus receives blood from the veins of the walls of the heart alone.

General Arrangement.—The veins of the body wall and limbs form two groups—(1) the superficial veins; (2) the deep veins.

The **superficial veins**, which commence in the capillaries of the skin and subcutaneous tissues, lie in the superficial fascia, and are very numerous. They frequently anastomose with one another, and they also communicate with the deep veins, in which, after piercing the deep fascia, they terminate. They may or may not accompany superficial arteries.

The **deep veins** accompany arteries, and are known as *venæ comites*. The large arteries have only one accompanying vein, but with the medium-sized and small arteries there are usually two *venæ comites*, which anastomose freely with each other by short transverse branches of communication.

Visceral veins usually accompany the arteries which supply viscera in the head, neck, thorax, and abdomen. As a rule there is only one vein with each visceral artery, and, with the exception of those which enter into the formation of the portal system, they terminate in the deep systemic veins.

SINUS CORONARIUS ET VENÆ CORDIS.

The **coronary sinus** (Fig. 750) is a short, but relatively wide, venous trunk which receives the majority of the veins of the heart. It lies in the inferior portion of the coronary sulcus, between the left atrium and the left ventricle, and it is covered superficially by some of the muscular fibres of the atrium.

It terminates in the lower and posterior part of the right atrium, between the orifice of the inferior vena cava on the right, and the right atrio-ventricular orifice anteriorly; an imperfect valve, consisting of one cusp, called the **valve of the coronary sinus** (*Thebesius*), is situated at the right margin of the opening of the sinus into the atrium.

The apertures of the tributaries of the coronary sinus, except those of the great and small cardiac veins, are not provided with valves, and the valves of the two veins mentioned are often incompetent.

Tributaries.—(1) The **great cardiac vein** (Fig. 754) commences at the apex of the heart. It ascends in the anterior interventricular sulcus to the coronary sulcus; it then turns to the left, and, passing round the left margin of the heart, into the inferior part of the coronary sulcus, terminates in the left extremity of the coronary sinus. It receives tributaries from the walls of both ventricles and from the wall of the left atrium. It receives also the *left marginal vein*; this vein commences at the lower extremity of the left margin of the heart, along which it ascends to its termination.

(2) The **small cardiac vein** is very variable; as a rule it commences at the inferior margin of the heart and passes to the right to the coronary sulcus in which it turns to the left, on the inferior surface of the heart, and terminates in the right extremity of the coronary sinus. It receives tributaries from the walls of the right atrium and the right ventricle.

(3) The **oblique vein of the left atrium (Marshall)** (Fig. 750) is a small venous channel which descends obliquely, on the posterior wall of the left atrium, and terminates in the coronary sinus. Its orifice is not provided with a valve. It is of special interest, inasmuch as it represents the left superior vena cava of some other mammals, and is developed from the left duct of Cuvier.

(4) The **inferior cardiac vein of the left ventricle** runs along the inferior surface of the left ventricle and ends in the coronary sinus.

(5) The **middle cardiac vein** commences at the apex of the heart, and, passing posteriorly, in the inferior interventricular sulcus, terminates in the coronary sinus near its right extremity. It receives tributaries from the inferior parts of the walls of both ventricles.

Veins of the Heart which do not end in the Coronary Sinus.—(a) The **anterior cardiac veins** are two or three small vessels which ascend on the anterior wall of the right ventricle to the coronary sulcus, where they either end in the right atrium or terminate in the small cardiac vein. (b) The **venæ minimæ cordis**.—A number of small veins, which commence in the substance of the walls of the heart and terminate directly in its cavities, principally in the atria; some few, however, open into the ventricles.

VENA CAVA SUPERIOR AND ITS TRIBUTARIES.

The **superior vena cava** (Figs. 756 and 757) returns the blood from the head and neck, the upper extremities, the thoracic wall, and a portion of the upper part of the wall of the abdomen. It is formed, at the lower border of the first right costal cartilage, by the union of the two innominate veins, and it descends, with a slight convexity to the right, to the level of the third right costal cartilage, where it opens into the upper and posterior part of the right atrium. It is about 75 mm. (three inches) long; in the lower half of its extent it is enclosed within the fibrous layer of the pericardium, and it is covered in front and on each side by the serous layer.

Relations.—It is overlapped *anteriorly* by the margins of the right lung and pleural sac and by the ascending aorta. The lung and pleura intervene between it and the second and third costal cartilages, the internal intercostal muscles in the first and second intercostal spaces, and the internal mammary vessels. It is in relation *posteriorly* with the right margin of the trachea, the right vagus nerve, the vena azygos, which opens into it at right angles, the right bronchus, the right pulmonary artery, and the upper right pulmonary vein. On its *left side* are the ascending portion of the aorta, and the commencement of the innominate artery, whilst on the *right side* it is in close relation with the right pleura, the phrenic nerve and the pericardiaco-phrenic (O.T. comes nervi phrenici) vessels intervening.

Tributaries.—In addition to the two innominate veins, by the union of which it is formed, the superior vena cava receives only one large tributary, viz., the vena azygos; but several small pericardial and mediastinal veins open into it.

VENA AZYGOS AND ITS TRIBUTARIES.

The **vena azygos** (O.T. **vena azygos major**) (Fig. 798) commences either from the posterior aspect of the inferior vena cava, at the level of the right renal vein, or as the direct upward continuation of an anastomosing channel which connects together the lumbar veins of the right side, and which is known as the *right ascending lumbar vein*. It ascends through the aortic orifice of the diaphragm, and is continued upwards through the posterior mediastinum. In the upper part of its course, it first passes posterior to the root of the right lung, and then arches anteriorly, above the root, to its termination in the posterior part of the superior vena cava, immediately before the latter vessel pierces the pericardium and at the level of the second costal cartilage. It frequently possesses imperfect valves.

Relations.—In the *abdomen* it lies on the anterior surfaces of the bodies of the upper lumbar vertebræ, posterior to the right crus of the diaphragm and the inferior vena cava, and to the right side of the cisterna chyli.

In the *thorax* it lies on the anterior surfaces of the bodies of the lower eight thoracic vertebræ, the intervening fibro-cartilages, and the anterior longitudinal ligament; and anterior to

the right aortic intercostal arteries. In the lower part of the posterior mediastinum the right pleura and lung lie anterior to it; at a higher level it is overlapped by the right margin of the œsophagus, and immediately before its termination it is crossed by the root of the right lung.

On its left side it is in relation, in the greater part of its extent, with the thoracic duct and, as it arches anteriorly over the root of the lung, with the right vagus nerve and the trachea. About the level of the seventh thoracic vertebra it receives the accessory hemiazygos vein, whilst at the level of the eighth thoracic vertebra the hemiazygos vein opens into it.

In addition to the two veins last mentioned it receives the right posterior intercostal veins, except that from the first space but including the right superior intercostal vein, the right subcostal vein, and, through the ascending lumbar vein, the upper right lumbar veins. It also receives the right bronchial veins and some small œsophageal, pericardial, and mediastinal tributaries.

Tributaries.—(1) The *vena hemiazygos accessoria* (O.T. *vena azygos minor superior*) is formed by the union of the fourth, fifth, sixth, seventh and eighth left posterior intercostal veins. It lies on the left sides of the bodies of the fifth, sixth, and seventh thoracic vertebrae, and the intercostal arteries. It crosses the vertebral column, from left to right, opposite the body of the seventh thoracic vertebra, passing posterior to the aorta, œsophagus, and thoracic duct; and it terminates either in the *vena azygos* or in the *vena hemiazygos*. In addition to its intercostal tributaries it receives the left bronchial veins, and some small posterior mediastinal veins, and it communicates with the left superior intercostal vein.

(2) The *vena hemiazygos* commences in the epigastric region of the abdomen. At its origin it is connected either with the left ascending lumbar vein or with the left renal vein. After piercing the left crus of the diaphragm it ascends on the left sides of the bodies of the lower thoracic vertebrae, and, opposite the seventh or eighth thoracic vertebra, it turns to the right, crosses the front of the vertebral column, posterior to the aorta, œsophagus, and thoracic duct, and terminates in the *vena azygos*. As it ascends, on the bodies of the vertebrae, it lies lateral to the aorta, and medial to the roots of the splanchnic nerves, and anterior to the lower left intercostal arteries. Through the left ascending lumbar vein it receives blood from the upper lumbar veins of the left side; the left subcostal vein, the lower three posterior intercostal veins, and small mediastinal tributaries also terminate in it.

(3) The *bronchial veins* do not quite correspond to the bronchial arteries, and they are not found on the walls of the smallest bronchi. On each side the tributaries run, anterior or posterior to the bronchial tubes to reach the root of the lung, where they unite, as a rule, into two small trunks; those of the right side open into the *vena azygos*, and those of the left into the accessory hemiazygos vein, or into the left superior intercostal vein. On both sides they are joined by tracheal and posterior mediastinal veins. Some few small bronchial veins, including most of those from the smaller tubes, open into the pulmonary veins.

(4) **Venæ Intercostales.**—There are two sets of *intercostal veins*, the anterior and the posterior.

The *anterior intercostal veins* are tributaries of the internal mammary or of the musculo-phrenic veins, and are described with those vessels (pp. 962, 963).

The *posterior intercostal veins* (Fig. 798) are eleven in number on each side. A single vein runs in each intercostal space; it is situated in the costal groove, above the corresponding artery.

On the right side the posterior intercostal vein of the first space accompanies the superior intercostal artery across the front of the neck of the first rib, and terminates in the vertebral or innominate vein. The second, third, and fourth intercostal veins of the right side unite together to form a common trunk, the *right superior intercostal vein*, which terminates by joining the *vena azygos*. The fifth to the eleventh posterior intercostal veins of the right side open separately into the *vena azygos*.

On the left side the first posterior intercostal vein follows a course similar to that taken by the corresponding vein on the right side, and terminates in the left vertebral or innominate vein. The second, third, and sometimes the fourth posterior intercostal veins of the left side unite to form the *left superior intercostal vein*, which runs from behind forwards along the left or anterior aspect of the aortic arch. It passes obliquely between the left vagus and phrenic nerves, crosses the root of the left subclavian artery, and ends in the lower border of the left innominate vein. The fifth, sixth, seventh, and eighth, and sometimes the fourth posterior intercostal veins of the left side terminate in the accessory hemiazygos vein, and the ninth, tenth, and eleventh end in the hemiazygos vein.

Each posterior intercostal vein is provided with valves, both at its termination and along its course, which prevent the blood flowing towards the anterior aspect of the thoracic wall. Its tributaries are derived from the adjacent muscles and bones, and a short distance from its termination it receives a posterior tributary which passes to it between the transverse processes of the vertebræ. This posterior vessel is formed by the union of small veins which issue from the muscles of the back, from the anterior and posterior spinal plexuses which lie respectively in front of the bodies and behind the arches of the vertebræ, and by venous channels which issue through the intervertebral foramina; the latter vessels commence in the vertebral canal, where they are connected with the anterior and posterior spinal veins.

VENÆ ANONYMÆ.

The **innominate veins** (Figs. 756 and 757) are two in number, right and left. They return blood from the head and neck, the upper extremities, the upper part of the posterior wall of the thorax, the anterior wall of the thorax, and the upper part of the anterior wall of the abdomen. Each innominate vein commences behind the medial end of the clavicle of the corresponding side, and is formed by the union of the internal jugular and subclavian veins; the two innominate veins terminate by uniting together, at the lower border of the first costal cartilage of the right side, to form the superior vena cava. To reach this point the left vein has to pass from left to right behind the manubrium sterni, and it is therefore about three times as long as the right vein. The innominate veins do not possess valves.

The **right innominate vein** is a little more than 25 mm. (1 inch) in length. It descends almost vertically to the lower border of the first costal cartilage, and terminates in the superior vena cava.

Relations.—It is in relation anteriorly with the medial end of the clavicle and the sterno-hyoid and sterno-thyroid muscles. It partly overlaps the innominate artery, which lies to its left side, and it is in front of the internal mammary artery, the right vagus nerve, and the upper end of the right pleural sac. The phrenic nerve and the accompanying vessels run along its right side, and intervene between it and the right pleural sac.

Tributaries.—In addition to the veins by the union of which it is formed, the right innominate vein receives the right vertebral and internal mammary veins, and sometimes the right inferior thyreoid vein and the first right posterior intercostal vein. The right lymphatic duct also opens into it.

The **left innominate vein** passes from left to right, with a slight obliquity downwards, behind the upper part of the manubrium sterni, to the lower border of the first right costal cartilage, where it terminates in the superior vena cava. It is about 60 to 75 mm. (3 inches) long.

Relations.—It is covered anteriorly, in the greater part of its extent, by the sterno-hyoid and sterno-thyroid muscles, but at its right extremity it is slightly overlapped by the right pleura, and in the median plane the remains of the thymus intervene between it and the posterior surface of the sternum. It rests, posteriorly, upon the left pleura, the left internal mammary artery, the left subclavian artery, the left phrenic, and the left vagus nerves, the left superior cardiac branch of the sympathetic, the inferior cervical branch of the left vagus, the left common carotid artery, the trachea, and the innominate artery.

Its lower border is in relation with the arch of the aorta, and on its upper border it receives the inferior thyreoid vein of one or both sides.

Tributaries.—It receives the vertebral, internal mammary, inferior thyreoid, superior intercostal veins of its own side, the first left posterior intercostal vein, and some pericardial, thymic, anterior bronchial, and anterior mediastinal veins. Sometimes the right inferior thyreoid vein joins it, but usually this vessel terminates in the right innominate vein or in the commencement of the superior vena cava.

The thoracic duct opens into it just at the angle of junction of the internal jugular and subclavian veins.

Venæ Mammariæ Internæ—The Internal Mammary Veins.—Each internal mammary artery is accompanied by venæ comites; they commence by the union of the venæ comites of the superior epigastric and musculo-phrenic arteries, between the sixth costal cartilage and the transversus thoracis; and at the upper part of the thorax

they fuse into a single vessel which enters the superior mediastinum and ends in the innominate vein of the same side.

The tributaries of the internal mammary veins are—(a) The **venæ comites** of the superior epigastric and musculo-phrenic arteries, which in their turn receive tributaries which correspond with the branches of the arteries they accompany. (b) Six **anterior perforating veins** which accompany the corresponding arteries, one lying in each of the upper six intercostal spaces. (c) Twelve **anterior intercostal veins** from the upper six intercostal spaces, two veins lying in each space with the corresponding branches of the internal mammary artery. (d) Small and irregular **pleural, muscular, mediastinal, and sternal veins**.

The internal mammary veins are provided with numerous valves which prevent the blood from flowing downwards.

Venæ Epigastricæ Superiores—The Superior Epigastric Veins.—The **venæ comites** of the superior epigastric artery receive tributaries from the substance of the rectus abdominis, the sheath of the muscle, and the superjacent skin and fascia; they pass, with the artery, between the sternal and costal origins of the diaphragm, and terminate in the internal mammary veins.

Musculo-phrenic Veins.—The **venæ comites** of the musculo-phrenic artery commence in the abdomen, pass through the diaphragm with the artery, and terminate in the internal mammary veins. They receive as tributaries the anterior intercostal veins of the seventh, eighth, and ninth intercostal spaces, and small venules from the substance of the diaphragm and walls of the abdomen.

Venæ Vertebrales—The Vertebral Veins correspond only to the extra-cranial parts of the vertebral arteries. Each commences by the union of offsets from the intraspinal venous plexuses, and, issuing from the vertebral canal, passes across the posterior arch of the atlas, with the vertebral artery, to the foramen in the transverse process of the atlas. In the foramina in the cervical transverse processes, a plexus of venous channels surrounds the artery. At the lower part of the neck these channels unite to form a single trunk which issues from the foramen in the transverse process of the sixth cervical vertebra, and descends, in the interval between the longus colli and scalenus anterior muscles, to terminate in the upper and posterior part of the innominate vein, where it possesses a uni- or bi-cuspidate valve.

Relations.—In the first part of its course the vein lies in the sub-occipital triangle. The second, plexiform portion, is in the canal formed by the foramina in the transverse processes of the cervical vertebrae, and, with the artery, which it surrounds, lies anterior to the trunks of the cervical spinal nerves. The third part, in the root of the neck, is between the longus colli and scalenus anterior muscles, in front of the first part of the vertebral artery, and behind the internal jugular vein.

Tributaries.—In addition to the offsets from the intraspinal venous plexuses by the union of which it is formed, each vertebral vein receives the following tributaries:—(a) Small vessels which issue from the muscles, ligaments, and bones of the deeper parts of the neck, and the lower and posterior part of the head. (b) Offsets from the intraspinal venous plexuses which pass out of the vertebral canal by the intervertebral foramina. (c) The **ascending cervical vein**, a vessel which is formed by the union of tributaries which issue from a venous plexus on the anterior aspects of the bodies and roots of the transverse processes of the cervical vertebrae. This vessel accompanies the ascending cervical artery, and terminates in the lower part of the vertebral vein, immediately after the latter has issued from the foramen in the sixth cervical transverse process. (d) The **deep cervical vein**; this commences in the sub-occipital triangle from a venous plexus with which the vertebral and occipital veins communicate. It descends, posterior to the transverse processes of the cervical vertebrae, in company with the profunda cervicis artery, turns forwards at the root of the neck, between the transverse processes of the sixth and seventh cervical vertebrae or between the latter and the neck of the first rib, and opens into the vertebral vein. It receives blood from the muscles, ligaments, and bones of the back of the neck. (e) The **posterior intercostal vein** from the first intercostal space sometimes opens into the vertebral vein.

Occasionally the venous plexus around the vertebral artery ends below in two terminal trunks, anterior and posterior, instead of one. In these cases the second terminal vessel lies behind the lower part of the vertebral artery, passes through the foramen in the transverse process of the seventh cervical vertebra, and turns forwards on the lateral side

of the artery to join the anterior trunk, thus forming a common terminal vein which ends in the usual manner.

Venæ Thyreoideæ Inferiores.—Each inferior thyroid vein commences by the union of a series of tributaries which issue from the isthmus and the corresponding lateral lobe of the thyroid gland. The two veins descend, along the front of the trachea, into the superior mediastinum, where the right inferior thyroid vein terminates in the junction of the two innominate veins, and the left in the upper border of the left innominate vein; or the two veins unite to form a single trunk, which ends usually in the left innominate vein, but occasionally in the right. In their descent through the neck the inferior thyroid veins frequently anastomose together, and sometimes these anastomoses are so frequent and irregular that a venous plexus is formed in front of the lower cervical portion of the trachea.

VEINS OF THE HEAD AND NECK.

Vena Jugularis Interna (Figs. 756, 787, 800 and 801).—Each internal jugular vein commences in the posterior compartment of the jugular foramen, as the direct continuation of the transverse sinus, and terminates behind the medial part of the clavicle, by uniting with the subclavian vein of the same side to form the innominate vein.

At its commencement it is dilated, forming the *superior bulb* of the jugular vein, and in this situation it lies postero-lateral to the internal carotid artery and the last four cerebral nerves. As it descends it accompanies first the internal and then the common carotid artery; inclining forwards during its descent, it gradually passes from its original position, behind and to the lateral side of the internal carotid artery, and lies more completely to the lateral side of the internal and common carotid arteries, and, indeed, somewhat overlaps the latter anteriorly. This is more especially the case on the left side, for both internal jugular veins trend slightly towards the right as they descend; consequently, at the root of the neck, the right vein is separated from the right common carotid artery by a small interval filled with areolar tissue, whilst the left vein is more directly in front of the corresponding common carotid artery.

A dilatation, the *inferior bulb*, is present at the inferior extremity of the vein, and this is bounded either above or below by a valve of two or three semilunar cusps. Sometimes both the superior and inferior ends of the bulb are bounded by valves.

Relations.—The vein lies anterior to the transverse processes of the cervical vertebrae, the rectus capitis lateralis, longus capitis, and scalenus anterior muscles, the ascending cervical artery, which runs upwards in the interval between the attachments of the two latter muscles, and the phrenic nerve; the suprascapular and the transverse cervical arteries intervene between it and the scalenus anterior. At the root of the neck the vein lies in front of the first part of the subclavian artery and the origins of the vertebral artery and the thyreo-cervical trunk, and on the left side it is anterior to the terminal part of the thoracic duct.

On the antero-medial side of the internal jugular vein, immediately below the skull, are the internal carotid artery and the last four cerebral nerves; in the rest of its extent it is in relation medially first with the internal and then with the common carotid artery, whilst to its medial side and somewhat posteriorly, between it and the large arteries, lies the vagus nerve.

Each internal jugular vein is covered superficially, in the whole of its length, by the sterno-mastoid muscle; near its upper end it is crossed by the styloid process, the stylo-pharyngeus and stylo-hyoid muscles, and the posterior belly of the digastric, whilst in its lower half, the omo-hyoid, the sterno-hyoid, and the sterno-thyroid muscles are superficial to it, beneath the sterno-mastoid. Just below the transverse process of the atlas, and under cover of the sterno-mastoid, the vein is crossed, on its lateral side, by the accessory nerve and by the occipital artery; about the middle of its course it is also crossed by the communicans cervicis nerve, and near its lower end by the anterior jugular vein; the latter vessel, however, is separated from it by the sterno-hyoid and sterno-thyroid muscles. Superficial to the vein are numerous deep cervical lymph glands.

Tributaries.—(a) A vein from the *cochlea* and (b) the *inferior petrosal sinus* joins it near its commencement. (c) *Pharyngeal branches* from the venous plexus on the wall of the pharynx. (d) *Emissary veins* from the cavernous sinus. (e) The *common facial vein*, which receives the anterior and posterior facial veins. (f) The *lingual veins*, which return part of the blood from the tongue. (g) The *vena comitans hypoglossi*, which accompanies the hypoglossal nerve. (h) The *superior thyroid vein*, which accompanies the corresponding artery. (i) The *middle thyroid vein*, which passes backwards from the lateral lobe of the thyroid gland and crosses the middle of the lateral aspect of the common carotid artery. (j) The *occipital vein* occasionally terminates in the internal jugular vein. In many cases, however, it ends in the sub-occipital plexus, which is drained by the vertebral and deep cervical veins (see p. 963).

The *common facial vein* is formed by the union of the *anterior* and *posterior facial veins*. It accompanies the first part of the external maxillary artery in the carotid triangle, and terminates in the anterior border of the internal jugular vein. Just before it disappears beneath the sterno-mastoid, the common facial vein frequently gives off a large branch which descends along the anterior border of the sterno-mastoid to the supra-sternal fossa, where it joins the anterior jugular vein.

The *anterior facial vein* (Fig. 785) commences at the medial commissure of the eyelids as the *angular vein*, which is formed by the union of the supra-orbital and frontal veins. It passes downwards and backwards on the face, to the lower and anterior part of the masseter muscle, which it crosses, lying in the same plane as the external maxillary artery, but following a much straighter course. After crossing the lower border of the mandible it passes across the submaxillary triangle, superficial to the submaxillary gland, and separate from the external maxillary artery, which here lies in a deeper plane. It terminates, a short distance below the angle of the mandible, by uniting with the posterior facial vein to form the common facial vein.

The anterior facial vein receives tributaries corresponding with all the branches of the external maxillary artery, except the ascending palatine and the tonsillar, which have no accompanying veins, the blood from the region which they supply being returned for the most part through the pharyngeal plexus. The anterior facial vein also communicates with the pterygoid plexus around the external pterygoid muscle, by means of an anastomosing channel, called the *deep facial vein*, which passes posteriorly, between the masseter and buccinator muscles, into the infra-temporal fossa.

The *posterior facial vein*, see p. 968.

The *inferior thyroid veins* have already been described (see p. 964).

Venæ Subclaviæ.—The *subclavian vein* of each side is the direct continuation of the main vein of the upper extremity, the axillary vein; but through its tributary, the external jugular vein, it also receives blood both from the head and neck.

From its commencement, at the external border of the first rib, it runs medially, below and anterior to the corresponding artery from which it is separated by the lower part of the scalenus anterior muscle, and it terminates, behind the medial end of the clavicle, in the innominate vein of the corresponding side. As it passes medially it forms a slight curve, the convexity of which is directed upwards.

Each subclavian vein possesses a single bicuspid valve which is situated immediately to the distal side of the opening of the external jugular vein.

Relations.—The subclavian vein is in relation *anteriorly* with the posterior layer of the costo-coracoid membrane, which separates it from the subclavius muscle, and the nerve to the subclavius, and with the back of the medial end of the clavicle, from which it is partly separated, however, by the fibres of the sterno-hyoid and sterno-thyroid muscles.

It is closely attached, anteriorly, to the posterior surface of the costo-coracoid membrane; consequently it is expanded when the clavicle is moved forwards, an arrangement which constitutes a distinct danger when operations are being performed in the neighbourhood of the vein; for, in the event of the vessel being wounded, forward movement of the clavicle may cause air to be sucked into the vein, with fatal results.

Posterior to the vein, and on a higher plane, is the first part of the subclavian artery, but it is separated from the second part by the scalenus anterior. As soon as it reaches the medial border of the anterior scalene the subclavian vein unites with the internal jugular vein, immediately anterior to the internal mammary artery.

The upper surface of the first rib is *below* the vein.

Tributaries.—Whilst the subclavian vein is the direct continuation of the axillary vein, and receives, therefore, the blood from the upper extremity, it has, as a general rule, only one named tributary, viz., the external jugular vein.

Vena Jugularis Externa.—The external jugular vein (Fig. 785) is formed on the superficial surface of the sterno-mastoid muscle, a little below and posterior to the angle of the jaw, by the union of the posterior auricular vein with a branch from the posterior facial vein (O.T. temporo-maxillary). In many cases the branch

FIG. 785.—SUPERFICIAL VEINS OF THE HEAD AND NECK.

from the posterior facial vein is so preponderantly large that it is more correct to describe the external jugular vein as commencing as a branch of the posterior facial vein. After its formation the external jugular vein descends, with a slight obliquity backwards, to the anterior part of the subclavian portion of the posterior triangle of the neck, where it pierces the deep fascia, and, after crossing in front of the third part of the subclavian artery, terminates in the subclavian vein.

Whilst on the surface of the sterno-mastoid muscle it is covered by the superficial fascia, and platysma muscle, and it lies parallel with the great auricular nerve; after crossing the nervus cutaneus colli (O.T. trans. cervical) it reaches the posterior border of the sterno-mastoid, where it receives a tributary called the **posterior external jugular vein**, which commences in the superficial tissues of the upper and back part of the neck, and runs downwards and forwards, across the

roof of the upper part of the posterior triangle, to its termination in the external jugular vein.

As the external jugular vein pierces the deep cervical fascia in the subclavian triangle, its wall is closely attached to the margin of the opening through which it passes; and as it is crossing in front of the third part of the subclavian artery it is joined by the transverse scapular, transverse cervical, and anterior jugular veins.

There are usually two valves in the lower part of the vein—one, at its termination, which is generally incompetent, and a second at a higher level.

Tributaries.—In addition to the posterior auricular vein and the branch from the posterior facial vein by which it is formed, the external jugular vein receives the posterior external jugular vein, which has already been described, the transverse cervical and transverse scapular veins from the region of the shoulder, and the anterior jugular vein. Occasionally the cephalic vein also opens into it.

The **posterior auricular vein** (Fig. 785) receives tributaries from the posterior parts of the parietal and temporal regions and from the medial surface of the auricle. It is considerably larger than the posterior auricular artery, which it accompanies only in the scalp. At the base of the scalp it leaves the artery and descends in the superficial fascia, over the upper part of the sterno-mastoid, to open into the commencement of the external jugular vein.

The **transverse cervical and transverse scapular veins** accompany the corresponding arteries; not infrequently they open directly into the subclavian vein.

The **anterior jugular vein** commences in the submental region, and is formed by the union of small veins from the lower lip and chin. It descends in the superficial fascia, at a variable distance from the median plane, perforates the superficial layer of the deep fascia a short distance above the sternum and enters the suprasternal space (Burns) between the first and second layers of the deep fascia. In the space it anastomoses with its fellow of the opposite side and receives a communication from the common facial vein. Then it turns laterally, between the sterno-mastoid superficially and the sterno-hyoid, sterno-thyroid, and scalenus anterior muscles deeply, and terminates in the external jugular vein at the posterior border of the sterno-mastoid.

The external jugular vein sometimes receives the occipital vein or a communication from it.

THE VEINS OF THE SCALP.

The veins which drain the blood from the superficial parts of the scalp are the frontal, the supra-orbital, the superficial temporal, the posterior auricular, and the occipital. The blood from the deeper part of the scalp, in the region of the temporal fossa, on each side, passes into the deep temporal veins, which are tributaries of the pterygoid plexus.

The **frontal and supra-orbital veins** receive blood from the medial and anterior part of the scalp. They unite together, near the medial commissure of the eyelids, to form the *angular vein*; before the union is effected the supra-orbital vein sends a branch backwards, through the supra-orbital notch, into the orbital cavity, where it terminates in the ophthalmic vein, and as this branch passes through the notch it receives the frontal diploic vein (p. 969).

The **superficial temporal vein** is formed by frontal and parietal tributaries which accompany the corresponding branches of the superficial temporal artery. They drain the lateral frontal, the superficial part of the temporal, and the anterior part of the parietal region of the scalp, and unite to form a single trunk which descends to the upper border of the zygoma, immediately anterior to the auricle, where it terminates in the posterior facial vein (see p. 968).

The **posterior auricular vein** drains the posterior portions of the temporal and parietal areas of the scalp. It runs downwards, across the mastoid portion of the temporal bone, and terminates in the external jugular vein (see above).

The **occipital vein** (Fig. 785) receives tributaries from the medial and posterior part of the parietal region and from the occipital region. As a rule it pierces the occipital origin of the trapezius, and, passing into the sub-occipital triangle, terminates in a plexus of veins which is drained by the vertebral and deep cervical veins. It sometimes communicates with the external jugular vein, and occasion-

ally an offset from it accompanies the corresponding artery and ends in the internal jugular vein.

It generally receives the mastoid emissary vein; one of its tributaries receives the parietal emissary vein, and occasionally an emissary vein from the confluens sinuum (O.T. torcular Herophili) opens into it.

THE VEINS OF THE ORBIT, THE NOSE, AND THE INFRA-TEMPORAL REGION.

The veins of these three regions are closely associated together; for although the orbital blood is returned for the most part to the cavernous sinus by the ophthalmic vein, the latter vein is closely connected with the pterygoid plexus, which lies in the infra-temporal region.

Veins of the Orbit.—The veins of the orbit correspond, with the exception of the naso-frontal vein, with the branches of the ophthalmic artery, and they gradually converge, as they pass backwards in the orbit, until they form two main trunks, a **superior ophthalmic vein** and an **inferior ophthalmic vein**; these terminate, separately or by a single trunk, in the anterior end of the cavernous sinus, to which they pass through the superior orbital fissure, and between the two heads of the lateral rectus muscle.

The superior ophthalmic vein communicates, at the supero-medial angle of the orbit, with the angular vein, and it receives the naso-frontal vein which accompanies the frontal nerve. The inferior ophthalmic vein communicates, through the inferior orbital fissure, with the pterygoid plexus.

Veins of the Nose.—The veins of the walls of the nasal cavity end partly in the ethmoidal tributaries of the superior ophthalmic vein, partly in the septal affluent of the superior labial and in the lateral nasal veins, both of which are tributaries of the anterior facial vein; but the majority of the veins of the nose, both from the septal and lateral walls, join together to form a sphenopalatine vein which passes through the sphenopalatine foramen and the pterygo-palatine fossa, and terminates in the pterygoid plexus.

Plexus Pterygoideus and the Vena Maxillaris Interna.—The **pterygoid plexus** of veins lies in the infra-temporal and pterygoid fossæ. It covers the lateral surface of the internal pterygoid muscle, and surrounds the external pterygoid. It receives tributaries which correspond with and accompany the branches of the internal maxillary artery—viz., sphenopalatine, pharyngeal, vein of pterygoid canal (Vidian), infra-orbital, posterior superior alveolar, descending palatine, buccinator, two or three deep temporal, pterygoid, masseteric, and inferior alveolar veins, and the middle meningeal vein. It communicates, superiorly, with the cavernous sinus through the foramen ovale; anteriorly with the inferior ophthalmic vein through the inferior orbital fissure; and between the masseter and the buccinator with the anterior facial vein by the deep facial anastomosing branch. It also communicates posteriorly and medially, on the medial side of the internal pterygoid, with the pharyngeal plexus, and it terminates posteriorly in the internal maxillary vein.

The **internal maxillary vein** is a short vessel which accompanies the first part of the internal maxillary artery, between the sphenomandibular ligament and the neck of the mandible. Between the neck of the mandible and the antero-medial surface of the parotid gland it joins the upper part of the posterior facial vein. Occasionally the internal maxillary vein is double, and sometimes it is represented by several channels.

The **posterior facial vein** is formed, immediately above the zygomatic arch, by the union of the superficial and middle temporal veins. It crosses the zygomatic arch, dips deep to the upper part of the parotid gland, and, whilst lying between the antero-medial surface of the gland and the posterior border of the mandible, it receives the internal maxillary vein or veins. Then it descends, through the substance of the parotid, and, emerging from its lower end at the angle of the mandible, it passes forwards and downwards to unite with the anterior facial vein in the formation of the common facial vein.

Whilst it is in the substance of the parotid it gives off a comparatively large

branch, which emerges from the lower and posterior part of the gland and forms the main commencing tributary of the external jugular vein.

VENOUS SINUSES AND VEINS OF THE CRANIUM AND OF ITS CONTENTS.

The venous channels met with in the cranial walls and cranial cavity are:—

(1) The diploic veins, which lie in the spongy tissue between the outer and inner tables of the cranial bones.

(2) The meningeal veins, which accompany the meningeal arteries in the outer layer of the dura mater.

(3) The veins of the brain, which lie between the folds of pia mater and in the subarachnoid space.

(4) The cranial venous sinuses, channels which are situated between the outer and inner layers of the dura mater; they receive the blood from the terminal cerebral veins.

DIPLOIC AND MENINGEAL VEINS.

Venæ Diploicæ.—The diploic veins are anastomosing spaces in the spongy tissue of the flat bones of the skull; they are lined with endothelium. The number of efferent vessels which emerge from these spaces is not constant, but usually there are at least four on each side—viz., a frontal, two temporal, anterior and posterior, and an occipital.

The frontal diploic vein is one of the most constant; it drains the anterior part

FIG. 786.—THE VEINS OF THE DIPLOË.

of the frontal bone, and, passing through a small aperture in the upper margin of the supra-orbital notch, terminates in the supra-orbital vein.

The anterior temporal diploic vein drains the posterior part of the frontal bone and the anterior part of the parietal bone; it pierces the great wing of the sphenoid, and terminates either in the spheno-parietal sinus or in the anterior deep temporal vein.

The posterior temporal diploic vein drains the posterior part of the parietal bone; it runs downwards to the posterior inferior angle of the parietal bone

and terminates in the transverse sinus, to which it passes either through a foramen in the inner table of the parietal bone or through the mastoid foramen.

The **occipital diploic vein** is usually the largest of the series; it drains the occipital bone, and terminates either externally in the occipital vein or internally in the lateral sinus.

Venæ Meningeæ.—The **meningeal veins** commence in two capillary plexuses, a deep and a superficial. The deep plexus is a wide-meshed network in the inner layer of the dura mater. Its efferent vessels terminate in the superficial plexus. The superficial plexus lies in the outer layer of the dura mater. It consists of numerous vessels of uniform calibre which frequently anastomose together, and terminate in two sets of efferents; of these, one set ends in the cranial blood sinuses, and the other accompanies the meningeal arteries. The efferent meningeal veins are peculiar, inasmuch as they do not alter much in size as they approach their terminations. They lie external to the arteries in the grooves in the inner wall of the cranium, and are very liable to be torn when the bones are fractured (Wood Jones).

VEINS OF THE BRAIN.

The veins of the brain include the veins of the cerebrum, of the mid-brain, of the cerebellum, of the pons, and of the medulla oblongata. They do not possess valves.

Venæ Cerebri—The **Veins of the Cerebrum**.—The **cerebral veins** are arranged in two groups, (*a*) the deep and (*b*) the superficial.

The deep veins issue from the substance of the brain. The superficial veins lie upon its surface in the pia mater and the subarachnoid space. The terminal trunks of both sets pierce the arachnoid membrane and the inner layer of the dura mater, and open into the cranial venous sinuses.

(*a*) The **deep cerebral veins** are the chorioid veins, the *venæ terminales*, the internal cerebral veins, the great cerebral vein (Galen), the vein of the septum pellucidum and the inferior striate veins.

Each **chorioid vein** is formed by the union of tributaries which issue from the chorioid plexus in the body and inferior horn of a lateral ventricle. It ascends along the lateral border of the tela chorioidea of the third ventricle (O.T. *velum interpositum*), and passes forwards in the lateral border of that fold of pia mater to the interventricular foramen (Monro), where it receives efferents from the chorioid plexus of the third ventricle, and unites with the *vena terminalis* to form the internal cerebral vein (Galen).

The **vena terminalis** (O.T. **vein of corpus striatum**), on each side, is formed by the union of tributaries which issue from the corpus striatum and from the thalamus. It runs forwards between the two bodies, in a groove in the floor of the lateral ventricle, and, after receiving tributaries from the walls of the anterior horn of the ventricle, and the vein of the septum pellucidum, it terminates at the apex of the tela chorioidea, where it joins the chorioid vein to form the internal cerebral vein (Galen).

Each **internal cerebral vein** (Galen) commences at the apex of the tela chorioidea, near the interventricular foramen (Monro), by the union of the *vena terminalis* with the chorioid vein. The two veins run backwards between the layers of the tela, receiving tributaries from the chorioid plexuses of the third ventricle and from the fornix and corpus callosum, and they terminate, beneath the splenium of the corpus callosum, by uniting to form the great cerebral vein (Galen).

The **great cerebral vein** (Galen) passes backwards and slightly upwards from its origin, and ends in the anterior extremity of the straight sinus. In addition to the two internal cerebral veins, by the union of which it is formed, it receives tributaries from the posterior parts of the gyrus cinguli of each side, from the pineal and quadrigeminate bodies, from the medial and inferior surfaces of the occipital lobes of the brain, and from the upper surface of the cerebellum. It also receives the basal vein of each side (see p. 971).

An **inferior striate vein** descends, on each side, from the substance of the corpus striatum, and, after passing through the anterior perforated substance, ends in the basal vein (see below), which, as already stated, is a tributary of the great cerebral vein.

(b) The **superficial cerebral veins** are more numerous and of larger calibre than the cerebral arteries. They lie upon the surface of the cerebrum, drain blood from the cerebral cortex, and they are divisible into two sets, the superior and the inferior.

The **superior cerebral veins**, twelve or more in number, lie in the pia mater and subarachnoid space on the upper and lateral aspect of the cerebral hemispheres. They run upwards and medially, to the margin of the longitudinal fissure where they receive tributaries from the medial surface of the hemisphere, and they terminate in the superior sagittal sinus or in the lateral lacunar expansions of the sinus. The anterior veins of this set are small and run transversely, but the posterior are large and run obliquely forwards and medially; they are embedded for some distance in the wall of the sinus, and their orifices are directed forwards against the blood stream.

The **inferior cerebral veins** lie on the lower and lateral aspects of the cerebral hemispheres; they run downwards and medially, and terminate in the sinuses which lie at the base of the skull—viz., the cavernous, the superior petrosal, and the transverse sinuses. One of these veins, the **superficial middle cerebral vein** (O.T. **superficial Sylvian**), runs along the posterior horizontal limb and stem of the lateral fissure (Sylvius) to the cavernous sinus; occasionally it is united by an anastomotic loop, known as the **great anastomotic vein** (Trolard), with the superior sagittal sinus, and sometimes by the **posterior anastomotic vein** with the transverse sinus.

The **anterior cerebral vein** of each side lies in the longitudinal fissure, and accompanies the corresponding anterior cerebral artery; it receives tributaries from the corpus callosum and the gyrus cinguli. Turning downwards, round the genu of the corpus callosum, it reaches the base of the brain, and terminates in the basal vein.

The **deep middle vein** (O.T. **deep Sylvian**) lies deeply in the lateral fissure (Sylvius); it anastomoses freely with the superficial middle vein, receives tributaries from the insula and the adjacent opercula, and terminates in the basal vein.

The **basal vein** commences at the anterior perforated substance; it is formed by the union of the anterior cerebral vein with the deep middle vein and with the inferior striate vein. Passing backwards round the pedunculus cerebri, it terminates in the great cerebral vein (Galen). Its tributaries are derived from the tuber cinereum, the corpus mamillare, the posterior perforated substance, the uncus, the inferior cornu of the lateral ventricle, and the pedunculus cerebri.

Veins of the Mid-brain.—The veins of the mid-brain terminate for the most part either in the great cerebral vein (Galen) or in the basal veins.

Cerebellar Veins.—These veins also are divisible into two groups, the superficial and the deep. The former are quite independent of and much more numerous than the arteries. They form two sets, the superior and the inferior.

The **superior superficial cerebellar veins** terminate in a single median or vermian efferent vessel which is sometimes double, and in several lateral efferents. The superior vermian vein runs anteriorly and ends in the great cerebral vein (Galen). The lateral superior cerebellar veins terminate in the transverse sinuses or in the superior petrosal sinuses.

The **inferior superficial cerebellar veins** also form a small vermian and numerous lateral efferents; the former runs backwards and joins either the straight sinus or one of the transverse sinuses, and the latter end in the inferior petrosal and occipital sinuses.

The **deep cerebellar veins** issue from the substance of the cerebellum and terminate in the superficial veins.

Veins of the Pons.—The deep veins from the substance of the pons pass forwards to its anterior surface, where they become superficial, and, anastomosing together, form a plexus which is drained by superior and inferior efferent veins.

The superior efferent veins join the basal vein; the inferior efferent veins either unite with the cerebellar veins, or they open into the superior petrosal sinus.

Veins of the Medulla Oblongata.—Deep veins of the medulla oblongata issue from its substance and end in a superficial plexus. This plexus is drained by an anterior and a posterior median vein and by radicular veins.

The **anterior median vein** is continuous below with the corresponding vein of the spinal medulla; it communicates above with the plexus on the surface of the pons.

The **posterior median vein** is continuous below with the posterior median vein of the spinal medulla, from which it ascends to the lower end of the fourth ventricle, where it divides into two branches which join the inferior petrosal sinus or basilar plexus.

The **radicular veins** issue from the lateral parts of the plexus and run with the roots of the last four cerebral nerves; they end in the inferior petrosal and occipital sinuses or in the upper part of the internal jugular vein.

SINUS DURÆ MATRIS.

The **venous sinuses** of the cranium are spaces between the layers of the dura mater; and they are lined with an endothelium which is continuous with the endothelium of the veins. They receive the veins of the brain, communicate frequently with the

FIG. 787.—DISSECTION OF THE HEAD AND NECK, showing the cranial blood sinuses and the upper part of the internal jugular vein.

meningeal veins and with veins external to the cranium, and terminate directly or indirectly in the internal jugular vein. Some of the cranial blood sinuses are unpaired, others are paired.

Unpaired Sinuses.—These are the superior sagittal, the inferior sagittal, the straight, the anterior and posterior intercavernous, and the basilar.

Sinus Sagittalis Superior.—The superior sagittal sinus commences in the anterior fossa of the cranium, at the crista galli, where it communicates, through the foramen cæcum, with the veins of the nasal cavity or with the angular vein. It passes first upwards, then posteriorly, and finally downwards in the convex margin of the falx cerebri, grooving the frontal, both the parietal bones, and upper

FIG. 788.—BASAL BLOOD SINUSES OF THE DURA MATER.

part of the occipital. As it descends it passes slightly to the right side, and it ends, at the level of the internal occipital protuberance, by becoming the right transverse sinus. Instead of passing to the right, it occasionally turns to the left, and ends in the left transverse sinus. In either case its termination is associated with a well-marked dilatation, the *confluens sinuum* (O.T. *torcular Herophili*), which marks a confluence of sinuses, and is lodged in a depression at one side of the internal occipital protuberance. The confluens sinuum is connected, across the protuberance, by an anastomosing channel, with a similar dilatation which marks the junction of the straight sinus with the lateral sinus of the opposite side. Opening into the

superior sagittal sinus are the superior cerebral veins, and it communicates on each side by small openings with a series of spaces in the dura mater, the *lacunæ laterales*, into which the arachnoideal granulations project. It also communicates, by emissary veins, which pass through the foramen cæcum and through each parietal foramen, with the veins on the exterior of the cranium. Its cavity, which is triangular in transverse section, is crossed by several fibrous strands called the *chorde Willisii*.

Sinus Sagittalis Inferior.—The inferior sagittal sinus lies usually in the posterior two-thirds of the lower free margin of the falx cerebri. It terminates posteriorly by joining with the great cerebral vein (Galen) to form the straight sinus. It receives tributaries from the falx cerebri and from the medial surface of the middle third of each cerebral hemisphere.

Sinus Intercavernosi.—The anterior intercavernous sinus is a small transverse channel which crosses from one cavernous sinus to the other in the anterior borders of the diaphragma sellæ.

The posterior intercavernous sinus also connects the two cavernous sinuses together. It lies in the posterior border of the diaphragma sellæ.

The anterior and posterior intercavernous sinuses and the intervening parts of the cavernous sinuses form collectively the circular sinus.

Plexus Basilaris.—The basilar plexus (O.T. basilar sinus) is situated in the dura mater on the basilar part of the occipital bone. It connects the posterior ends of the cavernous or the anterior ends of the inferior petrosal sinuses together, and communicates below with the anterior spinal veins.

Sinus Rectus.—The straight sinus is formed by the union of the inferior sagittal sinus with the great cerebral vein (Galen). It runs downwards and backwards, along the line of union between the falx cerebri and the tentorium cerebelli. As a general rule it turns to the left at the internal occipital protuberance, dilates somewhat, and becomes continuous with the left transverse sinus, its dilatation being united with the corresponding dilatation on the lower end of the superior sagittal sinus, the “*confluens sinuum*,” by a transverse anastomosing channel. Occasionally the straight sinus terminates in the right lateral sinus, and in that case the superior sagittal sinus ends in the left transverse sinus. It receives some of the superior cerebellar veins and a few tributaries from the falx cerebri.

Paired Sinuses.—There are six pairs of sinuses, viz., the transverse, the occipital, the cavernous, the superior petrosal, the inferior petrosal, and the sphenoparietal.

Sinus Transversi (O.T. Lateral Sinuses).—Each transverse sinus commences at the internal occipital protuberance, the right usually as the continuation of the superior sagittal, and the left as the continuation of the straight sinus. Each passes laterally in the postero-lateral part of the attached border of the tentorium cerebelli and in a groove in the occipital bone. From the lateral angle of the occipital bone it passes to the posterior inferior angle of the parietal bone, which it grooves; then it leaves the tentorium and turns downwards on the inner surface of the mastoid portion of the temporal bone; from the latter it passes to the upper surface of the jugular process of the occipital bone, and turns forwards and then downwards into the jugular foramen, where it becomes continuous with the internal jugular vein.

Its tributaries are some of the superior and inferior cerebellar veins, a posterior diploic vein, and the superior petrosal sinus. It is connected with the veins outside the cranium by emissary veins which pass through the mastoid foramen and the condyloid canal.

Sinus Occipitales.—The occipital sinuses lie in the attached border of the falx cerebelli and in the dura mater along the postero-lateral boundaries of the foramen magnum; frequently they unite above and open by a single channel into the commencement of either the right or the left transverse sinus, but their upper extremities may remain separate, and then each communicates with the commencement of the transverse sinus of its own side. On the other hand either the right or the left sinus may be absent. They open below into the terminal part of the corre-

sponding transverse sinuses, and they communicate with the posterior spinal veins. Each occipital sinus is an anastomosing channel between the upper and lower extremities of the transverse sinus of the same side, and each receives a few inferior cerebellar veins.

Sinus Cavernosi.—The cavernous sinuses lie at the sides of the body of the sphenoid bone. Each sinus commences anteriorly at the medial end of the superior orbital fissure, where it receives the corresponding ophthalmic veins, and it terminates, at the apex of the petrous portion of the temporal bone, by dividing into the superior and the inferior petrosal sinuses. Its cavity, which is irregular in size and shape, is so divided by numerous fibrous strands that it assumes the appearance of cavernous tissue; and in its lateral wall are embedded the internal carotid artery with its sympathetic plexus, the oculomotor, the trochlear, the ophthalmic and maxillary divisions of the trigeminal and the abducent nerves. Its tributaries are the sphenoparietal sinus and the inferior cerebral veins, including the middle cerebral vein (O.T. superficial Sylvian vein). It communicates with the opposite cavernous sinus by means of the anterior and posterior intercavernous sinuses; with the pterygoid plexus, in the infra-temporal fossa, by an emissary vein which passes either through the foramen ovale or through the foramen Vesalii; with the internal jugular vein by small venous channels which accompany the internal carotid artery through the carotid canal, and by the inferior petrosal sinus; with the transverse sinus by the superior petrosal sinus; and through the superior ophthalmic vein with the angular vein.

The sphenoparietal sinuses are lodged in the dura mater on the under surfaces of the small wings of the sphenoid bone close to their posterior borders. Each sinus communicates with the middle meningeal veins, receives veins from the dura mater, and terminates in the anterior part of the corresponding cavernous sinus.

Sinus Petrosi Superiores.—Each superior petrosal sinus commences at the apex of the petrous portion of the temporal bone, in the posterior end of the corresponding cavernous sinus, and it runs backwards and laterally, in the attached margin of the tentorium cerebelli, above the trigeminal nerve. It grooves the superior angle of the petrous portion of the temporal bone, at the lateral end of which it terminates in the transverse sinus, at the point where the latter is turning downwards on the medial surface of the mastoid portion of the temporal bone. It receives inferior cerebral, superior cerebellar, tympanic, and diploic veins.

Sinus Petrosi Inferiores.—An inferior petrosal sinus commences at the posterior end of each cavernous sinus; it runs backwards, laterally, and downwards, in the posterior fossa of the cranium, in a groove formed by the lower angle of the petrous part of the temporal bone and the adjacent border of the basilar part of the occipital bone, to the anterior compartment of the jugular foramen of the same side, through which it passes. It crosses the last four cerebral nerves either on their lateral or on their medial sides, and it terminates in the internal jugular vein. Its tributaries include inferior cerebellar veins and veins from the internal ear, which pass to it through the internal acoustic meatus, the aquæductus cochleæ, and the aquæductus vestibuli.

Emissaria.—The emissary veins are veins which convey blood from the blood sinuses in the interior of the cranium to the veins which lie outside the walls of the cranium. They may be single veins, or plexiform channels surrounding other structures which are passing through the walls of the cranium.

(1) **Frontal.**—In the child, and sometimes in the adult, an emissary vein passes from the anterior end of the superior sagittal sinus through the foramen cæcum. Its lower end divides into two channels which either terminate in the veins of the roof of the nasal cavities or they perforate the nasal bones and join the angular veins.

(2) **Parietal.**—The parietal emissary veins, one on each side, pass through the parietal foramina, from the superior sagittal sinus to the occipital veins.

(3) **Occipital.**—An occipital emissary vein is only occasionally present. It passes from the "confuens sinuum" through the occipital protuberance to one of the tributaries of an occipital vein, and it receives the occipital diploic vein.

(4) **Condylloid.**—When the condylloid canals are present in the occipital bone each is traversed by a condylloid emissary vein, which connects the lower end of the corresponding transverse sinus with the plexus of veins in the sub-occipital triangle.

(5) **Emissary Plexus of the Foramen Ovale.**—This plexus surrounds the mandibular nerve, as it passes through the foramen ovale, and connects the cavernous sinus with the corresponding

pterygoid plexus in the infratemporal fossa. If the foramen Vesalii is present, the plexus of the foramen ovale is replaced or supplemented by an emissary vein which passes through it.

(6) **Internal Carotid Plexus.**—The internal carotid plexus accompanies the internal carotid artery through the carotid canal of the temporal bone, and connects the cavernous sinus either with the pharyngeal plexus or with the upper part of the internal jugular vein.

(7) **Plexus of the Hypoglossal Canal.**—As the hypoglossal nerve passes through the hypoglossal canal (O.T. anterior condyloid foramen) it is accompanied either by a venous plexus or by a large vein which connects the veins of the medulla oblongata and the lower part of the occipital sinus with the upper end of the internal jugular vein, or with the extra-cranial part of the inferior petrosal sinus.

VERTEBRAL VEINS.

The vertebral veins include—

- (1) The basi-vertebral veins.
- (2) The external vertebral plexuses.
 - (a) anterior " "
 - (b) posterior " "
- (3) The internal vertebral plexus.
- (4) Vertebral longitudinal sinuses.
- (5) Intervertebral veins.

Venæ Basivertebrales.—The basi-vertebral veins are venous channels enclosed by endothelial walls which lie in the interiors of the bodies of the vertebræ. They communicate anteriorly with the plexuses of veins on the anterior surfaces of the bodies of the vertebræ, and they converge, radially, towards the posterior surfaces of the bodies of the vertebræ where they open into the transverse anastomoses between the longitudinal vertebral sinuses.

Plexus Venosi Vertebralis Externi.—The external vertebral plexuses, (a) *anterior* and (b) *posterior*.

(a) The anterior external vertebral plexuses are formed by anastomosing venous channels which lie on the anterior surfaces of the vertebræ. They communicate with the basi-vertebral veins and with the intervertebral veins.

(b) The posterior external vertebral plexuses lie around the postero-lateral aspects of the vertebræ, in the vertebral grooves, around the spines, the articular and the transverse processes of the vertebræ. They communicate with the internal plexuses and with the intervertebral veins, and they open into the vertebral, intercostal, and lumbar veins.

Sinus Vertebrales Longitudinales.—The Longitudinal Vertebral Sinuses.—The veins in the interior of the vertebral canal form a network, the *vertebral venous network*, which lies external to the dura mater and covers the internal surfaces of the arches of the vertebræ. The network communicates laterally with the intervertebral veins, posteriorly with the posterior external venous plexuses, whilst anteriorly it receives the basi-vertebral veins. In the anterior part of the network, on the posterior surfaces of the bodies of the vertebræ and at the sides of the posterior longitudinal ligament, there are two large longitudinal channels, the *anterior longitudinal vertebral sinuses*. Two less marked longitudinal channels, the *posterior longitudinal vertebral sinuses*, can sometimes be distinguished running along the internal surfaces of the vertebral arches.

The anterior longitudinal vertebral sinuses communicate above with the basilar plexus, the terminal parts of the transverse sinuses, and with the network of veins which accompanies each hypoglossal nerve through the hypoglossal canal.

The posterior longitudinal vertebral sinuses, when they are well established, communicate above with the occipital sinuses.

Venæ Intervertebrales.—The Intervertebral Veins.—The internal vertebral venous network is drained not only above into the cranial venous sinuses by the longitudinal vertebral sinus, but also by a series of intervertebral veins which pass through the intervertebral foramina. In the cervical region the intervertebral veins open externally into the vertebral veins, in the thoracic region into the intercostal veins, in the lumbar region into the lumbar veins, and in the sacral region into the lateral sacral veins. The intervertebral veins convey blood both from the internal vertebral venous plexus and also from the anterior and the posterior external vertebral plexuses.

THE VEINS OF THE SPINAL MEDULLA.

The veins of the spinal medulla issue from the substance of the spinal medulla, and terminate in a plexus in the pia mater. In this plexus there are six longitudinal channels—one *antero-median*, along the anterior fissure, two *antero-lateral*, immediately behind the anterior nerve-roots, two *postero-lateral*, immediately posterior to the posterior nerve-roots, and one *postero-median*, dorsal to the posterior septum. Radicular efferent vessels issue from the plexus, and pass along the nerve roots to communicate with the internal vertebral venous network. The veins of the spinal medulla vary very much in size, but they are largest on the lower and on the posterior portions.

The postero-median and antero-median veins are continued above into the corresponding veins of the medulla oblongata.

The antero-lateral and postero-lateral veins pour their blood partly into the median veins and partly into the radicular veins; indeed, the greater part of the blood from the spinal medulla is returned by the radicular veins.

THE VEINS OF THE SUPERIOR EXTREMITY.

The veins of each upper limb are divisible into two sets—viz., *superficial* and *deep*. Both sets open eventually into a common terminal trunk which is known as the *axillary vein*. This vein is, therefore, the chief efferent vein of the upper extremity. It is continued as the *subclavian vein* to the *innominate vein*, through which its blood, together with that from the corresponding side of the head and neck, reaches the *superior vena cava*.

THE DEEP VEINS OF THE UPPER EXTREMITY.

The deep veins of the upper limb, with the exception of the axillary vein, are arranged in pairs, *venæ comites*, which accompany the different arteries and are similarly named. So far as these veins are concerned it will be sufficient to state that they are provided with valves, that they are situated one on each side of the artery with which they are associated, and that they are usually united together by numerous transverse anastomoses which cross the line of the artery. The axillary vein, however, requires more detailed consideration.

VENA AXILLARIS.

The *axillary vein* (Figs. 766 and 806) commences as the direct continuation of the *basilic vein*, opposite the lower border of the *teres major* muscle. It passes upwards and medially, through the axilla, along the medial side of the axillary artery, and terminates at the external border of the first rib by becoming the *subclavian vein*. It possesses one or more bicuspid valves of which one is usually situated opposite the lower border of the *subscapularis* muscle.

Relations.—Its anterior relations are similar to those of the axillary artery, but, in addition, the vein is crossed anteriorly, under cover of the clavicular part of the *pectoralis major*, by the pectoral branches of the *thoraco-acromial artery*, and by branches of the *medial anterior thoracic nerve*, and it receives anteriorly, just above the upper border of the *pectoralis minor*, the termination of the *cephalic vein*.

Posterior to it are the muscles which form the posterior wall of the axilla, the axillary fat, and the first serration of the *serratus anterior*. The long thoracic nerve intervenes between it and the *serratus anterior*, and the *subscapular* and *thoraco-dorsal* nerves and the *subscapular artery* pass between it and the *subscapularis*.

It is separated from the axillary artery in the distal part of its extent by the *ulnar nerve* and *medial cutaneous nerves* of the forearm, in the middle of its course by the medial cord of the *brachial plexus*, and in the proximal part of the axilla, behind the *costo-coracoid membrane*, by the *medial anterior thoracic nerve*. To its medial side lie the lateral set of axillary glands, and, in the distal part of the axilla, the *medial cutaneous nerve* of the arm.

Tributaries.—In addition to tributaries corresponding with the branches of the axillary artery, it receives the *venæ comites* of the brachial artery, at the lower border of the subscapularis, and the cephalic vein, which joins it opposite the upper border of the pectoralis minor muscle.

THE SUPERFICIAL VEINS OF THE SUPERIOR EXTREMITY.

The superficial veins of the upper limb commence in the superficial fascia of the palm and dorsum of the hand and of the digits.

The Veins of the Digits and Hand.—The **proper volar digital veins** are two or more fine longitudinal channels which lie in the superficial fascia of the volar

FIG. 789.—SUPERFICIAL VEINS ON THE DORSUM OF THE HAND AND DIGITS.

aspects of the digits. They communicate, proximally, with a fine venous network which lies in the superficial fascia of the palm, and, at the proximal ends of the interdigital clefts, by means of *intercapitular veins*, which pass dorsally between the heads of the metacarpal bones, they open into the *proper dorsal digital veins*.

The **proper dorsal digital veins**, two in each digit, anastomose freely together on the dorsal aspects of the digits. At proximal ends of the interdigital clefts they communicate, through the intercapitular veins, with the *propervolar digital veins*, and then they unite together to form an indefinite series of *dorsal metacarpal veins* which terminate, a little

distal to the middle of the dorsum of the hand, in a **dorsal venous arch**.

The Veins of the Forearm and Arm.—The veins of the forearm emerge from the dorsal venous arch and from the volar venous plexus, and they vary considerably in number and in size. As a rule there are two main longitudinal channels, the *cephalic vein* on the radial side and the *basilic vein* on the ulnar side. In some cases there is an additional median vein on the volar aspect of the forearm.

The **cephalic vein** commences in the radial end of the dorsal venous arch. It receives the metacarpal veins of the thumb, turns round the radial margin of

the distal part of the forearm, and runs proximally, parallel with the volar border of the brachioradialis muscle, to the cubital region. There, frequently much reduced in size, it turns laterally and runs, along the lateral border of the prominence of the biceps, to the interval between the deltoid and pectoralis major, along which it ascends to the delto-pectoral triangle. At the delto-pectoral triangle it turns medially, between the pectoralis minor and the pectoralis major, to the anterior aspect of the costo-coracoid membrane, which separates it from the front of the first part of the axillary artery; then, turning backwards, it pierces the costo-coracoid membrane and ends in the axillary vein. In a few cases instead of piercing the costo-coracoid membrane it crosses the front of the clavicle, deep to the platysma, pierces the deep cervical fascia, and joins the lower part of the external jugular vein.

As it runs proximally, on the volar aspect of the forearm, a number of tributaries join its lateral border. Some of these commence in the dorsal venous arch of the hand and others in the superficial fascia of the dorsal aspect of the forearm.

In the cubital region it is connected with the basilic vein by a large obliquely placed anastomosing channel, the *median cubital vein*, which runs along the medial border of the distal part of the biceps prominence, superficial to the lacertus fibrosus which separates it from the distal part of the brachial artery. In the delto-pectoral triangle it is joined by tributaries which correspond with the acromial and pectoral branches of the thoraco-acromial artery.

The **median cubital vein** not only connects together the cephalic and basilic veins but it receives also the profunda vein which pierces the deep fascia and connects it with the deep veins of the forearm, and one or more superficial veins, of varying size which pass, proximally, along the volar aspect of the forearm.

In many cases the median cubital vein is relatively very large, and in such cases the more proximal part of the cephalic vein, which lies in the arm, is a comparatively small vessel.

The **basilic vein** commences in the ulnar end of the dorsal venous arch of the hand. It runs along the dorsal aspect of the forearm to the junction of the proximal and middle thirds, where it turns round the ulnar border of the forearm, and runs, anterior to the medial epicondyle of the humerus, to the medial bicipital groove. At the middle of the arm, it pierces the deep fascia. After piercing the fascia, it runs proximally, along the medial border of the brachial artery, to the axilla, and there becomes the axillary vein.

FIG. 790.—SUPERFICIAL VEINS ON THE FLEXOR ASPECT OF THE UPPER EXTREMITY.

As it runs proximally, in the forearm, it is joined by tributaries from both the volar and dorsal aspects and, in the cubital region, by the median cubital vein which connects it with the cephalic vein.

FIG. 791.—SUPERFICIAL VEINS AT THE BEND OF THE ELBOW.

arm it is either the median cubital vein or, in its absence, the median basilic vein which is opened.

The Median Vein of the Forearm.—In a certain number of cases a vein, which commences in the palmar venous plexus, runs along the middle of the volar aspect of the forearm to the cubital region. This is the median vein of the forearm. At the bend of the elbow it receives the profunda vein and then divides into two branches, the *median cephalic* and the *median basilic* veins (Fig. 791). The median cephalic vein runs along the lateral bicipital sulcus and joins the cephalic vein. The median basilic passes along the medial bicipital sulcus and joins the basilic vein. When the median vein of the forearm is present the median cubital vein is absent.

When venesection is performed in the fore-

VENA CAVA INFERIOR AND ITS TRIBUTARIES.

The **inferior vena cava** (Fig. 792) is a large venous trunk which receives the whole of the blood from the lower extremities, and the greater part of the blood from the walls and contents of the abdomen and pelvis. It commences opposite the right side of the body of the fifth lumbar vertebra, behind and to the right of the right common iliac artery. It ascends through the abdomen, anterior and to the right of the vertebral column and the right crus of the diaphragm, and it pierces the cupola of the diaphragm, between the middle and right sections of the central tendinous leaflet, at the level of the eighth thoracic vertebra. It then enters the middle mediastinum, pierces the fibrous pericardium, and terminates in the lower and posterior part of the right atrium. Its intra-thoracic portion is very short, and its intra-pericardial portion, which is still shorter, is covered anteriorly and on its right and left sides by the parietal portion of the serous layer. Attached to the inferior and anterior margin of its atrial orifice is the *valve of the inferior vena cava* (Eustachian). This is a remnant of an important fold of endocardium by which, in the fœtus, the blood from the inferior vena cava is directed, through the foramen ovale, into the left atrium.

Relations.—The inferior vena cava is in relation *posteriorly* with the bodies of the

lower lumbar vertebræ and the corresponding part of the anterior longitudinal ligament, the anterior portion of the right psoas major muscle, the right lumbar sympathetic trunk, the roots of the right lumbar arteries, the right crus of the diaphragm, the right renal artery, the right suprarenal artery, the right celiac ganglion, the right inferior phrenic artery, and the medial and upper portion of the right suprarenal gland.

Anterior to it, from below upwards, are the following structures—the right common iliac artery, the lower end of the mesentery and the superior mesenteric artery, the right

FIG. 792.—THE INFERIOR VENA CAVA AND ITS TRIBUTARIES.

internal spermatic artery and the third part of the duodenum, the head of the pancreas, the portal vein and the first part of the duodenum, the foramen epiploicum, and the posterior surface of the liver. More superficially are coils of small intestine, the great omentum, and the transverse colon and mesocolon.

To its left side are the aorta and the right crus of the diaphragm.

On its right side, below, is the right ureter, whilst at a higher level the right kidney is separated from the vein by a short interval only.

Tributaries.—In addition to the two common iliac veins, by the union of which it is formed, and through which it receives blood from the pelvis and from the lower extremities, the inferior vena cava receives the following tributaries:—The hepatic veins, the

right inferior phrenic vein, the right suprarenal vein, the right and left renal veins, the right internal spermatic vein, and the right and left lumbar veins.

Venæ Hepaticæ (Fig. 792).—The **hepatic veins** convey blood which has passed through the liver from the portal veins and from the hepatic artery, and they open into that portion of the inferior vena cava which lies immediately below the diaphragm, and behind the right lobe of the liver. They form two groups, an upper group of two or three large trunks, and a lower group of smaller veins.

The upper group occasionally consists of only two veins, a right and a left; more frequently there are three vessels, a right, a left, and a middle vein, and in the latter case the middle vein issues from the caudate lobe (Spigelian).

The veins of the lower group vary in number from six to twenty; they return blood from the right and caudate lobes.

The hepatic veins commence in the interiors of the lobules of the liver as *central veins*; these issue from the upper and posterior aspects of the lobules, and unite together to form *interlobular veins*; and the latter, uniting with one another, as they converge towards the posterior surface of the liver, form the larger hepatic veins.

Venæ Phrenicæ Inferiores.—The **inferior phrenic veins** are formed by tributaries which issue from the substance of the diaphragm. The right inferior phrenic vein terminates in the upper part of the inferior vena cava. The left vein passes posterior to the œsophagus, and usually terminates in the left suprarenal vein.

Venæ Suprarenales.—A single **suprarenal vein** issues from the hilus on the anterior surface of each suprarenal gland; the right vein terminates in the inferior vena cava; the left usually ends in the left renal vein, but sometimes it opens directly into the inferior vena cava.

Venæ Renales.—Each **renal vein** is formed by the union of five or six tributaries which issue from the hilus of the kidney, where they lie anterior to or are intermingled with the corresponding arteries.

The **right renal vein** is about 25 mm. (one inch long); it passes posterior to the second part of the duodenum, and terminates in the right side of the inferior vena cava.

The **left renal vein** is about 75 mm. long. It crosses anterior to the left psoas major, the left crus of the diaphragm, and the aorta immediately below the superior mesenteric artery. It lies behind the pancreas and the ascending part of the duodenum, and, running above the third part of the duodenum, terminates in the left side of the inferior vena cava. The left testicular or ovarian vein, according to the sex, and almost invariably the left suprarenal vein, open into it.

Venæ Lumbales.—There are usually four **lumbar veins** on each side, one with each lumbar artery; the vein with the subcostal artery is not included in this number. By their anterior and posterior branches the lumbar veins drain the lateral and posterior walls of the abdomen. The anterior branches commence in the lateral walls of the abdomen, where they communicate with the superior and inferior epigastric veins. The posterior divisions issue from the muscles of the back, in the lumbar region, and receive tributaries from the spinal plexuses. The main stems pass forwards on the bodies of the vertebræ; on each side they run postero-medial to the psoas major muscle, whilst those of the left side also pass posterior to the aorta. They terminate in the posterior part of the inferior vena cava. Not uncommonly the corresponding veins of opposite sides unite together to form a single trunk which enters the back of the inferior vena cava. All the lumbar veins of each side are united together by a longitudinal anastomosing vessel, the **ascending lumbar vein**.

The Ascending Lumbar Vein.—Each ascending lumbar vein passes upwards, between the psoas major and the roots of the transverse processes of the lumbar vertebræ. It commences in the lateral sacral vein of the same side, anastomoses with the ilio-lumbar vein, connects the lumbar veins together, receives tributaries from the anterior external vertebral plexus and anastomoses with the inferior vena cava and the renal vein. The right ascending lumbar vein terminates in the azygos and the left in the hemiazygos vein.

Venæ Testiculares.—The testicular veins on each side issue from the testis and epididymis and form a plexus, the *pampiniform plexus*. The plexus is one of the constituents of the spermatic cord, and consists of from eight to ten veins, most of which lie anterior to the ductus deferens; it passes upwards in the inguinal canal, and, near the abdominal inguinal ring, terminates in two main trunks which ascend with the corresponding testicular artery for some distance, receiving tributaries from the ureter; ultimately the two veins unite together and a single terminal vein is formed. The terminal testicular vein on the right side opens into the inferior vena cava, that on the left side into the left renal vein. The left testicular vein is longer than the right, the left testis being lower than the right, and the termination in the left renal vein being at a higher level than the termination of the right vein in the inferior vena cava. The testicular veins, on each side, lie anterior to the psoas major muscle and the ureter. They are covered by peritoneum, and they are crossed on the right side by the termination of the ileum and the third part of the duodenum, and on the left side by the iliac colon and the lower part of the pancreas. They are provided with valves, one of which usually lies at the terminations of each vein, but, occasionally, the valve at the orifice of the left testicular vein is absent.

Venæ Ovaricæ.—The ovarian veins, on each side, issue from the hilus in the anterior border of the ovary. They pass between the layers of the broad ligament, where they anastomose freely and form the *pampiniform plexus*, which extends laterally towards the upper margin of the pelvis minor. From the plexus two veins are formed which accompany the corresponding ovarian artery; they pass anterior to the external iliac artery, and then upwards, behind the peritoneum and anterior to the psoas major muscle and ureter. The veins of the right side, like the corresponding testicular veins, also pass behind the termination of the ileum and the third part of the duodenum; whilst the left veins, near the margin of the pelvis minor, pass behind the commencement of the pelvic colon.

The two veins on each side ultimately fuse together to form a single terminal vein which ends, on the right side in the inferior vena cava, and on the left side in the left renal vein.

VENÆ ILIACÆ COMMUNES.

The **common iliac veins** (Figs. 777 and 792), right and left, are formed by the union of the corresponding external iliac and hypogastric veins. Each commences at the superior aperture of the pelvis minor, immediately posterior to the upper part of the hypogastric artery of its own side, and both vessels pass upwards to the right side of the body of the fifth lumbar vertebra, at the upper part of which, posterior and lateral to the right common iliac artery, they unite together to form the inferior vena cava.

The **right common iliac vein** is much shorter than the left; it passes anterior to the obturator nerve and the ilio-lumbar artery, and at first posterior and then somewhat to the lateral side of the corresponding common iliac artery.

The **left common iliac vein** is much longer than the right, and is also placed more obliquely. It passes upwards and to the right, anterior to the body of the fifth lumbar vertebra, and the middle sacral artery. For some distance it runs along the medial side of the left common iliac artery, and then passes posterior to the right common iliac artery. It also passes posterior to the mesentery of the pelvic colon and the superior hæmorrhoidal vessels.

Tributaries.—Each common iliac vein receives the corresponding external iliac, hypogastric and ilio-lumbar veins. The left common iliac vein receives, in addition, the middle sacral vein.

The **ilio-lumbar veins** receive tributaries from the iliac fossa, from the lower parts of the vertebral muscles, and from the vertebral canal. There is a single vein on each side which accompanies the corresponding artery. It passes posterior to the psoas major muscle and terminates in the common iliac vein.

Vena Sacralis Media.—The venæ comites of the middle sacral artery commence by the union of tributaries which issue from the venous plexus in front of the sacrum,

through which they communicate with the lateral sacral veins and receive blood from the interior of the sacral canal. They unite above into a single **middle sacral vein**, which terminates in the left common iliac vein.

Vena Hypogastrica.—The **hypogastric vein** (Fig. 777) is a short trunk formed by the union of tributaries which correspond to all the branches of the hypogastric artery, with the exception of the umbilical and the ilio-lumbar branches.

It commences at the upper border of the greater sciatic notch, and ascends to the aperture of the minor pelvis; there it unites with the external iliac vein to form the common iliac vein. It lies immediately postero-medial to the hypogastric artery, is crossed laterally by the obturator nerve, and is in relation medially, on the left side with the pelvic colon, and on the right side with the lower part of the ileum.

Tributaries.—The tributaries, which are numerous, are conveniently divisible into extra-pelvic and intra-pelvic groups.

The *extra-pelvic tributaries* are all **parietal**, and include the obturator, internal pudendal, inferior, and superior glutæal veins.

Obturator Vein.—This vein is formed by the union of tributaries which issue from the hip-joint and from the muscles of the proximal and medial part of the thigh. It enters the pelvis minor through the obturator canal, runs backwards, along the lateral wall of the pelvis minor, lying medial to the pelvic fascia, immediately below the corresponding artery, and, passing between the hypogastric artery on the lateral side and the ureter on the medial side, it terminates in the hypogastric vein.

Inferior Glutæal Veins (O.T. Sciatic).—The *venæ comites* of the inferior glutæal artery commence in the subcutaneous tissues on the back of the thigh; they ascend with the artery, and pass into the buttock on the deep aspect of the glutæus maximus, where they receive numerous tributaries from the surrounding muscles. Entering the pelvis, through the greater sciatic foramen, they unite into a single vessel, which terminates in the lower and anterior part of the hypogastric vein below the termination of the obturator vein.

Superior Glutæal Veins (O.T. Glutæal).—The *venæ comites* of the superior glutæal artery are formed by tributaries which issue from the muscles of the buttock. They accompany the artery through the greater sciatic foramen, and terminate in the hypogastric vein; they frequently unite together before reaching their termination.

Internal Pudendal Veins.—The *venæ comites* of the internal pudendal artery commence by tributaries which emerge from the *pudendal plexus*, which lies below and posterior to the arcuate ligament of the pubis and constitutes the anterior part of the prostatic plexus. They receive blood from the corpus cavernosum penis, or the corpus cavernosum clitoridis, by the deep vein of the penis or clitoris. They follow the course of the internal pudendal artery, and usually join together into a single vessel (the internal pudendal vein) which terminates in the internal iliac vein. They receive as tributaries the veins from the bulb, the perineal and inferior hæmorrhoidal veins, and veins from the muscles of the buttock.

The **inferior hæmorrhoidal veins**, which commence in the substance of the external sphincter of the anus and in the walls of the anal canal, anastomose with the middle and superior hæmorrhoidal veins, and consequently connect the lowest parts of the portal and vena caval systems together.

The *intra-pelvic tributaries* of the internal iliac vein are either (a) **parietal** or (b) **visceral**; the former comprises the lateral sacral veins, the latter includes the efferent vessels from the plexuses around the several pelvic viscera.

(a) **Parietal: Lateral sacral veins** accompany the corresponding arteries, and terminate on each side in the postero-medial wall of the hypogastric vein.

(b) **Visceral tributaries** are derived from the rectum and from the plexuses associated with the uterus, vagina, bladder, and prostate. They include the middle hæmorrhoidal, the uterine, the vaginal, and the vesical veins.

The **middle hæmorrhoidal veins** are very irregular; sometimes they cannot be distinguished. When present they are formed by tributaries which commence in the submucous tissue of the rectum, where they communicate with the superior and inferior hæmorrhoidal veins in the hæmorrhoidal plexus; they pass through the muscular coat, and fuse together to form two middle hæmorrhoidal veins, right and left, each of which runs laterally, beneath the peritoneum, on the upper surface of the levator ani, to terminate in the hypogastric vein. In the male each middle hæmorrhoidal vein receives tributaries from the seminal vesicle and ductus deferens of its own side.

Uterine Plexuses and Veins.—The **uterine plexuses** lie along the lateral borders of the uterus; they receive tributaries, which are entirely devoid of valves, from the uterus; and they communicate above with the ovarian, and below with the vaginal plexuses.

The **uterine veins**, usually two on each side, issue from the lower parts of the uterine plexuses, above their communications with the vaginal plexuses. At first the uterine vein, on each side, lies in the medial part of the base of the broad ligament, above the lateral fornix of the vagina and the ureter; then it passes backwards, accompanying the corresponding artery, in a fold of peritoneum which lies between the back of the broad ligament and the recto-uterine fold; finally it ascends in the floor of the ovarian fossa, and terminates in the corresponding hypogastric vein.

Vaginal Plexuses and Vaginal Veins.—The **vaginal plexuses** lie at the sides of the vagina. They receive tributaries from the walls of the vagina, and communicate with the uterine plexuses above, and with the veins of the bulb below; anteriorly, with the vesical plexus; and posteriorly with the veins which issue from the middle and lower parts of the hæmorrhoidal plexus. A single **vaginal vein** issues from the upper part of the vaginal plexus on each side; it accompanies the corresponding artery, and terminates in the hypogastric vein.

Superior Vesical Plexus.—The superior vesical plexus of veins lies on the outer surface of the muscular coat of the bladder, at the fundus and the sides. It receives tributaries from the mucous and muscular walls, and its efferent vessels terminate in the prostatico-vesical plexus in the male, and in the inferior vesical plexus in the female.

Prostatico-vesical Plexus.—This plexus is distributed around the prostate and the neck of the bladder, and is enclosed between the proper fibrous capsule of the prostate and its sheath of recto-vesical fascia. Anteriorly it is continuous with the pudendal plexus which receives the dorsal vein of the penis; postero-superiorly it communicates with the superior vesical plexus, and receives tributaries from the seminal vesicles and deferent ducts. One or more efferent vessels pass from it on each side and open into the corresponding hypogastric vein.

The **inferior vesical plexus** of the female, which represents the prostatico-vesical plexus of the male, surrounds the upper part of the urethra and the neck of the bladder. It is continuous with the pudendal plexus which receives the dorsal vein of the clitoris, and its efferent vessels terminate in the hypogastric vein.

Dorsal Veins of the Penis.—There are two dorsal veins of the penis—the superficial and the deep.

The **superficial dorsal vein** receives tributaries from the prepuce, and runs backwards, immediately beneath the skin, to the symphysis, where it divides into two branches which terminate in the superficial external pudendal veins.

The **deep dorsal vein** lies on the dorsum of the penis deep to the deep fascia. It commences in the sulcus behind the glans, by the union of numerous tributaries from the glans and the anterior parts of the corpora cavernosa penis; and it runs backwards in the mid-dorsal line, in the sulcus between the corpora cavernosa penis, from which it receives many additional tributaries. At the root of the penis the vein passes between the two layers of the suspensory ligament, and then between the arcuate ligament and the deep transverse ligament of the perineum, where it lies above the membranous part of the urethra. It terminates by dividing into two branches which join the pudendal plexus.

The **dorsal vein of the clitoris** in the female has a similar course to that of the deep dorsal vein of the penis in the male. It terminates in the pudendal plexus.

THE VEINS OF THE LOWER EXTREMITY.

The veins of the lower extremity, like those of the upper extremity, are arranged in two groups, the **superficial** and the **deep**; and in the lower as in the upper limb the deep veins are associated with the arteries as *venæ comites*, whilst the trunks of the superficial veins, which lie, at first, in the subcutaneous tissues ultimately terminate in the deep veins. There is, therefore, a general similarity in the arrangement of the veins of the upper and the lower limbs, but there are differences in the details of the arrangement which are of some importance. Thus, in the upper extremity, there are two deep veins with each artery from the fingers to the root of the limb, where a single trunk, the axillary vein, is formed; but in the lower extremity each main artery has two *venæ comites* only as far as the middle of the limb, where a single trunk is frequently formed. This vessel, the **popliteal**

vein, is the commencement of the main venous stem of the lower extremity; it is continued proximally, through the thigh, as the **femoral vein**, and along the upper margin of the pelvis minor as the **external iliac vein**, which terminates by uniting with the hypogastric vein to form the common iliac vein.

Further, the superficial veins of the upper limb are more numerous than those of the lower limb, for in the arm there are two main superficial veins, and in the thigh only one.

In the upper limb the blood which passes through the superficial veins is poured into the efferent trunk vein at the root of the limb—that is, into the axillary vein; but in the lower limb the blood from the superficies of the lateral parts of the leg and foot passes into the commencement of the main efferent vein, the popliteal vein, at the middle of the limb—that is, in the region of the knee, whilst the blood from the superficial parts of the medial aspect of the lower limb is poured into the femoral vein near the root of the limb in the upper part of the femoral trigone.

In addition to the above-mentioned differences in the general arrangement of the veins of the upper and the lower extremities, it must be noted also that in the upper extremity all the blood of the limb, both that from the shoulder-girdle region as well as that from the free portion of the limb, is returned to the main efferent venous trunk; but in the lower extremity the greater part of the blood from the region of the pelvic girdle, and a considerable portion from that of the thigh, is returned by the gluteal, obturator, and pudendal veins to the hypogastric vein, which is not the main efferent vein of the lower extremity.

THE DEEP VEINS OF THE LOWER EXTREMITY.

All the arteries of the lower limb, except the popliteal and femoral trunks, are accompanied by two *venæ comites*. They usually lie one on each side of the artery; they are connected with each other by transverse channels which pass across the line of the artery, and they are provided with numerous valves.

Vena Poplitea.—The **popliteal vein** (Fig. 780) is formed, at the distal border of the popliteus muscle, by the union of the *venæ comites* of the anterior and posterior tibial arteries. At its commencement it lies to the medial side of and somewhat superficial to the popliteal artery, and to the lateral side of the tibial (O.T. internal popliteal) nerve. As it runs through the popliteal fossa it gradually inclines towards the lateral side of the artery, and in the middle of the space it is directly posterior to the artery, separating the artery from the tibial nerve, which is still more posterior, whilst at the proximal end of the space it is to the lateral side of the artery, and still between it and the tibial nerve. It then passes through the adductor magnus muscle and becomes the femoral vein.

The popliteal vein, which is provided with two or three bicuspid valves, is closely bound to the artery by a dense fascial sheath. Not uncommonly there are one or more additional satellite veins which anastomose with the popliteal vein, and in these cases the artery is more or less completely surrounded by venous trunks.

Tributaries.—In addition to the *venæ comites* of the anterior and posterior tibial arteries, it receives tributaries which correspond with the branches of the popliteal artery, and it also receives one of the superficial veins of the leg, viz., the small saphenous vein.

Vena Femoralis.—The **femoral vein** is the direct continuation of the popliteal vein. It commences at the junction of the middle and distal thirds of the thigh, at the opening in the adductor magnus muscle. It then ascends, through adductor canal (Hunter's), and through the femoral trigone, and terminates, a little to the medial side of the middle of the inguinal ligament (Poupart's), by becoming the external iliac vein.

In the adductor canal it lies at first postero-lateral to the femoral artery, and anterior to the adductors magnus and longus which separate it from the profunda vessels. In the distal part of femoral trigone it is postero-medial to the artery, and immediately anterior to the profunda vein which separates it from the profunda artery, but in the proximal part of the femoral trigone it is directly on

the medial side of the femoral artery. About 37 mm. (one and a half inches) below the inguinal ligament it enters the middle compartment of the femoral sheath, through which it ascends to its termination, lying between the compartment for the femoral artery on the lateral side and the femoral canal on the medial side.

It usually contains two bicuspid valves—one near its termination and the other just proximal to the entrance of its profunda tributary.

Tributaries.—It receives tributaries which correspond with the branches of the femoral artery and the larger of the two superficial veins of the lower extremity, viz., the

FIG. 793.—THE FEMORAL VESSELS IN THE FEMORAL TRIGONE.

great saphenous vein, which enters the femoral vein where that vessel lies in the middle compartment of the femoral sheath, and, not uncommonly, the medial and lateral circumflex veins.

Vena Iliaca Externa.—The external iliac vein (Figs. 773, 774, and 777) is the upward continuation of the femoral vein. It commences, on the medial side of the termination of the external iliac artery, immediately posterior to the inguinal ligament, and ascends along the aperture of the pelvis minor, to a point opposite the sacro-iliac joint, and at the level of the lumbo-sacral articulation, where it ends, immediately behind the hypogastric artery, by joining the hypogastric vein to form the common iliac vein. It lies, at first, on the medial side of the external iliac artery, but on a somewhat posterior plane, and then directly posterior to the

artery, whilst just before its termination it crosses the lateral side of the hypogastric artery, and separates that vessel from the medial border of the psoas major muscle. In its whole course the vein lies anterior to the obturator nerve.

It is usually provided with one bicuspid valve; sometimes there are two, but both are usually incompetent. Its tributaries correspond to the branches of the external iliac artery; that is, the deep circumflex iliac and inferior epigastric veins open into it, close to its commencement, whilst, in addition, it frequently receives the pubic vein.

The **pubic vein** forms a communication between the obturator vein and the external iliac vein. It varies in size, and may form the main termination of the obturator vein, from which it arises. Commencing in the obturator canal, it ascends, along the pubic branch of the inferior epigastric artery, to reach the external iliac vein.

FIG. 794.—THE GREAT SAPHENOUS VEIN AND ITS TRIBUTARIES.

dorsal digital vein from the medial side of the great toe ends in the great saphenous vein, and that from the lateral side of the little toe terminates in the small saphenous vein.

Arcus Venosus Dorsalis Pedis.—The **dorsal venous arch** lies in the subcutaneous tissue, between the skin and the dorsal digital branches of the superficial peronæal

THE SUPERFICIAL VEINS OF THE INFERIOR EXTREMITY.

The superficial veins of the lower limb terminate in two trunks, one of which, the **small saphenous vein**, passes from the foot to the popliteal space; whilst the other, the **great saphenous vein**, extends from the foot to the groin.

The superficial veins of the sole of the foot form a fine plexus, immediately under cover of the skin, from which anterior, medial, and lateral efferents pass. The anterior efferents terminate in a transverse arch which lies in the furrow at the roots of the toes, and the medial and lateral efferents pass round the sides of the foot to the great or small saphenous veins. The transverse arch receives also small plantar digital veins from the toes, and it communicates by **intercapitular veins** with the veins on the dorsum of the foot.

The superficial veins on the dorsal aspect of each toe unite to form two **dorsal proper digital veins**, which run along the borders of the dorsal surface. The proper dorsal digital veins of the adjacent borders of the interdigital clefts unite, at the apices of the clefts, to form four dorsal metatarsal veins which terminate in the dorsal venous arch. The

nerve, opposite the distal parts of the shafts of the metatarsal bones. It ends medially by uniting with the medial dorsal digital vein of the great toe to form the great saphenous vein, and laterally by joining the lateral dorsal digital vein of the little toe to form the small saphenous vein. The dorsal venous arch receives the dorsal metatarsal veins; interdigital efferents from the plantar transverse arch; and numerous tributaries from the dorsum of the foot, which anastomose freely together forming a wide-meshed dorsal venous plexus, open into it posteriorly.

Vena Saphena Magna.—The **great saphenous vein** is formed by the union of the medial extremity of the dorsal venous arch with the medial dorsal digital vein of the great toe. It passes anterior to the medial malleolus, crosses the medial surface of the distal third of the shaft of the tibia, and ascends, immediately posterior to the medial margin of the tibia, to the knee, where it lies just posterior to the medial condyle of the femur; continuing proximally, with an inclination forwards and laterally, it gains the proximal part of the femoral trigone, where it perforates the fascia cribrosa and the femoral sheath to reach its termination in the femoral vein. In the foot and leg it is accompanied by the saphenous nerve, and for a short distance distal to the knee by the superficial or saphenous branch of the *arteria genu suprema*. In the thigh, branches of the medial cutaneous nerve (O.T. internal) lie in close relation with it. It contains from eight to twenty bicuspid valves.

Tributaries.—It communicates freely, through the deep fascia, with the deep intermuscular veins. In the foot, it receives tributaries from the medial part of the sole and from the dorsal venous plexus. As it ascends in the leg it is joined by tributaries from the dorsum of the foot, the medial and posterior parts of the heel, the front of the leg and the back of the calf, and it anastomoses freely with the small saphenous vein. In the thigh it receives numerous tributaries, some of which usually converge to form two **superficial femoral veins**. Of these, one, the *lateral*, ascends from the lateral side of the knee and terminates in the great saphenous vein about the distal part of the femoral trigone; the other, the *medial*, ascends from the posterior aspect of the thigh along its medial side to terminate in the great saphenous vein near the fossa ovalis (O.T. saphenous opening). In many cases the medial superficial femoral vein communicates distally with the short saphenous vein, and when this condition exists the medial superficial femoral vein is called the *accessory saphenous vein*. The last tributaries to enter the great saphenous vein are the **superficial circumflex iliac**, **superficial epigastric**, and **superficial external pudendal veins**. They accompany the corresponding arteries, and terminate in the great saphenous vein immediately before it perforates the fascia cribrosa.

The superficial circumflex iliac vein receives blood from the lower and lateral part of the abdominal wall and the proximal and lateral parts of the thigh. The superficial epigastric vein drains the lower and medial part of the abdominal wall, and the superficial external pudendal vein receives blood from the dorsum of the penis and the scrotum in the male, and from the labium majus in the female.

FIG. 795.—THE SMALL SAPHENOUS VEIN AND ITS TRIBUTARIES.

Vena Saphena Parva.—The small sphenous vein is formed by the union of the lateral extremity of the dorsal venous arch with the lateral dorsal digital vein of the little toe. At first it passes posteriorly, along the lateral side of the foot and distal to the lateral malleolus, lying on the peronæal retinacula (O.T. ext. ann. lig.), in company with the nervus suralis; then it passes posterior to the lateral malleolus, and along the lateral border of the tendo calcaneus, still in company with the nervus suralis, to the middle of the calf, proximal to which it is continued in the superficial fascia, accompanied by the superficial sural artery, to the distal part of the popliteal fossa, where it pierces the deep fascia, and terminates in the popliteal vein. It communicates, round the medial side of the leg, with the great saphenous vein, and through the deep fascia with the deep veins, and it contains from six to twelve bicuspid valves.

Tributaries.—It receives tributaries from the lateral side of the foot, from the lateral side and back of the heel, from the back of the leg, and occasionally a descending tributary from the back of the thigh. Just before it pierces the popliteal fascia it frequently gives off a small branch which ascends round the medial side of the thigh and unites with the medial superficial femoral vein to form the accessory saphenous vein. In this way a communication is established between the great and small saphenous veins, which may become enlarged, and not uncommonly it constitutes the main continuation of the small saphenous vein.

THE PORTAL SYSTEM.

The **portal system** includes the veins which convey blood from almost the whole of the abdominal and pelvic parts of the alimentary canal, and from the spleen and pancreas, to the liver. The tributaries of origin of these veins agree closely with the terminal branches of the corresponding arteries. They are single vessels, which for some distance accompany the corresponding arteries, and are similarly named. The larger or terminal veins, however, leave their associated arteries; the **inferior mesenteric vein** joins the **splenic vein**, and the latter unites with the **superior mesenteric vein** to form the **portal vein**, which passes to the liver. These veins, together with their tributaries, constitute the portal system. All the larger vessels of this system are devoid of valves, but valves are present in the tributaries.

Vena Portæ.—The **portal vein** is a wide venous channel, about 75 mm. (three inches) long, which conveys blood from the stomach, from the whole of the intestine, except the terminal portion of the rectum, and from the spleen and pancreas to the liver. Unlike other veins, it ends like an artery, by breaking up into branches which ultimately terminate in capillaries in the substance of the liver; from these capillaries, which also receive the blood conveyed to the liver by the hepatic artery, the hepatic veins arise; and since these open into the inferior vena cava, the portal blood ultimately reaches the general systemic circulation.

The portal vein commences by the union of the superior mesenteric and the splenic veins, posterior and to the left of the neck of the pancreas, and either anterior to the left border of the inferior vena cava, at the level of the body of the first lumbar vertebra, or in front of the upturned extremity of the processus uncinatus of the head of the pancreas. It ascends, anterior to the inferior vena cava and posterior to the neck of the pancreas and the first part of the duodenum, to the lower border of the epiploic foramen (Winslow), where it passes forwards, in the right gastro-pancreatic fold of peritoneum, and enters the lower border of the gastro-hepatic ligament. Continuing its upward course, it lies posterior to the bile-duct and hepatic artery, and anterior to the epiploic foramen (Winslow); it ultimately reaches the right end of the porta hepatis, where it ends by dividing into a short and wide right and a longer and narrower left branch. Just before its termination it enlarges, forming the *sinus of the portal vein*.

The **right branch** generally receives the **cystic vein** and then enters the right lobe of the liver, in which it breaks up into numerous branches which terminate in the portal capillaries around the periphery and in the substance of the liver lobules.

The **left branch** runs from right to left along the porta hepatis, giving off

branches to the caudate and quadrate lobes; it crosses the umbilical fossa, and ends in the same manner as the right branch, but in the substance of the left lobe of the liver.

As it crosses the umbilical fossa, the left branch of the portal vein is joined anteriorly by the **round ligament** of the liver, a fibrous cord which is the remains of the left lateral umbilical vein of the foetus. One or more small veins which accompany the ligamentum teres connect the left branch of the portal vein with the superficial veins round the umbilicus. Somewhat to the right of the attachment of the round ligament anteriorly, a fibrous cord springs from it

FIG. 796.—THE PORTAL VEIN AND ITS TRIBUTARIES.

posteriorly and connects it with the upper part of the inferior vena cava; this cord is the **ligamentum venosum**. It is the remains of the **ductus venosus**, a blood-vessel of the foetus, through which blood, carried from the placenta by the umbilical vein, passed into the inferior vena cava without going through the liver.

The portal vein is accompanied by numerous lymph vessels, and it is surrounded, in the lesser omentum, by filaments of the hepatic plexus of nerves.

Tributaries.—Soon after its formation the portal vein receives the coronary and right gastric veins, and the cystic vein opens into its right branch.

Vena Coronaria Ventriculi.—The **coronary vein** commences in the lesser omentum by the union of tributaries from both surfaces of the stomach. It runs to the left

between the layers of the lesser omentum, and along the lesser curvature of the stomach, with the left gastric artery, to the œsophagus, where it receives œsophageal tributaries. It then turns posteriorly, in the left gastro-pancreatic fold, and reaches the posterior wall of the abdomen, where it again changes its direction to run from left to right, behind the omental bursa, to the right gastro-pancreatic fold, at the root of which it opens into the portal vein.

The **right gastric vein** is a small vessel which is formed by the union of tributaries from the upper parts of both surfaces of the stomach. It runs from left to right along the right portion of the lesser curvature, between the layers of the lesser omentum, and terminates in the portal vein, after that vessel has entered the lesser omentum.

Vena Cystica.—The **cystic vein** is formed by the union of tributaries which accompany the branches of the cystic artery on the anterior and posterior surfaces of the gall-bladder; it ascends along the cystic duct and, as a rule, terminates in the right branch of the portal vein. Some small veins pass directly from the gall-bladder into the substance of the liver.

THE MESENTERIC AND SPLENIC VEINS.

Vena Mesenterica Superior.—The **superior mesenteric vein** commences in the right iliac fossa in connexion with the lower part of the ileum. It ascends along the right side of the superior mesenteric artery, in the root of the mesentery, forming a curve with the convexity to the left.

As it ascends it passes anterior to the right ureter, the lower part of the inferior vena cava, the third part of the duodenum, and the uncinate process of the head of the pancreas; and, after passing behind the root of the transverse mesocolon, it terminates, behind the neck of the pancreas, by uniting with the splenic vein to form the portal vein.

Its **tributaries** correspond with the branches of the superior mesenteric artery. It is formed by the union of the ileo-cæcal and appendicular veins. Anteriorly and towards the left side it receives intestinal tributaries (*venæ intestinales*) from between the layers of the mesentery; the right colic and ileo-colic veins enter its right side; the middle colic vein joins it anterior to the lower border of the head of the pancreas, and close to its termination it receives the right gastro-epiploic and the pancreatico-duodenal veins.

The **right gastro-epiploic vein** runs from left to right along the lower border of the stomach, and between the two anterior layers of the greater omentum. It receives tributaries from both surfaces of the stomach, and near the pylorus turns posteriorly in the right gastro-pancreatic fold of peritoneum, passes in front of the neck of the pancreas, and ends in the superior mesenteric vein.

The **pancreatico-duodenal vein** receives tributaries from the head of the pancreas and the adjacent parts of the duodenum; it ascends along the superior pancreatico-duodenal artery, and terminates in the upper part of the superior mesenteric vein.

Vena Lienalis.—The **splenic vein** is formed by the union of five or six tributaries which issue from the hilus on the gastric surface of the spleen. It passes posteriorly and medially, in the lieno-renal ligament, to the kidney, then, turning to the right, it runs behind the upper border of the pancreas and below the splenic artery; it crosses the front of the abdominal aorta, immediately below the origin of the celiac artery, and terminates, behind the neck of the pancreas, by joining the superior mesenteric vein to form the portal vein.

Tributaries.—It receives the *vasa brevia* or short gastric veins, the left gastro-epiploic vein, the pancreatic veins, and the inferior mesenteric vein. Occasionally the coronary vein terminates in it.

The **short gastric veins** are a series of small venous channels which gather blood from the region of the left portion of the greater curvature of the stomach; they pass backwards towards the spleen, in the gastro-splenic ligament, and terminate either in the trunk of the splenic vein or in one of its main tributaries.

The **left gastro-epiploic vein** runs from right to left along the lower border of the stomach between the layers of the greater omentum. At the left extremity of the lower part of the greater curvature of the stomach it enters the gastro-splenic ligament, through which it passes towards the hilus of the spleen, and it terminates in the commencement of the splenic vein. It receives tributaries from both surfaces of the stomach.

The **pancreatic veins** issue from the substance of the pancreas, and terminate directly in the splenic vein.

The **inferior mesenteric vein** commences, as the **superior hæmorrhoidal vein**, in the venous plexus which lies between the muscular and mucous coats of the rectum. The **superior hæmorrhoidal vein** drains the greater part of the blood from the hæmorrhoidal plexus, through which it communicates with the middle and inferior hæmorrhoidal veins. It ascends, in company with the superior hæmorrhoidal artery and between the layers of the pelvic mesocolon,

to the aperture of the pelvis minor, where it passes in front of the left common iliac artery and becomes the inferior mesenteric vein.

The inferior mesenteric vein runs upwards, on the left of the aorta, behind the peritoneum and in front of the left psoas major muscle and the left internal spermatic artery. Near its termination it crosses in front of the left renal vein, and, passing behind the body of the pancreas, ends in the splenic vein. Occasionally it terminates in the angle of union of the superior mesenteric and splenic veins.

Tributaries.—In addition to the superior hæmorrhoidal vein, of which it is the direct continuation, the inferior mesenteric vein receives sigmoid tributaries from the iliac and pelvic colon, and the left colic vein from the descending colon and left colic flexure.

THE LYMPH VASCULAR SYSTEM.

The vessels of the lymph vascular system, *vasa lymphatica*, contain a colourless fluid, rich in white corpuscles, which is called **lymph**.

In many respects the lymph vessels resemble blood-vessels, especially veins, and, like the veins, many of the lymph vessels, but not all, contain numerous valves, which control the direction of the circulation. Unlike the veins, however, the lymph vessels communicate directly with the great serous cavities of the body, by openings called *stomata*; and also unlike the veins, the continuity of the lymph vessels is interrupted by interposed nodular aggregations of lymphoid tissue which are known as **lymph glands**.

The corpusculated fluid called lymph, which fills the interiors of the lymph vessels, is partly collected from the serous cavities, through the stomata already mentioned, and, in part, it passes into the vessels from the surrounding tissues. It is carried by the lymph vessels to the veins; for the smaller lymph vessels gradually unite together to form larger and larger channels until, ultimately, all the lymph passes into two main trunks—the **thoracic duct**, which terminates in the commencement of the left innominate vein, and the **right lymphatic duct**, which ends in the beginning of the right innominate vein.

Obviously, therefore, all the lymph vessels are afferent inasmuch as they carry the lymph towards the great central vessels, but it is customary to speak of some of the lymph vessels as *vasa afferentia* and others as *vasa efferentia*, the former being vessels which carry lymph to lymph glands, and the latter, those which convey the lymph from more peripheral towards more central glands.

The lymph vessels merely collect and convey lymph; the lymph glands probably serve in part as filters and in part as the sources of origin of some of the lymph corpuscles, which are called **lymphocytes** and become white blood corpuscles when they enter the blood stream.

In its course from the tissues to the blood-vessels the greater part, if not the whole, of the lymph passes through one and generally through more than one lymph gland.

All parts of the body which possess blood-vessels, except the central nervous

FIG. 797.—DIAGRAM OF MAIN LYMPH VESSELS.

system, the eye and the internal ear, are plentifully provided with lymph channels, which are divided, according to their positions, into superficial and deep vessels.

The *superficial lymph vessels* lie in the skin and subcutaneous tissues; they frequently accompany the superficial veins and, in the limbs, they join the deep vessels in definitely localised situations.

The *deep lymph vessels* drain the lymph from all parts of the body which lie internal to the deep fascia; they tend to accompany the blood-vessels of the various parts and organs.

The lymph glands also are divided into superficial and deep groups. The former lie in the superficial fascia and are comparatively few in number. They are associated more particularly with the superficial lymph vessels of the limbs. The deep lymph glands of the limbs are also comparatively few in number, but those of the head, neck, and trunk are very numerous.

Vasa Lymphatica.—The smaller lymphatics are channels of various shapes but of greater calibre than the blood capillaries. They anastomose freely together, forming lymphatic plexuses.

Their walls are formed by a single layer of endothelial cells of irregular shape and sinuous outline, which are in close contact, externally, with the tissue elements amidst which they lie. In some cases lymph vessels, or plexuses of lymph vessels, surround the blood-vessels forming *perivascular lymph channels*. It has been generally believed that such perivascular channels are numerous in the central nervous system, but the researches of Bruce tend to show that, whilst the lymphocytes travel along the walls of the blood-vessels of the central nervous system, they pass along cleft-like spaces in the adventitial sheaths, and not in distinct perivascular channels.

As the lymph vessels attain a larger size their walls are strengthened by the deposition of a layer of elastic fibres on the outer surface of the endothelial coat. The fibres run longitudinally, and in some cases fuse together to form a fenestrated elastic membrane.

The walls of all the largest lymph vessels, like those of the blood-vessels, are formed by three tunics, external, middle, and internal. The *tunica intima* consists of a layer of endothelium covered externally by elastic fibres or fenestrated elastic membrane. The *tunica media* is formed of transverse and oblique unstriated muscle fibres intermingled with elastic fibres. The *tunica externa* consists of longitudinal connective tissue elements with which are intermingled oblique and longitudinal unstriated muscle fibres; the latter feature being peculiarly characteristic, for it is not met with in the blood vascular system, except in the walls of the large veins.

Bicuspid valves formed by semilunar folds of the *tunica intima* are extremely numerous in the lymph vascular system. They are either absent or they are few and incompletely developed in the small vessels and the lymph plexuses, but they are very prevalent in the larger vessels; consequently when the latter are injected they assume a modulated outline. Valves are present also at the entrances of the great lymph channels into the venous system.

Lymphoglandulæ.—**Lymph glands** are globular, ovoid, flattened, or irregular bodies, and each gland presents a localised depressed area which is known as the *hilus*. They vary considerably in size, some being no larger than a pin's-head, whilst others are as large as a bean. In colour they are usually grayish pink, but the tint varies with the position, vascularity, and state of activity of the gland. The glands of the lung are generally blackened by the deposition of carbonaceous material in their substance, and those of the liver and spleen frequently have a brownish hue. The glands of the mesentery are creamy or white whilst the chyle is rapidly passing through them, but when the absorption of food-material from the intestine ceases they become a rosy pink.

The lymph glands are embedded in the connective tissues, some lying superficially in the subcutaneous tissues, but the majority more deeply and usually at the sides of the great blood-vessels. As a rule, they are arranged in groups of from two to fifteen, but a few of those which lie in the subcutaneous tissues are solitary.

They form centres to which afferent lymphatic vessels converge, and from which efferent vessels pass onwards to other glands or to the larger lymph channels.

The student should therefore acquaint himself with the various groups of glands, with their afferents and efferents, and with the exact position and relations of the large lymphatic trunks; he will then be in a position to understand the course which minute organisms or particles, which have gained access to the lymph spaces, may take as they are carried in the lymph stream; and he will realise that such structures may either be entangled in the glands through which the lymph passes, or, having escaped all obstructions, that they will finally enter the veins at the root of the neck. At the same time, if he bears in mind the existence of the numerous anastomoses between the lymph vessels, he will have no difficulty in appreciating that variations from any regular course may not infrequently occur, and his clinical experience at a later period will show that such variations are by no means uncommon.

Structure of Lymph Glands.—Lymph glands consist of (1) a skeleton or framework, (2) lymph sinuses, and (3) lymph follicles and cords; and each gland is separable into cortex and medulla. The cortex lies immediately internal to the capsule, except at the hilus, where it is absent. The medulla forms the internal part of the gland, and reaches the surface at the hilus.

(1) The **skeleton** or framework consists of a **capsule** and of primary, secondary, and tertiary **trabeculae**.

The **capsule** is formed of white fibrous tissue, interspersed with elastic fibres, and in some cases with unstripped muscular fibres.

The **primary trabeculae** spring from the deep surface of the capsule and radiate through the cortex into the medulla. In the cortex they are flattened lamellæ, but as they reach the medulla they break up into flattened, rounded, and angular bands which unite freely together; their structure is the same as that of the capsule, and from their surfaces the secondary trabeculae are given off. The **secondary trabeculae** spring from the surfaces of the primary trabeculae, cross the lymph sinuses and enter the follicles of the cortex and the cords of the medulla, where they terminate by dividing into tertiary trabeculae. As they cross the lymph sinuses they unite together freely, forming a fine mesh-work through which the lymph passes in its course from the afferent to the efferent vessels. The secondary trabeculae consist of fine strands of fibrous tissue devoid of nuclei, and their surfaces are covered with endothelial cells. The **tertiary trabeculae** are finer and more delicate than the secondary trabeculae, from the terminations of which they spring, but they have a similar structure. They unite together, forming a fine network in the lymph cords and follicles, and the spaces of the network are filled with lymph corpuscles.

(2) The **lymph sinuses** lie internal to the capsule and around the primary trabeculae which form their boundaries on one side, whilst on the other they are limited by the lymph cords and follicles. They are traversed by the secondary trabeculae, and their channels are thus converted into a kind of sponge-work through which the lymph stream flows. In the cortical parts of the glands they form more or less cylindrical channels, but in the medulla they become moniliform. Afferent vessels enter the sinuses of the cortex, and the efferent vessels emerge from the medulla at the hilus.

The **lymph follicles** lie in the cortical portions of the lymph glands, where they form the inner boundaries of the lymph sinuses. They consist of dense masses of lymphoid cells, embedded in a stroma formed by the tertiary trabeculae, and they are continuous internally with the lymph cords of the medullary substance.

The **lymph cords** are continuous with the lymph follicles, and have the same structure, but they lie in the medullary portions of the glands; they are cord-like and not nodular in shape, and they form the peripheral boundaries of the lymph sinuses of the medulla.

The Blood-Vessels of the Lymph Glands.—Blood-vessels are distributed to the capsule and through the capsule to the primary trabeculae of the glands; but the main blood-vessels to each gland enter the hilus and ramify in the lymph cords and follicles, amidst the tertiary trabeculae which are connected with the walls of the vessels.

Hæmal Lymph Glands.—In various parts of the body, but more particularly in the retro-peritoneal region, and especially along the line of the abdominal aorta, a number of bodies may be found which have all the ordinary structural characters of lymph glands, but they differ from lymph glands inasmuch as some of their sinuses contain blood. These structures are called hæmal lymph glands. The sinuses of the hæmal lymph glands which contain lymph are in continuity with lymphatics, whilst the blood-filled sinuses open into blood-vessels. It is stated that communications exist between the blood and the lymph containing sinuses of the hæmal lymph glands, but the evidence on this point is not quite satisfactory.

Hæmal Glands.—The term “hæmal gland” is applied to nodules possessing the structure of ordinary lymph glands, but which contain only blood in their sinuses; they probably belong, however, as their development shows, to the lymph vascular and not to the blood vascular system (see p. 1042).

THE TERMINAL LYMPH VESSELS.

The terminal lymph vessels are the **thoracic duct** and the **right lymphatic duct**.

Ductus Thoracicus.—The thoracic duct is by far the larger and the longer of the two terminal lymph vessels. It commences in the epigastric region of

FIG. 798.—THE THORACIC DUCT AND ITS TRIBUTARIES.

the abdomen as an elongated ovoid dilation—the **cisterna chyli**—which measures 6 to 8 mm. ($\frac{1}{4}$ to $\frac{1}{2}$ in.) in its broadest diameter, and from 50 to 75 mm. (2 to 3 in.) in length. The cisterna chyli lies between the aorta and the lower part of the vena azygos, posterior to the right crus of the diaphragm, and opposite the first and second lumbar vertebrae. Passing upwards from the cisterna, the thoracic duct traverses the aortic opening of the diaphragm and enters the posterior

mediastinum, through which it ascends, lying anterior to the vertebral column and to the right of the median plane, to the level of the fifth thoracic vertebra; it then crosses somewhat abruptly from the right to the left of the median plane, and ascends through the superior mediastinum to the root of the neck, where it turns laterally, between the vertebral and common carotid arteries, and it terminates, at the medial border of the scalenus anterior, by joining the left innominate vein at its commencement.

Length and Diameter.—The total length of the duct averages about 45 cm. (18 inches). It is dilated at both its origin and termination. As a rule it is narrowest opposite the fifth thoracic vertebra, but its calibre is very variable, and sometimes the thoracic portion is broken up into a series of anastomosing channels. The widest portion of the tube is usually the cisterna, but occasionally this dilatation is entirely absent. The duct is provided with several valves, formed by semilunar folds of the tunica intima, arranged in pairs, and the most perfect of these is situated at or near the orifice of communication with the left innominate vein.

Relations.—*In the abdomen* the cisterna chyli lies anterior to the upper two lumbar vertebræ and the corresponding lumbar arteries, between the aorta on the left and the vena azygos and the right crus of the diaphragm on the right. *In the posterior mediastinum* the thoracic duct is separated from the vertebral column and the anterior longitudinal ligament by the right aortic intercostal arteries and the transverse parts of the hemiazygos and accessory hemiazygos veins; it is covered, in front, in the lower part of its extent by the right pleural sac, and in the upper part by the œsophagus; to its right is the vena azygos, and to its left the descending aorta. *In the superior mediastinum* it passes forwards from the vertebral column, and it is separated from the left longus colli muscle by a mass of fatty tissue; the œsophagus lies in front of it in this region, but the left margin of the duct projects beyond the œsophagus, and is in relation anteriorly, and from below upwards, with the termination of the arch of the aorta, the left subclavian artery and the pleura. As the duct enters the root of the neck it passes behind the left common carotid artery, whilst to its right and somewhat anteriorly is the œsophagus, and the left pleura is still in association with its left border.

At the root of the neck it arches laterally above the apex of the pleura sac and the first part of the left subclavian artery. It passes anterior to the vertebral artery and vein, the roots of the inferior thyroid, transverse cervical, and transverse scapular arteries, the medial border of the scalenus anterior and the left phrenic nerve, and posterior to the left carotid sheath and its contents.

Tributaries.—The cisterna chyli commonly receives five tributaries. (1) **Truncus Intestinalis.**—The **intestinal trunk**, which is formed by the efferents of mesenteric and upper pre-aortic glands, and conveys lymph from the lower and anterior part of the liver, the stomach, the small intestine, the spleen, and the pancreas. (2) Two **trunci lumbales**, one on each side; they are formed by the efferents of the lumbar glands. They carry lymph from the lower extremities, from the deep portions of the abdominal and pelvic walls, the large intestine and the pelvic viscera, and from the kidneys, suprarenal glands, and genital glands. (3) Two **descending lymphatic trunks**, one on each side, each of which is formed by the efferent vessels from the corresponding lower intercostal glands; these descend to the cisterna through the aortic opening of the diaphragm. Occasionally they unite to form a single trunk, and in others they, or the tributaries from which they are usually formed, open directly into the thoracic duct (Figs. 797, 798).

In its course through the posterior mediastinum the thoracic duct receives efferents from the upper and posterior part of the liver, and from the posterior mediastinal and œsophageal glands; the latter carry lymph from the œsophagus, the pericardium, and the left side of the thoracic wall.

In the superior mediastinum the vessels which open into it are derived from the upper left intercostal glands; it receives lymph also from the heart and lungs by efferents from the left peritracheo-bronchial glands and the intertracheo-bronchial glands, though as a rule the efferents of these glands unite with the internal mammary lymphatic to form a common trunk which may open either into the thoracic duct or into the innominate vein. In the superior mediastinum, therefore, it may receive lymph from the upper and median part of the abdominal wall,

the liver, the diaphragm, the wall of the thorax, and the mammary gland of the left side, the thymus, the pericardium, the left lung, and the left part of the heart.

At the root of the neck, just before its termination, it receives the efferents from the glands of the left upper extremity, which frequently unite to form a subclavian trunk, and the left jugular trunk, which conveys the lymph from the left side of the head and neck; but either of these vessels or both of them may end separately in the innominate vein.

Ductus Lymphaticus Dexter.—The right lymphatic duct (Fig. 798) is not always present. It is a short trunk, from 12 to 17 mm. (half to three-quarters of an inch) in length, which lies at the right side of the root of the neck along the medial border of the scalenus anterior, and it is formed by the confluence of (1) the right jugular trunk, (2) the right subclavian trunk, and (3) the right broncho-mediastinal trunk, which carries lymph from the bronchial, posterior, and anterior mediastinal and sternal glands. It thus receives lymph from the right side of the head and neck, the right upper limb and the right side of the trunk, including the upper part of the thoracic wall, the right lung and pleura, the right half of the heart and pericardium, the right side of the diaphragm, and the upper surface of the liver. As a rule, the right lymphatic duct is not present as a definite stem, and the right jugular trunk carrying the lymph from the head and neck, the right subclavian trunk bearing lymph from the right upper extremity, and the right broncho-mediastinal trunk, end separately in the upper part of the right innominate vein, but any two of the three main trunks of the right side may unite together. The right broncho-mediastinal trunk may also communicate below with the thoracic duct.

LYMPH GLANDS OF HEAD AND NECK.

THE LYMPH GLANDS OF THE HEAD.

All the lymph glands of the head are extracranial.

Lymphoglandulæ Occipitales.—The occipital lymph glands, two or three in number, lie in or deep to the deep fascia upon the upper part of the trapezius muscle, or, if the trapezius is small, upon the upper part of the semispinalis capitis or on the splenius muscle. They receive *afferent* vessels from the occipital region of the scalp and from the superficial parts of the upper and back portion of the neck. Their *efferents* terminate in the deep cervical glands. Some of the lymph vessels of the occipital region pass directly to the deep cervical glands (Fig. 799).

Lymphoglandulæ Auriculares Posteriores.—The posterior auricular lymph glands (O.T. mastoid) lie on the upper part of the sterno-mastoid muscle and on the mastoid portion of the temporal bone, and they are bound down by a sheathing of deep cervical fascia. They receive *afferent* vessels from the posterior part of the parietal region of the scalp, and from the medial surface of the auricle. Their *efferents* join the superficial and the deep cervical glands (Fig. 799).

Lymphoglandulæ Faciales Profundæ.—The deep facial lymph glands are very variable both in number and size; they lie in association with the internal maxillary artery on the external pterygoid muscle, or on the adjacent part of the wall of the pharynx. Their *afferent* vessels are derived from the orbit, the temporal fossa, the infra-temporal fossa, the palate, the nose, and the cerebral meninges. Their *efferent* vessels open into the upper deep cervical glands.

Lymphoglandulæ Auriculares Anteriores.—The anterior auricular lymph glands (O.T. parotid) lie both superficial and deep to the parotid fascia on the lateral surface of the parotid gland. They receive *afferents* from the frontal and the temporal regions of the scalp, from the eyebrow, the upper and lower eyelids, the upper part of the cheek, the root of the nose, and the lateral surface of the auricle. Their *efferents* pass to the superficial and the upper deep cervical glands, and to the parotid lymph glands (Fig. 799).

Lymphoglandulæ Parotideæ.—The parotid lymph glands (O.T. deep parotid glands) lie embedded in the deeper parts of the parotid gland. They receive *afferents*

from the external acoustic meatus, the tympanum, the soft palate, the posterior part of the nose, and the deeper portions of the cheek. Their *effere*nts open into the upper deep cervical glands.

The Superficial Facial Lymph Glands.—Several lymph glands, or groups of lymph glands, have been found in the region of the face but, apparently, they are irregular, both in occurrence and in position. Those which appear to be most frequently found are: **Infra-orbital**, which lie along the angle between the nose and the cheek, and below the margin of the orbit. Their *affer*ents are derived from the

FIG. 799.—LYMPH GLANDS OF THE HEAD AND NECK AS SEEN WHEN THE STERNO-MASTOID IS IN ITS USUAL POSITION. The occipital and the posterior and anterior auricular glands are inserted in accordance with descriptions. The other glands were present in one or other of the two bodies from which the drawing was made. Compare Fig. 801.

surrounding parts; and their *effere*nts pass to the anterior auricular and the submaxillary lymph glands. **Buccinator lymph glands** have been found on the superficial surface of the buccinator, both anterior and posterior to the anterior facial vein. Those posterior to the vein usually lie close to the point where the parotid duct turns medially round the anterior border of the masseter. They receive lymph from the eyelids and cheeks, and transmit it to the anterior auricular glands. **Supra-mandibular lymph glands** lie superficial to the mandible at the anterior border of the masseter, between the anterior facial vein and the external maxillary artery. They receive lymph from the region of the lower lip, and transmit it to the anterior auricular and superficial cervical glands.

Lymphoglandulæ Linguales.—The lingual lymph glands lie between the genio-glossi muscles and, on the lateral surfaces of the hyo-glossi and genio-glossi muscles,

deep to the mylo-hyoid muscles; they are simply small lymph nodules interposed in the course of the lymphatics which are passing from the tongue and the floor of the mouth to the deep cervical glands.

THE LYMPH GLANDS OF THE NECK.

Lymphoglandulæ Cervicales Superficiales.—The superficial cervical lymph glands lie on or are embedded in the deep fascia along the course of the external jugular vein, superficial to the sterno-mastoid (Fig. 799). They receive *afferent* vessels from the superficial tissues of the neck, the posterior and anterior auricular, and the submaxillary lymphatic glands. Their *efferent* vessels terminate in the upper deep cervical glands and the supra-clavicular glands. The uppermost superficial cervical glands are sometimes described as infra-auricular glands.

Lymphoglandulæ Submaxillares.—The submaxillary lymph glands vary in number from three to six. They lie under cover of the deep fascia of the neck in the angle between the lower border of the mandible and the submaxillary gland, and the largest of the series is usually situated near the point where the external maxillary artery turns round the lower border of the mandible (Fig. 800). Occasionally some smaller gland nodules are found on the deep surface of the submaxillary gland, but these are comparatively rare. The *afferent* vessels of the submaxillary lymph glands carry lymph from the side of the nose, the upper lip, the lateral part of the lower lip, the anterior third of the border of the tongue, the gums, the submaxillary and sublingual glands, and the adjacent parts of the floor of the mouth. The *efferents* descend over the superficial surface of the submaxillary gland, and terminate in the upper deep cervical glands, more particularly in those in the immediate neighbourhood of the termination of the common carotid artery.

Paramandibular Lymph Gland.—This term is applied to one or more lymph glands which lie inside the capsule of the submaxillary gland, in close relation with the gland or embedded in its substance. They receive lymph from the gland and the adjacent parts of the mouth and transmit it to the submaxillary and deep cervical glands.

The **Submental Lymph Glands** lie below the chin superficial to the mylo-hyoid muscles and between the anterior bellies of the two digastric muscles. There are usually two on each side, a medial or superior close to the median plane, and a lateral or inferior on the anterior border of the anterior belly of the digastric. They are apt to become enlarged in diseased conditions of the middle part of the lower lip, the adjacent part of the gums, the anterior part of the floor of the mouth, the tip of the tongue, and the skin beneath the chin, for their afferent vessels drain those parts. The *efferents* from this group of glands pass partly to the submaxillary lymph glands, and partly to a deep cervical gland situated on the superficial surface of the internal jugular vein at the level of the cricoid cartilage (Figs. 799, 800, 801).

Lymphoglandulæ Retropharyngææ.—The retro-pharyngeal lymph glands lie posterior to the upper part of the pharynx, embedded in the fascia covering the superior constrictor muscle. They are separable into two groups, lateral and median.

The *lateral retro-pharyngeal glands*, 1-3, appear to be constant both in children and adults. Each lateral gland, or group of glands, lies at the level of the atlas, anterior to the upper part of the longus capitis, and posterior to the internal carotid artery.

The *median retro-pharyngeal glands*, commonly present in children and frequently absent in adults, lie at the same level as the lateral glands, but in the median plane. They are irregular in number and size.

The retro-pharyngeal lymph glands receive lymph from the adjacent muscles and bones, from the nasal part of the pharynx, from the auditory tube and tympanum, and from the posterior parts of the nasal cavities. Their *efferents* pass to the medial and the lateral deep cervical glands.

Lymphoglandulæ Cervicales Antiores.—The lymph glands of the anterior part of the neck are separable into two groups, superficial and deep.

The **superficial anterior cervical lymph glands** are very irregular in number and

size. When they are present they lie in association with the anterior jugular veins. The exact origin of their afferents and the terminations of their efferents are unknown, but it is probable that they receive lymph from the superficial tissues of the anterior parts of the neck, and transmit it to the lower deep cervical glands.

The **deep anterior cervical lymph glands** are—

(a) *Infra-hyoid glands*, which lie anterior to the hyo-thyroid membrane. They receive lymph from the region of the epiglottis and transmit it to the deep cervical glands. They are not constantly present.

(b) The *prelaryngeal gland*, which lies either anterior to the cricoid cartilage or to the crico-thyroid ligament. Its occurrence is very constant. It receives

FIG. 800.—LYMPH GLANDS OF THE NECK SEEN FROM THE FRONT.
Infra-hyoid glands and pretracheal glands were not present.

lymph from the anterior part of the larynx and from the isthmus and the adjacent parts of the lateral lobes of the thyroid gland. Its efferents terminate in the deep cervical and the pretracheal glands.

(c) The *pretracheal lymph glands* are numerous small nodules which lie along the inferior thyroid veins. They receive lymph from the trachea, the lower part of the larynx, and from the lateral lobes and the isthmus of the thyroid gland; and they transmit it to the lower deep cervical glands.

(d) The *paratracheal lymph glands* lie along the sulcus between the larynx and the trachea anteriorly and the pharynx and œsophagus posteriorly, in association with the branches of the superior and inferior thyroid arteries and the recurrent nerves. They receive lymph from the adjacent parts and transmit it to the deep cervical glands (Fig. 800).

Lymphoglandulæ Cervicales Profundæ Superiores et Inferiores.—The deep cervical lymph glands lie in the anterior and posterior triangles of the neck and under cover of the sterno-mastoid muscle. They form a more or less continuous sheet of gland nodules and inter-communicating lymph vessels; but the glands are divided into two main groups, the (a) superior, and (b) inferior, and each group is separable into (1) medial, and (2) lateral components.

(a) **The Superior Deep Cervical Lymph Glands.**—(1) The *medial group* of upper deep cervical lymph glands lies on the superficial surface of the internal jugular vein and in the carotid triangle of the neck. One of the largest, which is closely associated with the tongue, lips, gums, cheeks, and the outer part of the nose, is

FIG. 801.—LYMPH GLANDS OF THE HEAD AND NECK AS SEEN AFTER THE REMOVAL OF THE STERNO-MASTOID MUSCLE. The anterior and posterior auricular and the occipital glands are inserted in accordance with descriptions. The other glands were present in one or other or in both the bodies from which the figure was made. Compare Fig. 799.

frequently situated in the region of the union of the common facial vein with the internal jugular vein. The lowest gland of the group, which receives a communication from the submental glands, lies on the lateral surface of the internal jugular vein immediately above the omo-hyoid muscle. The highest members of the group may be under cover of the postero-medial surface of the parotid gland, in association with the posterior belly of the digastric muscle. (2) The members of the *lateral group* of superior deep cervical lymph glands lie under cover of the posterior part of the upper portion of the sterno-mastoid, and in the upper part of the posterior triangle of the neck. They are embedded in the fat-laden fascia which covers the roots of the cervical plexus and the upper part of the brachial plexus,

and the levator scapulæ and the scalene muscles, and several of them are in close relation with the accessory nerve (Fig. 801).

The superior deep cervical glands are connected by *afferent* vessels with the various groups of glands which lie in the regions of the pharynx, the face, and the upper part of the neck. They receive lymph, therefore, from the nose, the mouth, the tongue, the upper parts of the pharynx and larynx, the tonsil, the upper part of the thyreoid gland, the submaxillary, sublingual, and parotid salivary glands, and from the interior of the cranium. Their *effereents* pass either to the inferior deep cervical glands or to the jugular lymph trunk. In some cases the medial and lateral members of the superior group are connected with the corresponding members of the lower group only, but in other cases the medial or lateral members of the superior group may be connected with both the medial and the lateral members of the inferior glands.

The **inferior deep cervical lymph glands** (Figs. 800, 801), which are also termed the supra-clavicular glands, are situated below the level of the omo-hyoid muscle. (1) The members of the *medial group* lie in relation with the lower part of the internal jugular vein, opposite the interval between the sternal and the clavicular heads of the sterno-mastoid. They receive *afferents* from the members of the upper medial group and from the pretracheal and the paratracheal glands and from the upper part of the thorax. Their *effereents* unite with some of the efferents of the upper medial group and pass with them to the jugular lymph trunk.

(2) The members of the *lateral group* of inferior deep cervical glands lie in the subclavian triangle, in the fatty tissue superficial to the lower part of the brachial plexus and the third part of the subclavian artery. They receive lymph from the lower parts of the neck, from the upper part of the thorax, and from the upper lateral glands. They receive lymph also from the deep parts of the mammary gland, and they are in communication with the axillary glands. Their *effereents* join the jugular lymphatic trunk.

THE LYMPH VESSELS OF THE HEAD AND NECK.

The lymph vessels and the head and neck may be separated into two groups, intracranial and extracranial.

Intracranial Lymph Vessels and Lymph Spaces.—The cerebro-spinal fluid which fills the ventricles of the brain, the central canal of the spinal medulla, and the subarachnoid and subdural spaces, differs in chemical constitution from true lymph; nevertheless it plays the part of lymph, to some extent, and there can be little doubt that some of it eventually passes into lymph vessels; therefore it may be considered as a modified form of lymph. The fluid is secreted by the chorioid plexuses of the cerebral ventricles, and it passes through the medial and lateral foramina of the fourth ventricle into the cerebello-medullary subarachnoid cistern. Part of the fluid transudes through the arachnoideal granulations into the superior sagittal and other cerebral blood sinuses; and part, probably, passes by osmosis into the subdural space and thence into the meningeal lymphatics, by which it is conveyed to the exterior of the cranium.

Cerebral Lymph Channels.—It appears probable that the so-called peri-vascular and pericellular lymph spaces which have so frequently been described in the central nervous system are merely artifacts produced by unsatisfactory methods of preparation. Nevertheless, the fluid which pervades the cerebral substance must have some exit, and it is not unlikely that it passes, with the lymphocytes, through cleft-like intercommunicating spaces in the adventitial coats of the blood vessels, similar to those demonstrated by Bruce in the case of the spinal medulla, and so reaches the pia-mater and subarachnoid space; that is, it runs along the walls of the arteries, enters the meningeal lymphatics, and passes through them to the exterior of the cranium and where it enters the extracranial lymph vessels. The above statements are based upon Bruce's researches and the fact that the lymph vessels of the nose, the ear, and the deep lymph vessels of the neck have been injected from the subdural space.

The Superficial Lymph Vessels of the Head.—(1) The superficial lymphatics from the *frontal and anterior temporal regions* of the head accompany the branches of the superficial frontal artery and terminate in anterior auricular glands, from which efferents pass to the parotid, the superficial cervical, and to the medial glands of the superior deep cervical group.

(2) The lymphatics of the *posterior temporal and parietal region* run to the posterior auricular glands. It is stated that they sometimes communicate directly with the lateral glands of the superior deep cervical group.

(3) The lymphatics from the *occipital part of the scalp* pass along the branches of the occipital artery and terminate in the occipital glands, which transmit the lymph to the lateral superior deep cervical glands.

The Superficial Lymph Vessels of the Neck.—The majority of the lymph vessels from the skin and the subcutaneous tissues of the upper part of the neck pass to the inferior deep cervical glands, but some end in the occipital glands and others in the superior deep cervical glands.

The superficial lymph channels of the lower part of the neck terminate in the axillary glands.

The Lymph Vessels of the Eyelids and the Conjunctiva.—The lymph vessels which drain the region of the eyelids and the conjunctiva form two groups, a medial and a lateral. (a) The *medial vessels* pass from the superficial and deeper parts of the medial portions of the superior and inferior eyelids and, following the course of the angular and the external maxillary arteries, they pass to the submaxillary lymph glands. The more superficial vessels lie anterior, and the deeper vessels posterior to the orbicularis oculi. Both groups may be connected with infra-orbital and the anterior buccinator glands. (b) The lymph vessels from the *lateral parts of the eyelids* pass posteriorly along the line of the transverse facial artery. They end in the anterior auricular and the parotid lymph glands. In some cases they become connected also with the buccinator and superficial cervical glands.

Lymph Vessels of the Eyeball.—It is doubtful if any true lymph vessels exist in the eyeball. Lymph spaces have been described in association with the coats of the eyeball, and lymph vessels are stated to exist in the chorioid coat, but their existence is uncertain. The sinus venosus sclerae (Schlemm), formerly looked upon as a lymph channel, is probably a venous canal. If lymph vessels are absent then the fluids in the tissues and spaces of the eye must pass into

FIG. 802.—LYMPH VESSELS OF THE TONGUE.

the capillaries of the veins, unless channels exist in the adventitia of the vessels similar to those described by Bruce in the spinal medulla.

The Lymph Vessels of the Ear.—The lymph vessels from the upper and lateral parts of the auricle end in the anterior auricular glands. Those from the lower part of the auricle go to the upper superficial cervical glands. The lymph channels from the medial surface of the auricle end in the posterior auricular glands, but in a few cases they establish direct communication with the superior deep cervical glands.

The lymph vessels of the external acoustic meatus end in the anterior and posterior auricular glands.

The lymph vessels of the middle ear pass in two directions. Those from the more laterally situated parts of the walls of the cavity join the vessels of the external acoustic meatus and terminate in the posterior auricular glands. The lymph vessels which drain the more medial parts of the middle ear and the auditory tube terminate in the lateral retro-pharyngeal glands.

It is doubtful if any lymph vessels exist in the internal ear. It is possible that the perilymph drains into the subarachnoid space of the posterior fossa of the skull along the line of the ductus endolymphaticus and that the endolymph reaches the subarachnoid space along the fibres of the acoustic nerve.

The Lymph Vessels of the Nose.—The lymph vessels from the external part of the nose form two groups, superior and inferior. The *superior group* accompany the vessels from the lateral parts of the eyelids and end in the anterior auricular glands. The *inferior group* accompanies the angular and the external maxillary arteries, and the majority of the vessels end

in the submaxillary glands, but in some cases one or more vessels of this group pass to the upper superficial cervical glands.

The Lymph Vessels of the Nasal Muco-periosteum.—The vessels from the anterior part of the nasal muco-periosteum accompany the vessels of the lower portion of the external part of the nose and end in the submaxillary glands. Those from the posterior part of the muco-periosteum end partly in the medial superior deep cervical glands, and partly in the lateral retro-pharyngeal glands.

There is little definite knowledge regarding the lymph vessels of the accessory sinuses of the nose, but it is probable that they follow the lines of the blood-vessels which supply the muco-periosteum of the cavities.

The Lymph Vessels of the Lips.—The vessels from the skin of the medial part of the lower lip pass to the submental glands and, occasionally, direct to the superior deep cervical glands. The vessels from the deeper parts of the lower lip unite with those from the upper lip and end in the submaxillary glands, but some of the superficial vessels of the upper lip may end in the superficial cervical glands.

The Lymph Vessels of the Cheeks.—The majority of the superficial and deep lymph vessels of the cheeks pass to the submaxillary glands, but in some cases they communicate directly with the superficial or with the superior deep cervical glands. They may communicate also with the buccinator glands.

The Lymph Vessels of the Gums.—The vessels from the outer part of the anterior portion of the mandibular gum pass to the submental glands. Those from the posterior part, together with the vessels from the outer part of the gum of the maxilla, terminate in the submaxillary glands. The vessels of the gum of the maxilla may also communicate with the buccinator glands.

The vessels from the inner part of the gum of the mandible end in the submaxillary glands; those of the inner part of the gum of the maxilla, together with the vessels of the hard and the soft palate, end in the medial superior deep cervical glands.

The Lymph Vessels of the Teeth.—It is known that lymph vessels exist in connexion with the teeth of the mandible as well as with the mandible itself, but their terminations are not definitely established. It is probable that they end in the submaxillary or the superior deep cervical glands.

The lymph vessels of the teeth of the maxilla pass partly into the infra-orbital canal and so to the face, where they join the vessels from the lateral parts of the eyelids, and terminate in the anterior auricular and submaxillary glands. The remaining vessels of the maxillary teeth end in the submaxillary glands.

The Lymph Vessels of the Tongue.—The lymph vessels of the tongue form three groups—(1) anterior, (2) middle, (3) posterior. The anterior and middle groups communicate freely with each other and with their fellows of the opposite side, but the posterior group have little or no communication with the middle group (1) The anterior lymph vessels drain the tip and the

FIG. 803.—DIAGRAM OF SIDE-VIEW ORIGINS AND TERMINATIONS OF THE LYMPH VESSELS OF THE TONGUE. (After Poirier, modified.)

FIG. 804.—DIAGRAM OF LYMPH VESSELS OF ANTERIOR TWO-THIRDS OF TONGUE, SEEN FROM BELOW. (After Poirier, modified.)

lower surface of the anterior free portion of the tongue. The main trunks pierce the mylo-hyoid muscle and end in the submental glands. (2) The middle group of lymph vessels of the tongue drain the anterior two-thirds, exclusive of the tip, and they terminate partly in the submaxillary glands and partly in the medial superior deep cervical glands. Small lingual glands are intercalated in the course of some of these vessels. (3) The posterior lymph vessels drain the portion of the tongue which lies in the anterior wall of the pharynx posterior to the papillæ vallatæ; they pass to the medial superior deep cervical glands. (4) The lymph vessels from the deeper central portions of the tongue go mainly to the upper deep cervical glands.

The Lymph Vessels of the Salivary Glands.—The lymph vessels of the parotid gland terminate in the parotid and superior deep cervical lymph glands. The lymph vessels of the submaxillary gland terminate, according to Most, not in the submaxillary lymph glands but in the medial superior deep cervical glands. Practically nothing is known of the lymph vessels of the sublingual gland.

The Lymph Vessels of the Pharynx.—From the upper part of the pharynx, and from the posterior wall and lateral borders of the middle and lower parts, the lymph stream flows to the median line posteriorly. There the larger vessels pierce the walls of the pharynx, then they turn laterally and end in the lateral retro-pharyngeal glands.

From the lower and anterior part of the pharynx, that is, from the region of the piriform recesses and the adjacent part of the larynx, the lymph vessels pass along the course of the laryngeal branch of the superior thyroid artery, pierce the hyo-thyroid membrane and terminate in the medial superior deep cervical glands; they may be connected also with the infra-hyoid, and with the prelaryngeal glands.

The lymph vessels of the palatine tonsil and the adjacent parts of the glosso-palatine and pharyngo-palatine arches pierce the lateral wall of the pharynx and end in a gland, or group of glands, which lies on the lateral surface of the internal jugular vein, immediately below the posterior belly of the digastric at the level of the angle of the mandible.

The Lymph Vessels of the Thyroid Gland.—The lymph vessels of the thyroid gland form a plexus common to both lobes and the isthmus, therefore the lymph can pass from the lobe of one side to the terminal glands of the opposite side. The terminal vessels end in the prelaryngeal, the pretracheal, the paratracheal, the superior and inferior deep cervical, and the upper mediastinal glands.

The Lymph Vessels of the Larynx.—The lymph plexus of the larynx is separable into upper and lower portions; they are connected together on the posterior wall of the cavity, but are separated, laterally and anteriorly, by the plicæ vocales which contain extremely few lymph vessels. The efferent stems of the upper part pass mainly along the laryngeal branch of the superior thyroid artery, and they end in the superior deep cervical glands, but are frequently connected also with the infra-hyoid glands. The efferent vessels from the lower part of the larynx form two subordinate groups. Those from the anterior region pierce the median crico-thyroid ligament and end in the prelaryngeal, the pretracheal, and the deep cervical glands. The efferents from the posterior region pierce the crico-tracheal membrane and end in the paratracheal glands (Fig. 800).

The Lymph Vessels of the Cervical Part of the Trachea and Œsophagus.—The terminal vessels of the cervical part of the trachea and the adjacent portion of the Œsophagus and the upper part of the trachea

FIG. 805.—SCHEMA OF THE LYMPH VESSELS AND GLANDS OF THE UPPER EXTREMITY.

the paratracheal and the inferior deep cervical glands. From the upper part of the trachea some vessels pass to the prelaryngeal glands also.

LYMPH GLANDS OF THE SUPERIOR EXTREMITY.

The lymph glands of the upper extremity form two groups—(1) superficial, (2) deep.

(1) **Lymphoglandulæ Cubitales Superficiales.**—The superficial cubital lymph

glands, one or two in number, lie on the medial side of the basilic vein, a short distance proximal to the medial epicondyle of the humerus. They receive lymph from both aspects and from the ulnar border of the forearm, and their *effere*nts pass to the deep glands of the arm.

(2) **Lymphoglandulæ Cubitales Profundæ.**—Occasionally small glands are found in association with the arteries of the forearm, but in most cases the lymph from the deeper parts of the hand and forearm, below the region of the elbow, passes to the deep cubital glands or to the brachial or axillary glands.

FIG. 806.—DISSECTION OF AXILLA AND ANTERIOR PART OF THORACIC WALL, SHOWING LYMPH GLANDS AND VESSELS. (Semi-diagrammatic.)

The **deep cubital lymph glands** lie anterior to the elbow in the neighbourhood of the terminal part of the brachial artery. They receive many of the deep lymph vessels of the forearm and their *effere*nts pass to the brachial and axillary glands.

Brachial lymph glands, irregular in number and size, are found along the course of the brachial artery. Their *affer*ents are derived from the forearm, from the deep cubital and superficial cubital glands, from adjacent parts, and from the elbow-joint. Their *effere*nts end in lateral group of axillary glands.

In addition to the glands which lie along the course of the brachial artery other deep glands are occasionally met with in the arm. (1) One in the sulcus

FIG. 807.—SUPERFICIAL LYMPH VESSELS OF THE TRUNK, AND THE LYMPH GLANDS AND VESSELS—SUPERFICIAL AND DEEP—OF THE LIMBS (diagrammatic). All superficial lymph vessels are printed black; the deep lymph vessels are represented by continuous lines; efferent and interglandular vessels by dotted lines.

between the brachioradialis and the brachialis; (2) another in the radial sulcus. When they are present both of these glands receive lymph from the ligaments of the elbow-joint as well as from other adjacent soft parts.

Lymphoglandulæ Axillares.¹—

The axillary lymph glands lie in the region of the axilla, where they form several groups, some of which are practically constant, whilst others are very variable.

(a) The lateral or brachial group of axillary lymph glands, 1-7, lie in relation with the lateral boundary of the axillary space along the line of the great axillary vessels. They receive the lymph from the greater part of the upper extremity. Their *efferents* anastomose with the lymph vessels of the central glands; some terminate in the inferior deep cervical glands and others pass directly to the subclavian lymph trunk (Fig. 806).

(b) The posterior or subscapular lymph glands lie in relation with the posterior wall of the axilla, along the line of the subscapular vessels. Their *afferents* are the vessels of the lateral and posterior walls of the body, above the level of the umbilicus, and lymph vessels from the lower and posterior part of the neck. Their *efferents* join the lateral, the central, and the infra-clavicular axillary glands (Fig. 806).

(c) The anterior or pectoral group of axillary lymph glands, 2-4, lie along the line of the lateral thoracic artery, in the angle between the lower border of the pectoralis major and the serratus anterior. They extend from the third to the sixth intercostal space, sometimes in a single and sometimes in a double row. Occasionally one or two outlying members of this group, called the *paramammary glands*, are found on the superficial surface of the pectoralis major. The *afferents* of the

¹ The B.N.A. axillary lymph glands are the lateral glands of the axilla, but, as the other groups mentioned also lie in the axillary region, the general term "axillary" is used here to include all the groups.

anterior glands are derived from the anterior wall of the body above the umbilicus from the lateral two-thirds of the mamma. Their *efferents* pass to the central, lateral, and infra-clavicular axillary glands (Fig. 806).

(d) The **central axillary lymph glands**, 2-6, lie in the central part of the axilla, and frequently along the line of the intercosto-brachial nerve. They receive afferents from the anterior, the subscapular, and the lateral glands. Their *efferents* pass to the infra-clavicular glands (Fig. 806).

(e) The **subpectoral group of axillary lymph glands**, 3-14, is formed by several small glands which lie posterior to the pectoralis minor and anterior or medial to the axillary artery. They receive lymph from the glands situated at a lower level and from the lateral wall of the thorax. Their *efferents* pass to the infra-clavicular glands.

(f) The **infra-clavicular group of axillary lymph glands**, 1-11, lies in the region between the upper border of the pectoralis minor and the clavicle, along the medial side of the axillary artery. They receive efferents from the arm, from the other groups of axillary glands, and directly from the mamma and the pectoral muscles, along the line of the pectoral branches of the thoraco-acromial artery, and from the inter-pectoral glands. Their *efferents* pass to the inferior deep cervical glands and to the subclavian lymph trunk (Fig. 806).

(g) A **decto-pectoral lymph gland** is occasionally found in the groove between the deltoid and the pectoralis major muscles. It receives *afferents* from the superficial parts of the arm and the shoulder, and gives *efferents* to the subclavian trunk and to the infra-clavicular glands.

(h) Small **inter-pectoral lymph glands** are sometimes found between the great and small pectoral muscles. They are connected with the lymph vessels which pass from the posterior part of the mamma to the infra-clavicular glands (Fig. 806).

THE LYMPH VESSELS OF THE SUPERIOR EXTREMITY.

The lymph vessels of the upper extremity, like the glands, form two groups—(1) superficial, and (2) deep.

(1) The **superficial lymph vessels** lie in the skin and the subcutaneous tissues. They commence in cutaneous plexuses which are finest and most dense on the palmar aspects of the fingers and hand. The efferents from the volar digital plexus of each finger pass to the dorsum of the digit. There they unite to form dorsal digital vessels, 2-4, which run to the dorsum of the hand where they unite together to form new vessels.

FIG. 808.—SUPERFICIAL LYMPHATICS OF THE DIGITS AND OF THE DORSAL ASPECT OF THE HAND.

The efferents from the volar plexus of the hand run proximally, distally, and to the lateral and medial margins of the hand. The lateral efferents, as they turn round the lateral border of the hand, join the efferents of the thumb. The medial efferents turn round the medial border of the hand, and join the efferents of the little finger. The afferents which run proximally are few and variable; when they are present they lie along the line of the superficial median vein of the forearm. The efferents which run distally pass to the interdigital clefts where they turn dorsally and join the vessels on the dorsum of the hand (Figs. 807, 808).

As the superficial lymphatics pass towards the elbow they tend to form two main streams—(1) a lateral stream which accompanies the cephalic vein, and (2) a medial stream which accompanies the basilic vein. The lymph vessels which commence on the dorsum of the hand and forearm converge to one or other of the two main groups of vessels. In the region of

the elbow the vessels of the two streams anastomose together and some pass through the fascia and join the deep cubital glands.

As they pass from the forearm to the arm, the majority of the lymph vessels converge towards the medial side. Some join the superficial cubital glands, but others pass those glands and accompany their efferents, along the basilic vein, to the axilla where they join the lateral group of axillary glands. There is, however, a varying number of lymph vessels, from the lateral stream of the forearm, which accompany the cephalic vein in the arm. Some of these terminate in the delto-pectoral gland, if it is present, but, whether it is present or not, some pass directly to the infra-clavicular glands.

The superficial lymph vessels of the arm terminate, for the most part, in the lateral group of axillary glands.

The deep lymph vessels of the upper extremity accompany the deeper blood-vessels. Some of the lymph vessels of the hand and forearm end in the deep glands, which are occasionally present in the forearm, but the majority either end in the deep cubital glands, or they pass directly to the lateral group of axillary glands.

The Lymph Vessels of the Mamma.—As the mamma is a modified skin gland, and as it is embedded in the superficial fascia, the lymph vessels which issue from it pass first into the superficial fascia and thence into the deep fascia. Having traversed the deep fascia, more or less obliquely, they either end in lymph glands or enter and traverse other layers of the body wall.

The main outflow of lymph from the substance of the mamma is towards the areola, where a subcutaneous plexus of lymph vessels is formed. From this plexus two or more main vessels of large size pass laterally (Fig. 806), pierce the deep fascia and join the anterior group of axillary glands. There are, however, other groups of vessels by which lymph may pass from the mamma. Some vessels issue from the medial border of the gland and run along the lines of the neighbouring anterior perforating branches of the internal mammary artery to the anterior ends of the intercostal spaces, where they pass through the deeper parts of the thoracic wall and end in the sternal lymph glands. Clinical evidence (Sampson Handley) has shown that some vessels pass from the lower and medial part of the gland and pass to the angle between the seventh rib and the xiphoid process, where they pierce the fibrous layers of the abdominal wall and join the lymph vessels in the extra-peritoneal fascia of the upper part of the abdomen. It is through these vessels that cancer cells not uncommonly travel from the mamma to the abdomen (Fig. 806).

Lymph vessels pass also from the deep part of the mammary gland, through the deep fascia and the pectoralis major, and then ascend, along the line of the pectoral branches of the thoraco-acromial artery, to the infra-clavicular region, where they terminate either in the inter-pectoral or the infra-clavicular glands, or in both groups. It is possible that some of these vessels, after piercing the costo-coracoid membrane, may pass directly to the inferior deep cervical glands (Fig. 806).

It is stated, further, that some of the lymph vessels which issue from the mamma pierce the whole thickness of the thoracic wall and join the lymph vessels which lie in the endo-thoracic fascia, which intervenes between the ribs and the intercostal muscles externally and the pleural membrane internally.

THE LYMPH GLANDS OF THE THORAX.

The lymph glands of the thorax form 5 named groups, with subdivisions.

(1) **Lymphoglandulæ Sternales.**—The sternal lymph glands form two groups each of which lies at the margin of the sternum along the line of the corresponding internal mammary artery. The glands are variable in number (4-18) and in size. They receive *afferents* from the upper part of the muscles of the abdominal wall, from the diaphragm, from the anterior part of the wall of the thorax, and from the medial portion of the mamma. Their *efferents* communicate with the upper anterior mediastinal glands and with the inferior deep cervical glands, and they terminate on the right side in the right lymphatic or the right broncho-mediastinal duct and on the left in the thoracic duct. Occasionally, also, they end directly in the internal jugular or the subclavian vein.

(2) **Lymphoglandulæ Intercostales.**—The intercostal lymph glands are lateral and medial. The *lateral glands* lie in the posterior parts of the intercostal spaces, the *medial* are placed in front of the heads of the ribs. Their *afferents* are derived from the boundaries and contents of the spaces. The *efferents* of the glands of the upper spaces pass either to the posterior mediastinal glands or to the thoracic

duct. Those of the lower spaces, on each side, form a descending trunk which passes through the aortic opening of the diaphragm and ends in the cisterna chyli.

(3) **Lympho-glandulæ Mediastinales Anteriores.**—The anterior mediastinal lymph glands form two groups, a lower and an upper. The *lower group* consists of 3 or 4 glands, and is situated, posterior to the sternum, in the lower part of the anterior mediastinum. It receives *afferents* from immediately adjacent parts and from the liver and the diaphragm. Its *efferents* communicate with the upper anterior mediastinal glands, and they end, for the main part, in the broncho - mediastinal trunk.

The *upper group* consists of from 8 to 19 glands which lie posterior to the manubrium sterni and anterior to the thymus and the great vessels of the superior mediastinum. Their *afferents* are derived from the lower group of anterior mediastinal glands, from the pericardium, the heart, the thymus, the thyroid gland, and from the sternal glands. Their *efferents* pass mainly to the broncho-mediastinal trunk, but they communicate with the medial inferior deep cervical glands and possibly also with the thoracic duct.

FIG. 809.—DEEP LYMPHATIC GLANDS AND VESSELS OF THE THORAX AND ABDOMEN (diagrammatic).

Afferent vessels are represented by continuous lines, and efferent and interglandular vessels by dotted lines.

C.	Common iliac glands.	M.	Mediastinal glands and vessels.
C.I.	Common intestinal trunk.	P.A.	Pre-aortic glands and vessels.

E.I.	External iliac glands.	R.L.D.	Right lymphatic duct.
I.	Intercostal glands and vessels.	S.	Sacral glands.
I.I.	Hypogastric glands.	S.A.	Scalenus anterior muscle.
L.	Lumbar glands.	T.D.	Thoracic duct.

(4) **Lymphoglandulæ Mediastinales Posteriores.**—The posterior mediastinal lymph glands, 8-12, lie along the descending part of the thoracic aorta and the thoracic part of the œsophagus. They receive *afferents* from the diaphragm, the pericardium, the œsophagus, and other immediately adjacent tissues. Some of their *efferents* join the thoracic duct, others the broncho-mediastinal trunk, and some pass to the bronchial glands.

FIG. 810.—THE GLANDS IN RELATION TO THE TRACHEA AND THE MAIN BRONCHI.

are situated in the lateral angle between the trachea and the bronchus, on each side. On the right side they vary in number from 5 to 9, on the left from 3 to 6. Those on the left are in close relation with the left recurrent nerve. Their *afferents* are derived from the other groups of bronchial glands and from the adjacent parts of the trachea and bronchi. They are connected with the anterior and posterior mediastinal glands. Their *efferents* pass to the broncho-mediastinal trunk and also to the inferior deep cervical glands. They are associated, also, by interglandular vessels, with the paratracheal glands.

(2) The **Lymph Glands of the Bifurcation** (intertracheo-bronchial) lie below the trachea, in the angle between the two main bronchi. They are situated between the roots of the great vessels anteriorly and the œsophagus and the aorta posteriorly. Their *afferents* are derived from the broncho-pulmonary glands and from adjacent parts; their *efferents* terminate in the tracheo-bronchial glands. They are connected with the posterior mediastinal glands.

(3) The **Broncho-Pulmonary Lymph Glands.**—Each group of broncho-pulmonary glands, right and left, lies in the hilus of the corresponding lung, in the angles between the branches of the bronchial tube. They vary considerably in number, and they receive *afferents*, either directly or through the pulmonary glands, from the lung substance. They also receive afferents from the pleura; and their *efferents* pass to the tracheo-bronchial glands and to the glands of the bifurcation.

(4) The **Pulmonary Lymph Glands** lie in the lung substance and usually in the angles between two bronchial tubes. Their *afferents* are derived from the lung substance, and their *efferents* pass to the broncho-pulmonary glands.

(5) **Lymphoglandulæ Bronchiales.**—Under the term bronchial lymph glands are included all the lymph glands which are closely associated with the walls of the intra-thoracic part of the trachea and with the main bronchi and their intra-pulmonary branches. The glands are extremely numerous, and they are conveniently classified, by Bartels, into four groups—(1) tracheo-bronchial right and left; (2) the glands of the bifurcation, also called intertracheo-bronchial; (3) broncho-pulmonary; (4) pulmonary. At birth and for some years afterwards they are pink in colour, but later they become blackened by the deposit of carbonaceous particles derived from the atmosphere.

(1) The **Tracheo-Bronchial Lymph Glands** are those which

THE LYMPH VESSELS OF THE THORAX.

The lymph vessels of the thorax form two main groups—(a) the vessels of the thoracic wall, and (b) the vessels of the contents of the thorax.

(a) The **Lymph Vessels of the Thoracic Wall** are the intercostal lymph vessels and the lymph vessels of the diaphragm.

(1) The **Intercostal Lymph Vessels** receive lymph from the ribs and from the content of the intercostal spaces, and they terminate in the intercostal and sternal glands. Communications are said to exist between the intercostal vessels and the glands of the axilla.

(2) The **Lymph Vessels of the Diaphragm**.—The lymph vessels from the anterior part of the diaphragm pass to the lower sternal and anterior mediastinal glands, and those from the posterior part to the posterior mediastinal glands.

(b) The **Lymph Vessels of the Contents of the Thorax** are:—

(1) The **Lymph Vessels of the Heart**, which follow the courses of the coronary arteries, and pass to the anterior mediastinal glands.

(2) The **Lymph Vessels of the Pericardium**, which terminate in adjacent glands.

(3) The **Lymph Vessels of the Thymus**, some of which pass to the anterior mediastinal glands, some to the tracheo-bronchial glands, others to the medial inferior deep cervical glands.

(4) The **Lymph Vessels of the Thoracic Part of the Œsophagus**, which are separable into upper and lower groups. The upper pass to the bronchial, the posterior mediastinal, and the lower deep cervical glands. The lower group end in the glands situated at the cardiac end of the stomach. The two groups anastomose together.

(5) The **Lymph Vessels of the Pleura**.—The vessels from the apical parts of the parietal portion of the pleura pass to the adjacent lymph trunks or their tributaries. The vessels from the posterior part of the parietal pleura join the intercostal glands, and those from the anterior part end in the sternal glands.

The **Lymph Vessels of the Lungs and the Visceral Pleura** pass to the broncho-pulmonary glands.

FIG. 811.—DIAGRAM OF THE LYMPH VESSELS AND LYMPH GLANDS OF THE LOWER EXTREMITY.

THE LYMPH GLANDS OF THE INFERIOR EXTREMITY.

The lymph glands of the inferior extremity, like those of the upper, are separable into a superficial and a deep group.

The **Superficial Lymph Glands** lie, almost entirely, in the subinguinal region, though occasionally one or more may be situated above the level of the inguinal ligament, and therefore in the inguinal region. On this account they are separated in the B.N.A. into inguinal and subinguinal groups. Both groups lie in the superficial fascia.

Lymphoglandulæ Inguinales.—The inguinal lymph glands, when they exist, are merely scattered members of the subinguinal group which lie above the level of the inguinal ligament. They receive *afferents* from the lower and anterior part of the abdominal wall. Their *efferents* terminate either in the superficial or the deep subinguinal glands.

Lymphoglandulæ Subinguinales Superficiales.—The superficial subinguinal glands (Figs. 811, 817) form two groups, a proximal and a distal, each of which is separable into medial and lateral parts; but the various members of the groups are intimately connected together by communicating vessels.

The *proximal group* lies along the line of the inguinal ligament. It may extend from the anterior superior spine of the ilium to the pubic tubercle. Its lateral members receive *afferents* from the lower and lateral part of the abdominal wall, from the buttock, and the proximal and lateral part of the thigh.

The more medial members of the proximal group receive afferents from the anal canal, the perineum, the scrotum, the penis, and the pubic region in the male, and from the corresponding parts, including the lower part of the vagina, in the female.

The *distal group* of superficial subinguinal glands lies along the line of the proximal part of the great saphenous vein—some on its lateral and some on its medial side. They receive *afferents* bearing lymph from the superficies of the greater part of the inferior extremity, with the exception of the lateral part of the foot, the heel, and a part of the posterior aspect of the leg.

The *efferents* of both proximal and distal groups of subinguinal glands pass to the deep subinguinal glands.

The **Deep Lymph Glands** of the inferior extremity are the popliteal and the deep subinguinal glands. Occasionally a deep gland is met with in the leg in relation with the proximal third of the anterior tibial artery.

Lymphoglandulæ Popliteæ.—The **popliteal lymph glands** (Fig. 812) lie in the popliteal fossa. One is usually situated, comparatively superficially, at the point where the small saphenous vein pierces the deep fascia and enters the fossa. It receives *afferents*, which accompany the small saphenous vein, from the lateral part of the foot, the heel, and the posterior part of the calf. Its *efferents* pass to the deeper glands.

The deeper glands lie in the fat around the popliteal vessels and are sometimes separated into inter-condylar and supra-condylar groups. Their *afferents* are derived from the more superficial gland and from the deeper tissues of the leg and foot. Their *efferents* pass to the deep subinguinal glands.

Lymphoglandulæ Subinguinales Profundæ.—The **deep subinguinal glands** (Figs. 807, 811, 817) lie in the femoral trigone. They are small glands, three to seven in number, which are difficult to demonstrate. Some of them lie in the femoral canal, the most proximal being situated in or

FIG. 812.—DIAGRAM OF THE LYMPH VESSELS OF THE POSTERIOR PART OF THE LOWER EXTREMITY.

close to the femoral ring. Their *afferents* are the efferents of the other glands of the lower extremity, and, in addition, vessels from the deeper parts of the penis or the clitoris. Their *efferents* pass to the external iliac glands.

THE LYMPH VESSELS OF THE INFERIOR EXTREMITY.

The arrangement of the **superficial lymph vessels** of the toes and the foot is very similar to that met with in the fingers and the hand. From lymph plexuses on the plantar aspect vessels pass to the dorsum of the foot and toes, where they unite into a number of vessels, the majority of which accompany the great saphenous vein and terminate in the distal group of superficial subinguinal glands. Some of the lymph from the lateral part of the plantar surface and from the lateral border of the foot, and the lymph from the heel enters vessels which accompany the small saphenous vein; they end either in the more superficial gland of the popliteal fossa or in the deeper glands of that region (Fig. 812).

With the exception of the lymph vessels from the lateral and posterior part of the leg, which accompany the small saphenous vein to the popliteal glands, all the superficial lymph vessels of the leg, thigh, and buttock pass to the superficial subinguinal glands; those from the leg and thigh mainly to the glands of the distal group; those of the buttock chiefly to the lateral glands of the proximal group.

The **deep lymph vessels** of the inferior extremity accompany the deep blood-vessels. Many of the vessels from the leg and foot end in the popliteal glands, but some pass directly to the deep subinguinal glands. The deep vessels of the more proximal parts of the inferior extremity end in the deep subinguinal glands and in the hypogastric glands.

THE LYMPH GLANDS OF THE ANTERIOR ABDOMINAL WALL.

Some lymph glands are regularly, and others are occasionally present in the anterior wall of the abdomen. Those fairly regularly present are :—

The **inferior epigastric lymph glands**, 3-6, which lie along the course of the inferior epigastric artery. Their *afferents* are from the deep part of the umbilicus and their *efferents* pass to the inferior external iliac glands.

The **Pubic Gland or Glands**.—One or more small glands which lie anterior to the suspensory ligament of the penis or clitoris. Their *afferents* are vessels from the superficial parts of the penis or clitoris, and their *efferents* end in the proximal superficial subinguinal glands.

The occasional glands are :—

(1) A **superior epigastric gland** which sometimes lies in the superficial fascia of the median part of the epigastric region. Its *afferents* are from the adjacent parts and its *efferents* pass to the sternal glands. It is probably very rare.

(2) **Circumflex iliac glands**, 2-4, which lie along the course of the deep circumflex iliac artery.

(3) An **umbilical gland** which lies in the extra-peritoneal tissue below the umbilicus. When it is present it receives vessels from the umbilicus and its *efferents* go to the external iliac glands.

(4) **Supra-umbilical glands**, 1-2, small glands which lie in the extra-peritoneal tissue above the umbilicus. Its *afferents* are from the region of the umbilicus. The *efferents* probably pass to the inferior anterior mediastinal glands.

THE LYMPH VESSELS OF THE ANTERIOR WALL OF THE ABDOMEN.

The superficial lymph vessels of the upper part of the anterior wall of the abdomen go, for the most part, to the anterior or pectoral group of axillary glands; but some pierce the wall of the lower part of the thorax and end in the sternal glands.

The superficial lymph vessels of the lower part of the anterior wall of the abdomen terminate in the proximal group of superficial subinguinal glands.

The deep lymph vessels of the upper part of the anterior abdominal wall accompany the superior epigastric vessels and terminate in the sternal glands; but some may be connected with the supra-umbilical glands if they are present.

The deep lymph vessels of the lower part of the anterior wall of the abdomen accompany the inferior epigastric vessels, and end in the inferior external iliac glands or the inferior epigastric glands.

THE LYMPH VESSELS OF THE EXTERNAL GENITALS.

The **lymph vessels of the scrotum** in the male and of the **labia majora** in the female pass to the proximal superficial subinguinal glands, and mostly to the medial group.

The **superficial lymph vessels of the penis** go to the medial glands of the proximal subinguinal group.

The **deep lymph vessels of the penis**, including those of the penile portion of the urethra, end either in the medial glands of the proximal subinguinal group or in the deep subinguinal glands.

The termination of the **lymph vessels of the clitoris** is similar to that of the lymph vessels of the penis.

LYMPH GLANDS OF THE PELVIS AND ABDOMEN.

The lymph glands of the pelvis are separable into visceral and parietal groups.

The Visceral Glands of the Pelvis.

Lymphoglandulæ Vesicales.—The lymph glands of the urinary bladder form an anterior and two lateral groups.

(a) The anterior lymph glands of the bladder are variable in number. They lie in the retro-pubic fat and receive *afferents* from the anterior and antero-lateral parts of the bladder wall. Their *efferents* go to the external iliac glands.

(b) The lateral lymph glands of the bladder lie along the course of the umbilical artery on each side. Their *afferents* are derived from the lateral parts of the bladder and their *efferents* end in the external iliac glands.

Lymphoglandulæ Anorectales.—The ano-rectal lymph glands (2-8) lie in the lower part of the pelvis minor in relation with the ampullary part of the rectum,

between its muscular wall and its external fibrous coat. Their *afferents* are derived from the muscular and mucous coats of the rectum and from the upper part of the anal canal, and their *efferents* pass to the superior hæmorrhoidal glands.

Lymphoglandulæ Parauterinæ.—The para-uterine lymph glands (1-6), lie at the sides of the neck of the uterus in the bases of the broad ligaments. They receive *afferents* from the neck of the uterus and the *efferents* pass to the hypogastric glands.

Lymphoglandulæ Hæmorrhoidales Superiores.—The superior hæmorrhoidal lymph glands lie along the course of the superior hæmorrhoidal artery in the pelvic meso-colon. They receive *afferents* from the walls of the rectum, and from the ano-rectal glands. Their *efferents* go to the inferior mesenteric glands.

The Parietal Lymph Glands of the Pelvis.

Lymphoglandulæ Sacrales.—The sacral lymph glands, variable in number, lie along the anterior aspect of the sacrum, between the anterior sacral foramina.

FIG. 813.—DIAGRAM OF THE LYMPH GLANDS OF THE PELVIS.

Their *afferents* are from the rectum, the prostate, and the adjacent parts of the wall of the pelvis. Their *efferents* end in the sub-aortic, the aortic, and the hypogastric glands.

Lymphoglandulæ Subaorticæ.—The subaortic lymph glands (1-3) lie on the anterior aspect of the fifth lumbar vertebra. Their *afferents* are from the sacral glands, the hypogastric glands, and the external iliac glands. Their *efferents* go to the aortic glands (Fig. 817).

Lymphoglandulæ Hypogastricæ.—The hypogastric lymph glands form right and left groups, which are associated with the corresponding hypogastric vessels. As a rule they lie near the origins of the main branches of the hypogastric artery, or in the angles between the branches, and some are, therefore, separable into a number of groups.

The **Gluteal Lymph Glands** lie in relation to the superior gluteal artery and receive *afferents* from the gluteal region. Their *efferents* pass to the common iliac glands.

The **Pubo-gluteal Lymph Glands** (1-2) lie in relation to the origins of the inferior gluteal and internal pudendal arteries. They receive *afferents* from the thigh and perineum and their *efferents* end in the common iliac glands.

The **Middle Hæmorrhoidal Gland** lies more medially than the other glands of the group, close to the lateral wall of the rectum at the point where the middle hæmorrhoidal artery breaks up into its terminal branches. It receives *afferents* from the rectum and gives *efferents* to the other hypogastric and to the external iliac glands.

The **Inter-iliac Glands** lie in the angle between the external iliac and the hypogastric arteries, and cannot be clearly disassociated from the medial external iliac glands. They receive *afferents* from the lower parts of the genito-urinary organs. Their *efferents* pass to the common iliac glands.

The **Obturator Gland** lies at the inner end of the obturator canal, above the obturator vessels. It receives *afferents* from the upper and medial parts of the thigh and its *efferents* join the inter-iliac and common iliac glands.

Lymphoglandulæ Iliacæ.—The iliac lymph glands are separable into a lower group, associated with the external iliac artery, **lymphoglandulæ iliacæ externæ**, and an upper group, the **lymphoglandulæ iliacæ communes**.

The External Iliac Glands.—According to Poirier and Cuneo, the external iliac lymph glands form three chains, lateral, intermediate, and medial, which lie, respectively, at the lateral side, anterior to, and at the medial side of the external iliac vessels. The three lowest members of the group, that is the lowest member of each chain, lie in close relation to the abdominal aperture of the femoral ring, and are frequently spoken of as supra-femoral glands. They receive *afferents* from the superficial subinguinal and the deep subinguinal glands, from the urethra and the deeper parts of the penis, and from the portions of the abdominal wall supplied by the deep circumflex iliac and inferior epigastric arteries. Their *efferents* end in the upper glands of the external iliac group.

The higher members of the external iliac lymph glands receive *afferents* from the membranous part of the urethra, the prostate, the bladder, the vagina, and the neck of the uterus. They are connected by anastomoses with the hypogastric glands, particularly the middle hæmorrhoidal gland, and their *efferents* pass to the common iliac glands.

The Common Iliac Lymph Glands.—The glands of the common iliac group are sometimes separated into a lateral and intermediate and a medial series. The lateral and intermediate groups are quite distinct, the former lying along the lateral margin of the artery and the latter posterior to it, but the medial group is not clearly defined from the sub-aortic group already mentioned. Indeed the sub-aortic group may be looked upon as constituted by the medial common iliac glands of opposite sides.

The common iliac glands receive *afferents* from the external iliac and the hypogastric glands, and consequently from practically the whole of the pelvic contents, except the ovaries of the female.

THE LYMPH VESSELS OF THE PELVIC VISCERA.

The Lymph Vessels of the Urethra of the Male.—It has been pointed out that the lymph vessels of the greater part of the penile portion of the urethra are said to pass to the deep subinguinal glands. The lymph vessels of the bulbar and membranous parts of the

urethra have not yet been satisfactorily demonstrated, but it is stated that they pass to the hypogastric glands, to the medial supra-femoral gland of the external iliac group, and to the higher glands of the external iliac group. The lymph vessels of the prostatic part of the urethra unite with the other lymph vessels of the prostate.

The Lymph Vessels of the Prostate pass to the anterior and lateral vesical glands, to the external iliac glands, to the hypogastric glands, and to the sacral and hæmorrhoidal glands. They anastomose with the lymph vessels of the bladder and the deferent duct.

The Lymph Vessels of the Urethra of the Female have terminations corresponding with those of the vessels of the membranous and prostatic portions of the urethra of the male.

The Lymph Vessels of the Seminal Vesicle, on each side, pass to the medial glands of the external iliac group.

The Lymph Vessels of the Ductus Deferens, on each side, anastomose with those of the seminal vesicle, and they pass to the hypogastric and external iliac glands.

The Lymph Vessels of the Urinary Bladder.—Many of the lymph vessels from the antero-lateral aspect of the urinary bladder pass to the corresponding anterior and lateral vesical lymph glands and, through them, become connected with the external iliac and hypogastric glands, but some apparently pass directly to the hypogastric lymph glands.

The lymph vessels from the superior, and many from the posterior part of the bladder, on each side, end in the external iliac and hypogastric glands, but some from the posterior part pass directly to the sub-aortic glands.

The Lymph Vessels of the Ureter.—Little is known of the lymph vessels of the ureter except that those of its lower extremity anastomose with the lymph vessels of the urinary bladder. It is suggested that the vessels pass to the nearest lymph glands.

The Lymph Vessels of the Vagina.—The lymph vessels of the lower part of the vagina anastomose with the lymph vessels of the labia minora and so transmit lymph to the superficial subinguinal glands. The lymph vessels of the upper parts of the vagina pass to the hypogastric glands and also, with the lymph vessels of the cervix uteri, to the external iliac glands. Some of the lymph vessels from the posterior wall of the vagina terminate in the ano-rectal glands.

The Lymph Vessels of the Uterus.—The Lymph Vessels of the Lower Part of the Uterus.

The majority of the lymph vessels

FIG. 814.—DIAGRAM OF LYMPH VESSELS OF FEMALE GENITAL ORGANS.

from the lower part of the uterus, including the cervix, unite with the lymph vessels of the upper part of the vagina and pass to the hypogastric glands including the inter-iliac group (p. 1017). Some pass to the external iliac glands, and others from the lower and posterior part become associated with the ano-rectal, the sacral, and the sub-aortic glands.

The Lymph Vessels of the Body of the Uterus run in several directions. The most important outflow is along the upper part of the broad ligament, below the uterine tube, to the region of the ovary where there is an anastomosis with the ovarian lymph vessels. Afterwards the lymph vessels of this stream cross the brim of the pelvis minor and ascend to the lumbar lymph glands. The accessory outflows are to the external iliac glands; to the sub-aortic glands; and, along the round ligament, to the superior group of sub-inguinal glands.

The Lymph Vessels of the Uterine Tube accompany the vessels of the main outflow from the body of the uterus, and those from the ovary, and pass to the lumbar lymph glands.

The Lymph Vessels of the Ovaries.—The lymph vessels of each ovary accompany the ovarian artery and some of the uterine lymph vessels, along the upper part of the broad ligament, to the brim of the pelvis minor and then upwards to the lumbar lymph glands.

The Lymph Vessels of the Testis and Epididymis.—The testis and the epididymis are not normally pelvic organs in the adult, but their lymph vessels may be considered here, inasmuch as the testes correspond, morphologically, with the ovaries. The lymph vessels of each testis and its epididymis accompany the testicular arteries and ascend to the lumbar region where they terminate in the lumbar lymph glands.

The Lymph Vessels of the Rectum.—The lymph vessels of the rectum and the upper part of the anal canal pass for the most part along the middle and superior hæmorrhoidal vessels.

Those which accompany the branches of the middle hæmorrhoidal artery, on each side, pass to the corresponding middle hæmorrhoidal gland of the hypogastric group; whilst the lymph vessels of the rectum which accompany the branches of the superior hæmorrhoidal artery become associated with the ano-rectal, the sacral, and the inferior mesenteric lymph glands.

THE LYMPH GLANDS OF THE ABDOMEN.

The lymph glands of the abdomen are separated into visceral and parietal groups. The visceral groups are those more directly associated with the lymph vessels which issue from the walls of the abdominal part of the alimentary canal, although they may lie posterior to the peritoneum in relation to the posterior wall of the abdomen. The parietal glands lie in relation with the abdominal part of the aorta and the inferior vena cava and the adjacent parts of the posterior abdominal wall.

Visceral Lymph Glands of the Abdomen.

Lymphoglandulæ Gastricæ.—The gastric lymph glands are arranged in two main groups, the *lymphoglandulæ superiores* which lie in association with the arteries of the smaller curvature, and the *lymphoglandulæ inferiores* associated with the greater curvature. Jamieson and Dobson have separated the superior gastric glands into several subdivisions.

Lymphoglandulæ Gastricæ Superiores.—(a) The **Anterior Left Gastric Glands** (lower coronary glands, J. and D.). The anterior left gastric glands lie between the layers of the lesser omentum along the course of the left gastric artery. They receive *afferents* from the greater part of the lesser curvature of the stomach and the adjacent parts of its anterior and posterior walls, and they send *efferents* to the posterior left gastric glands.

(b) The **Right Paracardial Glands** are essentially members of the anterior left gastric group which lie to the right of the cardiac orifice of the stomach. Their *afferents* are derived from the cardiac part of the stomach and their *efferents* go to the posterior left gastric glands.

(c) The **Left Paracardial Glands** lie to the left of the œsophageal orifice. They receive *afferents* from the adjacent parts of the cardiac portion of the stomach, and their *efferents* end in the posterior left gastric glands.

(d) The **Posterior Paracardial Glands** lie on the posterior aspect of the stomach, between the layers of the gastro-phrenic ligament. Their *afferents* are from the neighbouring parts of the cardia and their *efferents* go to the posterior left gastric glands.

(e) The **Posterior Left Gastric Glands** (upper coronary, J. and D.) lie around the left gastric artery as it passes forwards through the left gastro-pancreatic fold of peritoneum. They receive *afferents* from the previously mentioned groups of gastric glands and *direct afferents* from the cardiac portion of the stomach. Their efferents pass to the middle supra-pancreatic glands of Jamieson and Dobson (coeliac glands, B.N.A.).

(f) The **Right Gastric Gland** (pyloric of J. and D.) is a small gland, occasionally present, which lies immediately above the pylorus or the first part of the duodenum,

FIG. 815.—LYMPH VESSELS AND GLANDS OF THE STOMACH.
(After Jamieson and Dobson, modified.)

in association with the right gastric artery. It receives *afferents* from the pylorus, and its *efferents* end in the sub-pyloric glands.

(g) The **Right Gastro-epiploic Glands** lie along the lower part of the greater curvature of the stomach, in association with the right gastro-epiploic artery. Their *afferents* are from the adjacent parts of the anterior and posterior surfaces of the stomach and their *efferents* pass to the sub-pyloric glands.

(h) The **Left Supra-pancreatic Glands** of Jamieson and Dobson (lymphoglandulæ pancreaticolinales, B.N.A.) lie along the course of the splenic artery and in the gastro-splenic ligament: they receive *afferents* from the left part of the stomach and from the spleen. Their *efferents* pass to the middle supra-pancreatic glands.

(i) The **Right Supra-pancreatic Glands** (J. and D.) lie in relation with the stem of the hepatic artery as it passes through the right gastro-pancreatic fold. They receive *afferents* directly from the pyloric part of the stomach and the liver, and give off *efferents* to the middle supra-pancreatic glands.

(j) The **Sub-pyloric Glands** (J. and D.). The sub-pyloric lymph glands lie at the right border of the omental bursa, in the angle between the superior and descending parts of the duodenum, between the head of the pancreas posteriorly and the peritoneum of the posterior wall of the great sac anteriorly. Their *afferents* are from the right gastro-epiploic glands, the right gastric gland, and from the pyloric portion of the stomach. The *efferents* pass to the middle supra-pancreatic glands.

(k) The **Biliary Lymph Glands** (J. and D.) lie along the line of the bile duct. They receive *afferents* from the gall-bladder and liver. One of the lower glands of the group, which lies posterior to the head of the pancreas, close to the lower end of the bile-duct, is associated, by direct afferents, with the upper part of the pylorus. Their *efferents* pass to the right and middle supra-pancreatic glands.

The highest member of the series is associated with the cystic artery and the gall-bladder and is called the *cystic gland*.

Lymphoglandulæ Hepaticæ (B.N.A.) The **Hepatic Lymph Glands** of the Basle nomenclature are a few small glands which lie in the region of the porta hepatis, between the layers of the lesser omentum; they receive *afferents* from the liver and give *efferents* to the right supra-pancreatic glands (J. and D.).

Lymphoglandulæ Mesentericæ (B.N.A.)—The **Mesenteric Lymph Glands** lie between the layers of the mesentery, where they form three main groups: (a) a series of juxta-intestinal glands which lie close to the walls of the small gut; (b) an intermediate series of larger glands which lie in relation with the trunks of the rami intestinales of the superior mesenteric artery; and (c) a terminal group of large glands which lie round the upper part of the stem of the superior mesenteric artery. They receive lymph from all parts of the small intestine, from the cæcum, the vermiform process, the ascending colon, the transverse colon, and the part of the descending colon. Their *efferents* unite to form a common intestinal trunk, which enters the cisterna chyli.

The Lymph Glands of the Cæcum and the Vermiform Process and the Terminal part of the Ileum.—The lymph glands particularly associated with the terminal part of the ileum, the cæcum and its vermiform process, according to Jamieson and Dobson, are (1) the ileal, (2) the anterior ileo-colic, (3) the posterior ileo-colic, and (4) the appendicular. All these glands give off vessels which pass to the larger ileo-colic glands which lie along the ileo-colic branch of the superior mesenteric artery.

The **Ileal Glands** lie in the lower part of the mesentery. They receive *afferents* from the lower part of the ileum and give *efferents* to the main ileo-colic glands.

An **Appendicular Lymph Gland** is sometimes met with in the mesentery of the vermiform process. When it is present it may be associated with the vessels which pass from any part of the vermiform process. - Its *efferents* pass to the main ileo-colic glands.

The **Anterior Ileo-colic Glands**, 1-4, lie in the anterior ileo-colic fold of peritoneum. Their *afferents* are derived from the anterior part of the cæcum and the root of the vermiform process, and *efferents* pass to the main ileo-colic glands.

The **Posterior Ileo-colic Glands**, more numerous than the anterior, lie in the

angle between the ileum and the cæcum, and in the angle between the ileum and the ascending colon. Their *afferents* are from the posterior part of the cæcum and the root of the vermiform process. Their *efferents* pass to the main ileo-colic glands.

The **Lymph Glands of the Colon**, according to Jamieson and Dobson, may be considered as forming four groups, epicolic, paracolic, intermediate, and main.

The **Epicolic Glands** are small nodules which lie in the appendices epiploicæ and in relation with the wall of the gut. The **paracolic glands** lie along the medial borders of the ascending and descending colon; along the upper border of the transverse colon, and on the mesenteric border of the pelvic colon. The intermediate glands lie along the branches of the colic arteries and the main groups are situated

FIG. 816.—DIAGRAM OF THE LYMPH GLANDS AND LYMPH VESSELS OF THE LARGE INTESTINE. (After Jamieson and Dobson.)

around the stems from which the colic arteries arise. The lymph gathered by the lymph plexuses in the walls of the gut passes through one or more of the groups of glands, and that which issues from the main group, in association with the ileo-colic and middle colic arteries, enters the main mesenteric glands which surround the upper part of the superior mesenteric artery. It is then carried by the efferents of these glands to the common intestinal lymphatic trunk. The lymph from the descending, the iliac, and the pelvic parts of the colon passes to the intermediate groups of inferior mesenteric glands and thence, for the main part, to the lumbar glands, but some of the efferents from the upper intermediate inferior mesenteric glands pass to the main group of superior mesenteric glands.

The lymph glands associated with the middle colic artery and its branches are the *lymphoglandulæ mesocolicæ* of the Basle nomenclature.

The **Main Glands of the Inferior Mesenteric Group** receive lymph from the intermediate left colic glands and transmit it to the lumbar glands through which it passes, by the lumbar lymph trunks, to the cisterna chyli; but some of the lymph from the upper intermediate left colic glands passes to the main mesenteric glands, and so to the common intestinal lymph trunk.

The **Middle Supra-pancreatic Lymph Glands** of Jamieson and Dobson correspond fairly closely with the *lymphoglandulæ celiacæ* of the Basle terminology. They lie at the upper border of the pancreas around the celiac artery. Their *afferents* are from the right and left supra-pancreatic glands, from the posterior left gastric glands, and from the subpyloric glands. They are connected by intermediate channels with the superior mesenteric glands, and they give *efferents* to the common intestinal lymph trunk and also to the common lumbar trunks.

Lymphoglandulæ Lumbales, B.N.A.—The **Lumbar Lymph Glands** lie behind the peritoneum of the posterior wall of the abdomen, in association with the aorta, the inferior vena cava, the psoas and quadratus lumborum muscles, and the crura of the diaphragm. Those which are situated on the anterior aspect of the aorta are frequently spoken of as **pre-aortic glands** and those situated more laterally as **para-aortic glands**.

The *afferents* of the lumbar lymph glands are (1) the efferents of the common

iliac glands, (2) efferents from the sub-aortic glands, (3) efferents from the sacral glands, (4) some efferents from the hypogastric glands, (5) efferents from the main inferior mesenteric glands, (6) the lymph vessels from the testes and epididymides and their coverings in the male, and from the ovaries, the uterine tubes, and the upper part of the uterus in the female, (7) lymph vessels from the

FIG. 817.—SEMI-DIAGRAMMATIC VIEW OF THE LYMPH GLANDS AND VESSELS OF THE PROXIMAL PARTS OF THE LOWER EXTREMITIES, THE PELVIS MAJOR AND THE POSTERIOR PART OF THE ABDOMEN.

kidneys, (8) lymph vessels from the suprarenal glands, (9) lymph vessels from the muscles of the back and of the posterior wall of the abdomen.

The *efferents* of the lumbar glands form two common lumbar lymph trunks, which pass to the cisterna chyli.

THE LYMPH VESSELS OF THE ABDOMINAL VISCERA AND THE SUPERIOR AND POSTERIOR WALLS OF THE ABDOMEN.

The Lymph Vessels of the Abdominal Part of the Alimentary Canal.—The lymph vessels in the walls of the alimentary canal form four plexuses: (1) a mucous plexus, in the mucous membrane, (2) a submucous plexus, in the submucous tissue, (3) a muscular plexus, between the two muscle coats, (4) a subserous plexus which lies in the areolar tissue between the peritoneal covering and the outer muscular coat. The four plexuses communicate freely with each other. The lymph is eventually collected from the subserous plexus and carried to the various groups of lymph glands. The vessels which carry away the lymph from the sub-

serous plexuses of the various parts of the alimentary canal are spoken of in the following account as the lymph vessels of those parts.

The Lymph Vessels of the Stomach.—The lymph vessels of the stomach communicate freely with the lymph vessels of the œsophagus on the one hand and those of the duodenum on the other.

From the point of view of lymph outflow the area of each surface of the stomach may be divided into four parts. First a small right portion of the region of the pyloric canal, and, second, the remaining larger portion which is subdivided into three parts by two lines: (1) A line from the apex of the fundus to the pyloric canal along the junction of the upper and right two thirds with the left and lower third, (2) a line, parallel with the œsophagus, dividing the left and lower part into left and right portions (J. and D.). It must be understood, however, that the lymph vessels of the various areas communicate freely with each other (Fig. 815).

The Lymph Vessels of the Region of the Pyloric Canal pass (*a*) partly to the anterior left gastric glands, (*b*) partly to the right supra-pancreatic lymph glands, and (*c*) partly to the lower biliary group of lymph glands. If the right gastric gland is present some of the vessels of the upper pyloric region go to it, and in some cases vessels from the pyloric region pass directly to the posterior left gastric lymph glands.

The Lymph Vessels from the Right Upper Area of the larger portion of the stomach pass (*a*) to the anterior left gastric lymph glands, (*b*) to the posterior left gastric lymph glands, (*c*) to the paracardial lymph glands.

The Lymph Vessels from the Left Section of the Left and Lower Portion of the stomach pass along the gastro-splenic ligament to the splenic glands, which are occasionally present near the hilus of the spleen, and partly to the left supra-pancreatic lymph glands.

The Lymph Vessels from the Right Part of the Lower and Left Area follow the course of the right gastro-epiploic artery and terminate in the sub-pyloric glands.

The Lymph Vessels of the Duodenum are apparently few and difficult to inject; they communicate with those of the stomach above and the jejunum below, and the collecting vessels which pass from the subserous plexus end in the biliary, the sub-pyloric, and the mesenteric lymph glands.

The Lymph Vessels of the Jejunum and Ileum, with the exception of those from the terminal part of the ileum, pass to the mesenteric lymph glands. The lymph vessels from the terminal part of the ileum go to the ileo-colic lymph glands.

The Lymph Vessels of the Cæcum, the Vermiform Process, and the Ascending Colon pass to the ileo-colic lymph glands, either directly or after having traversed glands which lie nearer to the walls of the various parts of the gut.

The Lymph Vessels of the Right Colic Flexure and the Transverse Colon pass to the meso-colic and the superior mesenteric lymph glands.

The Lymph Vessels of the Left Colic Flexure, the Descending Colon, the Iliac Colon, and the Pelvic Colon pass to the inferior mesenteric lymph glands. From these glands the greater part of the lymph is conveyed to the lumbar lymph glands, but part passes to the mesenteric lymph glands and part to the common intestinal lymph trunk.

The Lymph Vessels of the Liver.—The lymph vessels of the liver are described as forming superficial and deep groups. The superficial vessels pass to subserous plexuses from which collecting vessels arise.

The collecting vessels from the superior, anterior, and right lateral surfaces converge to a series of posterior and anterior efferent trunks.

The posterior collecting trunks form three groups: (1) a right group, which runs through the right triangular ligament of the liver and then downwards and medially on the posterior wall of the abdomen, to the middle supra-pancreatic lymph glands; (2) the middle group runs towards the inferior vena cava, passes with it through the diaphragm, and ends in the posterior mediastinal lymph glands; (3) the left group passes through the left triangular ligament to the posterior left gastric glands and the posterior paracardial glands.

The anterior collecting trunks are inferior and superior. The inferior pass from the anterior part of the right lobe, turn round the lower border, and end in the hepatic lymph glands. The superior group pass to the falciform ligament. Some turn posteriorly towards the inferior vena cava, pass through the diaphragm with it and end in the posterior mediastinal lymph glands; others turn forwards and downwards to the round ligament, which they accompany to the porta hepatis where they join the hepatic glands. The remaining vessels pass upwards to the anterior part of the diaphragm which they perforate, and they end in the anterior mediastinal glands.

The superficial collecting vessels of the inferior surface of the right lobe pass (*a*) backwards to the inferior vena cava and along that vessel to the posterior mediastinal glands, (*b*) to the cystic gland of the biliary chain. The collecting vessels of the lower part of the left lobe end in the hepatic glands. The collecting vessels of the caudate lobe pass partly to the posterior mediastinal glands, along the inferior vena cava; and partly to the hepatic lymph glands in the porta hepatis.

The Deep Lymph Vessels of the Liver pass to ascending and descending collecting trunks. The ascending trunks follow the hepatic veins and the inferior vena cava and end in the posterior mediastinal lymph glands. The descending collectors accompany the bile-ducts, the branches of the portal vein, and the branches of the hepatic artery, and terminate in the hepatic lymph glands.

The Lymph Vessels of the Gall Bladder.—The lymph vessels from the gall bladder terminate chiefly in the cystic gland but some pass to other members of the biliary chain.

The Lymph Vessels of the Pancreas.—The efferent vessels from the pancreas end in the adjacent glands, that is, some pass to the sub-pyloric, some to the supra-pancreatic, some to the mesenteric glands, and some to the posterior left gastric lymph glands.

The Lymph Vessels of the Spleen.—The collecting vessels from the spleen pass to the splenic lymph glands which occasionally lie near the hilus of the spleen and the left supra-pancreatic lymph glands.

The Lymph Vessels of the Kidneys.—The lymph vessels of each kidney run along the renal blood-vessels and terminate in the lumbar glands, especially in the pre- and para-aortic lymph glands.

The Lymph Vessels of the Ureters.—The lymph vessels from the abdominal part of each ureter pass to the lumbar and the common iliac and the sub-aortic lymph glands.

The Lymph Vessels of the Suprarenal Glands anastomose with the vessels of the kidneys and pass to the lumbar and to the posterior mediastinal lymph glands.

The Lymph Vessels of the Diaphragm.—The collecting lymph vessels from the diaphragm pass to the thoracic lymph glands, that is, to the anterior and posterior mediastinal lymph glands, and lower sternal glands.

The Lymph Vessels of the Posterior Wall of the Abdomen terminate in the lumbar lymph glands.

DEVELOPMENT OF THE BLOOD-VASCULAR SYSTEM.

THE ARTERIES AND THE HEART.

In the general account of the development of the primitive vascular system and the establishment of the foetal circulation, given in a previous chapter, it was pointed out that the germ of the whole blood-vascular system appears in the wall of the yolk-sac as a series of strands of cells which constitute the **angioblast**. Some of the angioblast cells remain *in situ* and form the blood-vessels of the walls of the yolk-sac and the corpuscular contents of the blood-vessels; other angioblastic cells wander into the embryonic area and form the blood-vessels of the embryo; whilst still others become located in the developing liver and other organs, where they become foci for the formation of new blood corpuscles.

The first blood-vessels developed in the embryonic area are the primitive aortæ. They appear, either just before the embryonic area begins to be folded into the form of the embryo or as the folding is commencing, in the pericardial or anterior region of the embryonic area, where they are continuous with the earlier-formed vessels on the wall of the yolk-sac. From the pericardial region they extend caudalwards, one on each side of the notochord, and as they pass caudalwards they give off a series of dorsal and ventral branches.

FIG. 818.—SCHEMA OF CIRCULATION OF AN EMBRYO, 1.35 MM. LONG, WITH SIX SOMITES. (After Felix, modified.)

FIG. 819.—SCHEMA OF VASCULAR SYSTEM OF AN EMBRYO, 2.6 MM. LONG, WITH FOURTEEN SOMITES. (Arteries after Felix, modified.)

The dorsal branches are intersegmental in arrangement; they lie in the intervals between the mesodermal somites. The ventral branches are more irregular, and are not strictly segmental in arrangement; moreover, they are not only distributed to the wall of the alimentary canal, but they also pass across it to the yolk-sac. Further, those which are situated nearest the tail anastomose together, on the side wall of the hind-gut area, forming a plexus, and it is from this plexus, on each side, that the umbilical artery is prolonged along the body-stalk to the chorion (Figs. 818, 819).

As the head fold forms, the cephalic part of each primitive aorta is bent into the form of a loop, and the whole vessel assumes a hook-shaped form. The long or dorsal limb of the hook, which lies along the dorsal wall of the primitive alimentary canal, is the **primitive dorsal aorta**;

the bend of the hook is the **first aortic arch**; and the short ventral limb of the hook, which lies in the ventral wall of the fore-gut and the dorsal wall of the pericardium, is the **primitive ventral aorta**, which is continuous, at the anterior margin of the umbilical orifice, that is at its caudal end, with a venous vessel, the **vitelline vein**, which is carrying blood from the yolk-sac to the embryo.

The condition described is that found in embryos about 1.4 mm. long, possessing six mesodermal somites (Fig. 818).

In embryos in which the mesodermal somites have increased to fourteen pairs the posterior, or caudal, portions of the primitive ventral aortæ have fused together to form a single heart (Fig. 819).

The Primitive Heart.—The primitive heart lies in the dorsal wall of the pericardium and, therefore, in the ventral wall of the fore-gut. As it grows more rapidly in length than the wall to which it is attached, it bends upon its long axis and bulges ventrally into the interior of the pericardium. As it projects into the pericardium it pushes before it the immediate bounding wall of the pericardial cavity, which thus becomes converted into the **visceral pericardium**. The visceral pericardium surrounds the heart, and passes from its dorsal border to the ventral wall of the fore-gut as a double layer which constitutes the *dorsal mesocardium*.

The portion of each primitive ventral aorta which lies cephalwards of the heart forms the ventral root of the first aortic arch. At this stage the primitive dorsal aortæ are still separate from one another, and each gives off a series of dorsal intersegmental branches and a series of ventral branches which pass across the side walls of the primitive gut on their way to the wall of the yolk-sac.

The caudally situated ventral vessels, as in the earlier stage, form a plexus on the side walls of the primitive gut from which the umbilical arteries arise (Fig. 819).

FIG. 820.—SCHEMA OF VASCULAR SYSTEM OF AN EMBRYO WITH TWENTY-THREE SOMITES. (Arteries after Felix, modified.)

When the embryo has attained a length of 2.5 mm., and possesses about twenty-three mesodermal somites, the two primitive dorsal aortæ have fused together, from the tenth to the sixteenth somite, forming in the region of fusion a single dorsal aorta, which becomes the descending aorta of the adult.

At a slightly later stage the fusion of the two primitive dorsal aortæ extends caudalwards to the level of the twenty-third somite, where one of the ventral branches of each primitive

vessel becomes enlarged and forms the origin of the stem of the primitive umbilical artery. Still later the comparatively small continuations of the primitive dorsal aortæ, which are continued caudalwards from the twenty-third somite to the end of the caudal region, fuse together to form the middle sacral artery—the dorsal aorta, as such, terminating at the twenty-third body somite.

The Primitive Veins.—In embryos 1.4 mm. long two primitive veins are present on each side in the body of the embryo—the lateral umbilical veins and the vitelline veins. The lateral umbilical veins are the divisions of the vena umbilicalis impar, which returns blood from the placenta to the embryo; and the vitelline veins return blood from the yolk-sac (Fig. 819). During the time in which the embryo increases from 1.4 mm. to 2.6 mm. additional veins appear. As the body and head of the embryo become larger definite venous channels are formed to return blood from them to the heart, and in association with the more rapid development of the cephalic portion of the embryo the first entirely intra-embryonic veins to appear are the anterior cardinal veins, one on each side, which return blood from the head, and from the cephalic portion of the body of the embryo. These veins are present in embryos possessing fourteen mesodermal somites, and each terminates in the common trunks formed by the union of the vitelline and umbilical veins of the same side (Fig. 819).

A little later the posterior cardinal veins, one on each side, develop in the caudal or posterior part of the body. They join the anterior cardinal veins at the level of the caudal end of the heart, and the common trunk formed by the union is the **duct of Cuvier**, which opens directly into the caudal part of the heart. In the meantime the venous trunk, produced by the union of the lateral umbilical with the vitelline vein, and into which the anterior cardinal vein opened, is absorbed into the heart; therefore, when the ducts of Cuvier are formed, six vessels, three on each side, open into the caudal portion of the heart—the vitelline veins, the lateral umbilical veins, and the ducts of Cuvier. Whilst these changes in the veins are taking place, two additional aortic arches are formed, one on each side. They spring from the cephalic extremity of the heart, immediately caudal and somewhat dorsal to the ventral roots of the first arch; and they terminate, dorsally, in the dorsal aortæ (Fig. 820).

The Aortic Arches and their Ventral and Dorsal Roots.—The aortic arches are the vessels which connect the ventral portions of the primitive ventral aortæ with the primitive dorsal aortæ. Six such arches are formed on each side. They spring from the ventral aortæ or from the heart, they pass round the lateral walls of the fore-gut, in the branchial arches, and they terminate, in relation with the dorsal wall of the pharynx, in the primitive dorsal aortæ. All six arches are not present at the same time, for as the more caudally situated arches are formed those situated more cephalwards disappear (Figs. 821, 822). Five pairs of arches, the first four and the sixth, are present in embryos 5 mm. long; but by the time the length of the embryo has increased to 7 mm. the first two arches on each side have begun to disappear, and the very transitory fifth arch has been formed (Fig. 822).

The first aortic arch, on each side, is part of the primitive aorta, and is formed as the head fold is developed and the fore-gut is enclosed. It passes through the mandibular or first branchial arch, and connects the cephalic parts of the ventral and dorsal portions of the primitive aortæ together (Fig. 821). When the number of mesodermal somites has increased to twenty-three pairs and the embryo is about 2.5 mm. long, a second pair of aortic arches has appeared. They spring from the cephalic end of the heart, dorsal to the ventral roots of the first arches, and pass through the hyoid or second pair of branchial arches to the dorsal aortæ.

In embryos 5 mm. long the number of aortic arches has increased to five on each side—the first four and the sixth, the fifth appearing later, between the fourth and the sixth. At the period when five pairs of arches are present only four vessels spring from the cephalic end of the heart, which is now called the bulbus cordis; they are, on each side, an anterior stem which forms the ventral roots of the first and second arches, and a posterior stem common to the third, fourth, and sixth arches (Fig. 821). Up to this period the head lies quite close to the thorax, and a distinct neck can scarcely be said to exist.

As the neck appears and the head is moved away from the thorax the third and fourth aortic

FIG. 821.—SCHEMA OF THE STAGE OF FIVE AORTIC ARCHES. The cardinal veins and ducts of Cuvier are not shown.

FIG. 822.—SCHEMA OF AORTIC ARCHES OF AN EMBRYO, 9 MM. LONG. (After Tandler, modified.) The second and third arches have atrophied and the transitory fifth has appeared.

arches also move headwards and are transposed from the posterior to the anterior stem, which is simultaneously elongated. When the transposition is completed the condition depicted in Fig. 822 is attained; the most cephalic, or anterior, part of each dorsal aorta is connected with the cephalic end of the heart by the sixth aortic arch; and by the first, second, third, and fourth arches it is connected with a ventral vessel which springs from the cephalic end of the heart. The portion of each dorsal aorta which is caudal to any given arch is called the dorsal root of the arch,

and the portion of the ventral stem which lies caudal to any arch is the ventral root of that arch. The sixth arch has no ventral root, for it arises directly from the heart. Its dorsal root converges towards and meets its fellow of the opposite side about the level of the tenth mesodermal somite, where the two fuse together to form the single dorsal aorta, which becomes the descending aorta of the adult, and which extends caudalwards to the level of the twenty-third somite, where it gives off the umbilical arteries and becomes the middle sacral artery.

By the time the embryo has attained a length of 7 mm. the first two arches have partly disappeared, only their dorsal and ventral extremities being left, and the transitory fifth arch has

been formed. It runs from the ventral root of the fourth arch to the dorsal part of the sixth arch (Fig. 822), persists for a short time, and then disappears.

At a still later period the dorsal roots of the third arches on both sides and the dorsal roots of the fourth and sixth arches on the right side disappear. The vessels which remain form

FIG. 823.—SCHEMA OF PART OF THE ARTERIAL SYSTEM OF A FETUS SEEN FROM THE LEFT SIDE. Parts of the first and second arches, the dorsal roots of the third arches, the dorsal part of the right sixth arch, and the dorsal roots of the right fourth and fifth arches have atrophied. The position of the fifth arch is not indicated; see Fig. 822.

becomes the **common carotid**. The ventral root of the fourth arch on the right side is converted into the **innominate artery**, and the fourth arch of the right side forms part of the **right subclavian artery**, i.e. a portion of that part of the right subclavian artery which lies medial to the vertebral artery. On the left side the ventral root of the fourth arch, and the fourth arch itself and its dorsal root, take part in the formation of the **arch of the aorta**, and the dorsal root of the sixth arch is converted into the most cephalward or anterior portion of the thoracic part of the **descending aorta**; the remainder of the descending aorta being formed by the earlier fusion of the primitive dorsal aortae. Occasionally the dorsal roots of the fourth and sixth arches on the right side persist (see p. 1051), and in such cases the right subclavian artery, of which they form a part, springs from the descending aorta at the level of the fifth thoracic vertebra. It is probable, therefore, that the portion of the descending aorta formed from the dorsal roots of the left fourth and sixth arches is a comparatively small part. The left subclavian artery, which springs from the aortic arch, in the adult, is an intersegmental artery which sprang originally from the primitive dorsal aorta. It may be presumed, therefore, that that portion of the aortic arch which lies dorsal to the origin of the left subclavian artery is formed from the dorsal roots of the fourth and sixth arches of the left side—a presumption which is strengthened by the fact that the **ligamentum arteriosum**, which is a remnant of the left sixth arch, is attached to the opposite border of the aortic arch immediately dorsal to the origin of the left subclavian artery.

The sixth arch on the right side forms part of the extra-pulmonary portion of the right pulmonary artery, the remainder of the extra-pulmonary part of the artery being derived from a branch given off from the right sixth arch to the lung bud.

The ventral part of the left sixth arch becomes absorbed into the stem of the pulmonary artery; therefore the left pulmonary artery is merely the branch from the left sixth arch to the lung bud.

The dorsal part of the left sixth arch forms, during foetal life, the **ductus arteriosus**, which carries the venous blood from the right ventricle of the heart to the aorta. After birth it is converted into the **ligamentum arteriosum**.

The Branches of the External Carotid Artery.—All the typical branches of the external carotid artery are present in embryos 15.5 mm. long; little is known, however, regarding the details of their development. It is probable that the internal maxillary artery and its branches are evolved partly from the ventral part of the first aortic arch and partly from an anastomosis with the branches of a temporary **stapedial artery**, which develops from the dorsal end of the second arch; but it is not known whether the other branches of the external carotid spring as offsets from the ventral roots of the first or second arches or from the ventral parts of the arches themselves.

The Descending Aorta.—The greater part of the descending aorta is formed by the fusion of the primitive dorsal aortae. In embryos about 2.6 mm. long, possessing twenty-three mesodermal somites, the primitive dorsal aortae are fused together from the tenth to the sixteenth segment (Fig. 820). At a later period the fusion is continued caudalwards to the twenty-third body segment—the level of the fourth lumbar vertebra—where the common iliac arteries arise. Still later the small terminal portions of the primitive dorsal aortae fuse together to form the unpaired middle sacral artery, which terminates at the extremity of the coccygeal region.

If the three somites which lie nearest the head end, in embryos possessing twenty-three somites,

the main stems of the permanent arterial system (Figs. 823, 824). The ventral roots of the first and second arches form the **external carotid**. The third arches themselves and the dorsal roots of the second and first arches are converted into the **internal carotids**, which are prolonged headwards into the cerebral region coincident with the growth of the head.

The ventral root of the third arch on each side

are cephalic somites, then the point of commencement of the median aorta would be situated at the level of the seventh body somite, that is, at the situation of the future seventh cervical vertebra. The position of the anterior point of fusion of the primitive dorsal aortæ is indicated in the adult by the origin of the abnormal right subclavian artery, and is situated at the level of the fifth thoracic vertebra; therefore the anterior end of that part of the descending aorta which is formed by the process of the primitive dorsal aortæ must move caudalwards during the developmental period.

The Branches of the Dorsal Aortæ.—Each primitive dorsal aorta gives off a series of dorsal, lateral, and ventral branches. The dorsal branches are distributed to the neural tube and body wall; the lateral branches to the primitive excretory organs—the Wolffian bodies; and the ventral branches pass to the alimentary canal, the yolk-sac, and to the placenta.

The dorsal branches are intersegmental in arrangement, and when they first appear they pass dorsally, in the intervals between the mesodermal somites, supplying the walls of the neural tube and the adjacent mesoderm and nerve ganglia. After a time each primitive dorsal intersegmental artery gives off a ventral branch which passes first laterally and then ventrally in the body wall, towards the ventral median line. At this time each intersegmental artery consists of a stem and a dorsal and a ventral branch. As the ventral part of the body increases in size more rapidly than the neural tube and the vertebral region, the ventral branch of each primitive intersegmental artery soon exceeds in size the dorsal continuation, and simultaneously the stem of each primitive intersegmental vessel enlarges. Thus it is that the stems of the intersegmental arteries and their lateral branches become the trunks of the intercostal and lumbar arteries, whilst the dorsal continuation of each primitive vessel is reduced to the position of a posterior ramus.

The dorsal branches of the intersegmental arteries become connected together by longitudinal anastomosing channels, some of which lie ventral and others dorsal to the rudiments of the transverse processes of the vertebræ. Each ventral branch of an intersegmental artery, as it passes towards the mid-ventral line, gives off a lateral branch to the tissues of the lateral part of the body wall, and at its termination it becomes connected, by longitudinal anastomosing channels, with its more cephalward and caudal neighbours. The lateral branches also become connected by longitudinal anastomoses.

The dorsal branch of each intersegmental artery gives off a neural ramus to the walls of the neural tube, which divides into dorsal and ventral neural branches; these accompany the posterior and anterior roots of the spinal nerves. As the dorsal and ventral neural branches approach the median plane, those of each side become connected together by a longitudinal plexus of fine vessels, and on the ventral surface of the neural tube the longitudinal plexuses of opposite sides are connected together at or near the median plane.

The permanent arteries derived partially or wholly from the primitive dorsal intersegmental arteries and their branches and anastomoses are: (1) The intercostal and lumbar arteries and their posterior or dorsal rami; (2) the subclavian and axillary arteries and their continuations in the upper extremities; (3) the vertebral arteries; (4) the spinal arteries; (5) the basilar artery; (6) the superior intercostal arteries; (7) the internal mammary and the superior and inferior epigastric arteries.

In the cervical region the stems of the first six intersegmental arteries disappear, but the seventh persists and forms, on each side, a portion of the stem of the corresponding subclavian artery. The dorsal branch of the seventh segmental artery and the anastomoses, between it and the first six dorsal branches, which pass ventral to the true transverse processes of the cervical vertebræ, form the vertical part of the vertebral artery of the adult. The neural ramus of the first cervical segmental artery and its preneural branch form the part of the vertebral artery which lies on the atlas and passes to the ventral surface of the medulla oblongata. The cranial or upward prolongation of the vertebral to its union with the basilar is developed from the network of vessels which connects the medial ends of the preneural arteries.

FIG. 824.—SCHEMA OF PART OF THE VASCULAR SYSTEM OF A FŒTUS SEEN FROM THE FRONT. Showing the origin of the positions of the first and second arches, the dorsal roots of the third arches on both sides, and the dorsal roots of the fourth and fifth arches on the right side are shown in dotted lines. The positions of the fifth arches are not shown.

The ventral branch of the seventh cervical segmental artery on each side forms the trunk of the subclavian artery, from the origin of the vertebral to the origin of the internal mammary, and that part of the internal mammary which extends from its origin to the upper margin of the first costal cartilage. The remainder of the internal mammary artery, and the superior and inferior epigastric arteries, are derived from a longitudinal anastomosis which forms between the terminal extremities of the ventral branches of the intersegmental arteries.

The lateral ramus of the ventral branch of the seventh cervical intersegmental artery forms the trunk of the subclavian artery beyond the origin of the internal mammary branch, and from its prolongation into the upper extremity are formed the main arterial stems of the upper limb.

The superior intercostal arteries are derived from longitudinal anastomoses which connect together the lateral rami of the ventral branches of the intersegmental arteries, on the inner sides of the dorsal parts of the ribs.

The anterior and posterior spinal arteries are derived from plexiform anastomoses which form on the dorsal and ventral aspects of the neural tube between the terminal ends of the dorsal and ventral neural branches of the neural rami of the posterior divisions of the intersegmental arteries.

The lateral branches of the primitive dorsal aortæ supply structures derived from the intermediate cell tract, and from them are formed the renal, the suprarenal, the inferior phrenic, and the internal spermatic and ovarian arteries.

The ventral branches of the primitive dorsal aortæ are not definitely segmental or intersegmental in arrangement. In the early stages they pass not only to the gut wall but also, beyond it, to the wall of the yolk-sac. They are connected together by longitudinal anastomosing channels which lie in the dorsal mesentery of the gut and also upon the wall of the gut itself. As the yolk-sac atrophies the prolongations of the ventral branches which pass to its walls disappear and, simultaneously, the portions of the corresponding vessels of opposite sides which lie in the mesentery, dorsal to the gut, and the longitudinal anastomoses which connect them, fuse together to form unpaired stem-trunks from which the three great vessels of the abdominal part of the alimentary canal are derived, namely, the celiac, the superior mesenteric, and the inferior mesenteric arteries; but the original stem of each of these three important vessels is not that which eventually forms its origin from the abdominal part of the aorta, for the celiac artery, which originally arose opposite the seventh cervical segment, wanders caudalwards to the twelfth thoracic segment as the roots of origin of the ventral vessels which are situated nearer the head disappear; and in the same manner the superior mesenteric is transposed from the level of the second thoracic to the level of the first lumbar segment, and the inferior mesenteric wanders from the twelfth thoracic to the third lumbar segment.

The Umbilical and Iliac Arteries.—It was pointed out, in the account of general features of embryology, that the umbilical arteries which carry blood to the placental area of the chorion arise, in a human embryo about 1.38 mm. long, about the level where the fourth cervical mesodermal somite will be developed at a later stage. They spring from plexuses formed, on

FIG. 825.—DIAGRAM SHOWING THE FORMATION OF THE SECONDARY PART OF THE PRIMITIVE UMBILICAL ARTERY.

the lateral walls of the caudal part of the primitive gut, by the anastomosis of some of the most caudally situated ventral or vitelline branches of the primitive dorsal aorta. The origins of the arteries are gradually moved caudally as the embryo grows, until, eventually, they spring from the primitive dorsal aorta, opposite the twenty-third body somite, that is the fourth lumbar segment. As each umbilical artery passes from its origin on the ventral wall of the primitive dorsal aorta to the body-stalk it lies to the medial side of the Wolffian duct. The ventral origin is, however, but temporary; for, by the time the embryo has attained a length of 5 mm., and the primitive dorsal aortæ have fused to form the permanent descending aorta, a new vessel has arisen on each side from the lateral part of the caudal end of the aorta. This new vessel passes ventrally, to the lateral side of the Wolffian duct, and then unites, on a plane ventral to the aorta, with the primitive umbilical artery of the same side. After the union has taken place the ventral origin of the umbilical artery disappears, and the primitive umbilical artery then arises from the side of the caudal end of the aorta. From the newly formed vessel which now constitutes the only origin of the umbilical artery, the inferior gluteal artery, which is the primitive main artery of the lower limb, arises. At a later period, and at a more dorsal level, a second branch arises from the dorsal root of origin of the umbilical artery; this is the second main vessel of the lower extremity, which becomes the external iliac and the femoral arteries of the adult. As soon as the external iliac artery is formed that portion of the umbilical stem which lies dorsal to it becomes the common iliac artery, and the more ventral part, which descends into the pelvis minor, becomes the hypogastric artery. But that portion of the original umbilical artery which runs along the side of the pelvis minor to the ventral wall of the abdomen, then cephalwards to the umbilicus and through the umbilicus to the placenta, is still called the umbilical artery. After birth, when the placental circulation ceases, the greater part of the intra-abdominal portion of the umbilical artery atrophies and

becomes converted into the lateral umbilical ligament, but a portion of the part which lies in the pelvis minor remains pervious and from it springs the superior vesical artery.

The Arteries of the Limbs.—Our knowledge of the development of the arteries of the limbs is still very deficient, but during the last few years some investigations have been made and certain facts have been established. The very earliest stages of development have not yet been seen in the human subject, but it is not probable that they differ, in any essential respects, from those found in other mammals; therefore it may be assumed that the upper limb is supplied, at first, by a number of branches which spring from the sides of the primitive dorsal aortæ. As development proceeds the number of the vessels is reduced until only one remains. This loses its direct connexion with the aorta and becomes attached to the seventh segmental artery forming the ventral branch of that vessel, and the lateral division of the branch; the ventral continuation, past the lateral branch, being, apparently, a later formation. In the earlier stages the portion of the artery which lies in the free part of the limb does not consist of a single stem but of a plexiform series of vessels which only gradually become reduced to a stem. When the stem is definitely established it is divisible into subclavian, axillary, brachial, and volar interosseous portions. The median, the radial, and the ulnar arteries are of later formation.

In the case of the lower limb the earliest known artery is the primitive inferior glutæal, which springs from the secondary root of origin of the umbilical artery. It is converted into the inferior glutæal and popliteal arteries of the adult. The external iliac and femoral arteries are parts of a later formation which arises from the cephalic aspect of the secondary root of the umbilical artery above the origin of the inferior glutæal. This secondary vessel anastomoses distally, at the level of the proximal part of the popliteal fossa, with the primitive inferior glutæal, and, afterwards, the proximal part of the primitive inferior glutæal undergoes a certain amount of atrophy. The developmental history of the arteries of the leg and foot is not definitely known.

The Heart.—The rudiments of the heart are the caudal portions of the primitive ventral aortæ, which lie in the ventral wall of the fore-gut and the dorsal wall of the pericardium; therefore the heart may be said to consist, at first, of two tubes; these two tubes fuse, and the heart is then a single median tube, separated by constrictions into five compartments which, from the caudal to the cephalic end, are the sinus venosus, the atrium, the ventricle, the bulbus cordis, and the truncus arteriosus. The constricted region between the atrium and the ventricle is called the atrio-ventricular canal.

At a later stage the longitudinal tube becomes folded on its long axis and at the same time twisted. The caudal limb of the loop thus produced is formed by the sinus venosus, the atrium, and part of the ventricle; and the cephalic limb by the remainder of the ventricle, the bulbus cordis, and the short truncus arteriosus. Subsequently, for a time, the ventricular and bulbar

FIG. 826.—DEVELOPMENT OF THE HEART.

part of the cephalic limb of the loop become placed transversely (Fig. 827), but after a short period its ventricular extremity again passes caudally until the original cephalic limb of the loop lies to the right and somewhat ventral to the original dorsal limb. Still later, the bulbus cordis is partly absorbed into the truncus arteriosus and partly into the ventricle; the right segment of the sinus venosus is absorbed into the atrium, and the left segment forms the coronary sinus. At a still later period the atrium is divided, by intra-atrial septa, into right and left atria. The atrio-ventricular canal becomes converted into the right and left atrio-ventricular apertures. The ventricle, including the absorbed portion of the bulbus cordis, is

FIG. 827.—VENTRAL VIEW OF A MODEL OF THE HEART OF A HUMAN EMBRYO 2.5 MM. LONG. (Meyer's collection. Modelled by Professor P. Thompson.)

FIG. 828.—DORSAL VIEW OF A MODEL OF THE HEART OF A HUMAN EMBRYO 2.5 MM. LONG. (Meyer's collection. Modelled by Professor P. Thompson.)

separated into the right and left ventricles of the adult heart; and the truncus arteriosus, and the part of the bulbus cordis which becomes incorporated with it, is separated into the ascending aorta and the pulmonary artery. Thus, from the embryonic heart are eventually produced the adult heart, the ascending aorta, the pulmonary artery, and the coronary sinus.

The main outlines of the transformation of the simple tubular heart of the young embryo into the four-chambered heart of the adult are, therefore, comparatively simple, but the details of the process are intricate and some of them are still imperfectly understood.

The Sinus Venosus.—In embryos possessing fourteen mesodermal somites the primitive single heart, formed by the fusion of the caudal portions of the primitive ventral aorta, receives at its caudal end two venous stems, each of which is the common termination of the lateral umbilical vein, the vitelline vein, and the anterior cardinal veins of the same side (Fig. 819). At a later period, after the heart has begun to fold on its longitudinal axis, the two common venous stems are absorbed into the heart and form its most caudal section, the **sinus venosus**, which consists of a right and a left cornu, united by an intermediate segment. In the meantime, however, the posterior cardinal veins have appeared and have united with the anterior cardinals. After this union occurs the portion of the anterior cardinal vein ventral to the point of union becomes the duct of Cuvier. At this period, therefore, each cornu of the sinus venosus receives three veins—the vitelline vein, the lateral umbilical vein, and the duct of Cuvier.

As development proceeds the left vitelline vein and the left lateral umbilical vein lose their connexion with the left horn of the sinus venosus and pour their blood into the liver, through which it reaches the cephalic end of the right vitelline vein. The latter in the meantime has become the only outflow from the liver to the heart, and it ultimately forms the terminal part of the inferior vena cava. In association with these changes the right horn of the sinus venosus becomes considerably larger than the left horn (Fig. 828), and the left horn and the intermediate portion of the sinus become reduced to the form of a comparatively narrow channel which opens into the right horn, whilst the latter opens into the dorsal part of the atrial chamber, by a cleft-like aperture which is bounded by right and left lateral lips called the **right and left venous valves** (Figs. 829, 830).

As the right horn of the sinus venosus is absorbed into the right part of the dorsal portion of the atrium the caudal or lower portion of right venous valve becomes the valve of the inferior vena cava and the valve of the coronary sinus. The cephalic or upper portion is united with a septal projection into the cavity of the atrium called the **septum spurium**, and forms with it the **crista terminalis** of the completed heart, which indicates, therefore, the line of union of the right horn of the sinus with the atrium proper. The left venous valve becomes incorporated with the interatrial septum, and the angle in the posterior wall of the sinus venosus which indicates the line of union of the right cornua and the intermediate part of the sinus appears in the dorsal wall of the right atrium, where it unites with the dorsal part of the caudal or inferior portion of the septum secundum of the atrium, and takes part in the formation of the **limbus ovalis**.

Whilst these changes have been proceeding the right duct of Cuvier has become the lower part of the superior vena cava, the intermediate part of the sinus venosus and the left cornu are transformed into the coronary sinus, and the left duct of Cuvier has become the oblique vein of the left atrium. Thus when the changes mentioned are completed the right part of the atrium receives the superior and the inferior vena cava and the coronary sinus.

The Atrio-ventricular Canal.—In the early stages the atrio-ventricular canal opens through the dorsal wall of the ventricular chamber towards the left side, but, as the ventricle increases in size, the atrio-ventricular opening moves to the right till it occupies the middle part of the dorsal wall of the ventricle. Whilst the change in position is occurring the atrio-ventricular canal becomes compressed into a transverse cleft which is bounded by a cephalic (upper in adult position) and a caudal wall. On the middle part of each of these walls an endocardial thickening appears which is called an **endocardial cushion**. Each cushion is a flattened eminence, and when the two eminences meet and fuse the atrio-ventricular canal is divided into right and left portions, of which the right portion forms a passage from the right part of the still incompletely divided atrium into the right portion of the incompletely divided ventricle, and the left portion in a similar manner forms a channel of communication between the left part of the atrial chamber and the left part of the ventricle. These two parts of the primitively single atrio-ventricular canal become the right and left atrio-ventricular apertures of the adult heart, and the margins of the apertures take part in the formation of the cusps of the atrio-ventricular valves.

FIG. 829.—SECTION OF THE HEART OF A HUMAN EMBRYO. (Edinburgh University collection.)

The Division of the Atrium.—It has already been pointed out that as the tubular heart bends on its long axis the atrial chamber forms part of the dorsal limb of the loop. It lies, therefore, dorsal to the truncus arteriosus and the bulbus cordis, and retains this position throughout all the later stages of development; consequently, it forms the dorsal part or base of the fully developed heart. It has been stated also that, as development proceeds and the atrial chamber expands, the right horn of the sinus venosus is absorbed into the right segment of the dorsal portion of the expanding atrium. Whilst this process of absorption of the sinus venosus is proceeding two other events are taking place: (1) The right and left margins of the atrium grow

FIG. 830.—MODEL SHOWING THE INTERIOR OF THE RIGHT ATRIUM OF A HUMAN EMBRYO 5.5 MM. LONG. (Edinburgh University collection. Modelled by C. C. Wang.)

ventrally round the sides of the truncus arteriosus and the adjacent part of the bulbus cordis; and (2) the primitive atrium is divided into the right and left permanent atria by the formation of two interatrial septa.

By the ventral growth of the right and left margins of the atrium the auricles of the right and left permanent atria are formed, and by the formation and fusion of the two interatrial septa the permanent interatrial septum of the fully developed heart is established.

The septa by which the atrial chamber is divided are the **septum primum** and the **septum secundum**; so named because the first appears and partly disappears before the second is formed.

Both the septum primum and the septum secundum grow from the dorsal towards the ventral wall of the primitive atrium, the septum secundum to the right of the septum primum.

When the septum primum reaches the ventral wall of the atrium it fuses with the dorsal ends of the endocardial cushions of the atrio-ventricular canal. Until this fusion occurs an aperture, the *primary foramen ovale*, exists between the two atria and a number of perforations are formed in the more dorsal portion of the septum; therefore the passage of blood from the inferior vena cava through the right part of the atrium into the left part is never prevented.

The perforations eventually blend together to form the *secondary foramen ovale* of the interatrial septum. As soon as the septum primum is completed the primitive atrium is divided into the permanent right and left atria, each of which communicates through the secondary foramen ovale, with the atrium of the opposite side and with the corresponding portion of the ventricle through an atrio-ventricular aperture which is completely separate from its fellow of the opposite side.

As the ventral border of the septum primum fuses with the endocardial cushions of the atrio-ventricular canal, the septum secundum appears immediately to the right of the septum primum. It grows from the dorsal and cephalic (superior in adult) walls of the atrium. As the septum secundum develops, the right cornu of the sinus venosus is absorbed into the atrium, the left venous valve fuses with the septum primum or disappears, and the angle between the right horn and the intermediate part of the sinus appears in the caudal part of the dorsal wall of the right atrium. As the septum secundum in-

FIG. 831.—VIEW OF THE INTERIORS OF THE RIGHT AND LEFT ATRIA OF A HUMAN EMBRYO 5.5 MM. LONG. (Edinburgh University collection. Modelled by C. C. Wang.)

creases in size its cephalic part grows first ventrally and then caudally and lastly dorsally; consequently the free border soon becomes concave and the concavity of its margin is directed dorsally.

Both extremities of the free margin of the septum secundum fuse with the right lateral surface of the septum primum, and the more ventrally situated part of the border, growing along the

FIG. 832.—DEVELOPMENT OF THE HEART AND THE MAIN ARTERIES.

Diagram of the heart, showing the formation of its septa, and of the cephalic portion of the arterial system

septum primum, fuses with the angle between the right horn and the intermediate part of the sinus venosus forming with it the lower part of the limbus fossæ ovalis of the fully developed heart. The remainder of the limbus is formed by the thickened free margin of the septum secundum.

As soon as the septum secundum passes beyond the level of the foramen ovale that portion

of the dorsal part of the septum primum which is not yet fused with the septum secundum acts as a flap valve, permitting blood to pass from the right to the left atrium, but preventing its return. This condition persists until birth, when the thickened free margin of the septum secundum fuses with the right lateral face of the septum primum, and the foramen ovale of the foetus becomes the fossa ovalis of the child. The fossa ovalis is bounded ventrally and caudally (anteriorly and inferiorly) by the limbus fossæ ovalis, which is formed mainly by the originally free margin of the septum secundum, but to a small extent also by the angle between the right cornu and the intermediate part of the sinus venosus.

The Division of the Primitive Ventricle, the Bulbus Cordis, and the Truncus Arteriosus.—Two facts have already been pointed out with regard to the bulbus cordis; firstly, that it forms part of the cephalic or anterior limb of the early loop-shaped heart, and secondly, that it disappears by being absorbed partly into the ventricle and partly into the truncus arteriosus. The part absorbed into the ventricle enters into the formation of that part of the ventricle which afterwards becomes the right ventricle of the completed heart, and the part absorbed into the truncus arteriosus lengthens that trunk.

The division of the elongated truncus arteriosus into the pulmonary artery and the ascending aorta is a complicated process in which three factors are associated: (1) a proximal and (2) a distal set of endocardial swellings in the bulbar part of the truncus aorticus, which are known as the proximal and distal bulbar swellings, and (3) a septum called the aorto-pulmonary septum, which appears at the cephalic end of the truncus aorticus, growing from the angle between the orifices of the more dorsally situated sixth aortic arches, and the orifices of the two stems which form the ventral roots of the first four aortic arches. The three sets of elements are, at first, entirely distinct from one another, but ultimately they blend together to form a spiral septum by which the lumen of the truncus arteriosus is divided into two channels. One of these channels communicates with the right ventricle and the other with the left ventricle. After the septum is completed it is cleft longitudinally into two parts, and so the truncus is divided into two vessels, the pulmonary artery which communicates with the right ventricle, and the aorta which is connected with the left ventricle.

The proximal bulbar swellings, which take part in the separation of the truncus into pulmonary artery and aorta are prolonged into the ventricular region as the ventral part of the bulbus cordis is absorbed into the ventricle, consequently the septum which they form by their fusion is prolonged into the ventricular chamber, and helps to separate that cavity into two parts, by fusing with the dorsal end of the cephalic or anterior portion of the interventricular septum.

The **interventricular septum** appears as a semilunar ridge on the inner surface of the ventral part of the wall of the ventricle. At a later period its position is marked on the outer surface of the ventricle by the **interventricular sulcus** (Fig. 829) which persists in the completed heart. As the interventricular septum increases in height it fuses with the fused endocardial cushions which divided the atrio-ventricular canal into right and left parts, and with the ventral border of the bulbar septum which projects into the dorsal part of the ventricular chamber. The completed interventricular septum consists, therefore, of two distinct parts: a ventral part formed by the proper interventricular septum, and a dorsal part formed by the lower portion of the fused bulbar endocardial cushions. The two parts can be distinguished quite easily in the adult heart, for the interventricular septum is muscular, and it forms by far the greater part of the permanent septum, whilst the bulbar part of the septum, being developed from endocardial thickenings, is membranous, and it forms the small pars membranacea of the permanent septum, which lies between the aortic vestibule of the left ventricle and the upper part of the right ventricle and the adjacent lower part of the right atrium.

DEVELOPMENT OF THE VEINS.

Simultaneously with the formation of the arteries, by which blood is distributed to the embryo and to all parts of the zygote, and in a similar manner, a series of vessels is developed by means of which the blood is returned to the heart. These vessels are the **primitive veins**; they form two main groups which make their appearance at different periods.

The *first group* consists of (1) the **vitelline veins**, and (2) the **umbilical veins** which return the blood from the placenta.

The *second group* consists of (1) the **anterior cardinal veins**, (2) the **posterior cardinal veins**, the (3) **ducts of Cuvier**, and (4) the **subcardinal veins**.

The ducts of Cuvier, one on each side, are the common stems by which the blood of the anterior and posterior cardinal veins is conveyed to the primitive heart. The anterior cardinal vein returns blood from the head and neck and fore limbs. The posterior cardinal veins carry blood from the body walls, the Wolffian bodies, and the hind limbs. The subcardinal veins also are closely associated with the return of blood from the Wolffian bodies.

The veins of the first group are largely transitory. The umbilical veins entirely disappear as blood channels, but a part of the left lateral umbilical vein is recognisable in the adult as the ligamentum teres of the liver. Portions of the intra-embryonic parts of the vitelline veins, and anastomoses which form between them, remain as the portal vein, its right and left branches, and the upper end of the inferior vena cava.

The anterior cardinal veins, and a transverse anastomosis which forms between them in the more cephalward or upper portion of the thoracic region, are converted into the (1) cavernous sinuses of the cranium, (2) the internal jugular veins, (3) the innominate veins, (4) the upper part of the superior vena cava, and (5) the upper part of the left superior intercostal vein. The

other venous channels of the cranium and the head and neck and the upper extremities are later formations.

The right duct of Cuvier forms the inferior half of the superior vena cava, and the left duct of Cuvier becomes the oblique vein of the left atrium.

The posterior cardinal veins take part in the formation of the inferior vena cava, the azygos, hemiazygos, and accessory hemiazygos veins, and the hypogastric veins. The right subcardinal takes part in the formation of the inferior vena cava, and an anastomosis between the right and left subcardinal veins forms a large part of the left renal vein.

The Vitelline and Umbilical Veins and their Association with the Formation of the Portal System and the Upper End of the Inferior Vena Cava.—The vitelline veins, left and

FIG. 833.—SCHEMATA, showing four stages of the development of the portal system and part of the inferior vena cava.

right, pass over the wall of the yolk-sac, and, later, along the sides of the vitello-intestinal duct and the duodenum towards the caudal end of the heart. For a time each unites with the corresponding lateral umbilical vein to form a common stem, but at a later period each vitelline vein opens separately into the corresponding cornu of the sinus venosus of the heart.

The umbilical veins are three in number—the *vena umbilicalis impar*, which passes first along the body stalk, and later along the umbilical cord, and divides into the *right* and *left lateral umbilical veins*, which run, in the edges of the body wall, along the margin of the umbilical orifice to their union first with the corresponding vitelline veins, and later with the corresponding cornua of the sinus venosus of the heart.

On their way to the heart, both the vitelline and the lateral umbilical veins pass through

the mass of mesoderm, called the septum transversum, which lies in the cephalic margin of the umbilical orifice and at the caudal end of the pericardium. The septum transversum afterwards takes part in the formation of the diaphragm, the liver, the falciform ligament of the liver and the lesser omentum. As the liver is formed from it the cardiac ends of the vitelline and lateral umbilical veins become enclosed in the liver substance, and pour their blood into a number of freely communicating channels or *sinusoidal spaces*, which form by far the greater portion of the liver in the early stages of its development.

Whilst the formation of the sinusoidal spaces is occurring in the liver, the parts of the fore-gut have been defined, and the vitelline veins, as they approach the growing liver, pass along the sides of the duodenum and become connected around it by three transverse anastomoses, two of which lie ventral and one dorsal to the duodenum. Cephalwards of these anastomoses each vitelline vein is broken up by the formation of the sinusoidal channels in the liver substance, into a caudal part, the *vena advehens*, which enters the liver substance, and a cephalic part, the *vena revehens*, which passes from the liver to the heart. After a time the left vena revehens loses its direct connexion with the heart, moves across towards the right, and opens into the cephalic end of the right vena revehens. When this change has occurred all the blood passing to the liver by the vitelline veins reaches the heart by the cephalic extremity of the right vena revehens, which now becomes the upper end of the inferior vena cava. This also receives the ductus venosus—a new channel, which is evolved from the sinusoidal spaces, and carries the major part of the blood from the left lateral umbilical vein to the upper end of the inferior vena cava.

In the meantime degeneration takes place in the ventral and caudal parts of the vitelline veins and the loops formed by the three transverse anastomoses between them. The ventral parts of the veins disappear with the degeneration of the yolk-sac, and the right half of the caudalward and the left part of the more cephalward situated loops also disappear. Simultaneously the superior mesenteric vein, which has been evolved in association with the formation of the intestine from the mid-gut, opens into the left vitelline vein caudal to the dorsal transverse anastomosis, and, a little later, the splenic vein enters at the same point. The final result is the formation of the permanent *vena portæ*, which is formed from (1) the cephalic end of the left limb of the caudal loop between the vitelline veins; (2) the dorsal anastomosis between the vitelline veins; (3) the right limb of the cephalic loop formed by the vitelline veins. The right branch of the portal vein is the right vena advehens. The left branch of the portal vein is formed from the left vena advehens, and the most cephalward of the two ventral anastomoses between the vitelline veins. It is connected with the ligamentum teres of the liver, because the left lateral umbilical vein, which opened at one time into the left horn of the sinus venosus of the heart, and afterwards into the sinusoids of the liver, finally becomes connected with the left vena advehens, at the level of the cephalward ventral anastomosis between the two vitelline veins; and it is connected with the ductus venosus so that a channel may exist by which the blood from the placenta can pass to the right vena revehens without much admixture with the venous blood passing to the liver through the left branch of the portal vein and the left vena advehens. Therefore the ductus venosus is developed from the sinusoidal spaces of the liver when the left lateral umbilical vein is transferred to the left vitelline vein.

The *venæ revehentes*, which transfer the blood from the liver to the heart, are the cephalic ends of the primitive vitelline veins. The left vena revehens, as already stated, eventually loses its connexion with the heart and ends in the right vena revehens, which receives the ductus venosus also. The right vena revehens thus becomes the only channel by which blood is returned to the heart from the alimentary canal and from the placenta: that is, it becomes the upper or cephalic end of the inferior vena cava. The stems of the right and left *venæ revehentes* become the right and left hepatic veins which convey to the inferior vena cava the blood which was carried from the alimentary canal to the liver by the portal vein and its branches.

The sinusoidal spaces become reduced to the blood capillaries of the liver, and the ductus venosus which, during fetal life, conveyed the greater part of the placental blood to the inferior vena cava becomes reduced, after birth, to the ligamentum venosum, which connects the left branch of the portal vein with the upper end of the inferior vena cava.

As the cephalic part of the right vitelline vein is transformed from the right vena revehens into the upper end of the inferior vena cava, an outgrowth passes caudally from it, along the dorsal aspect of the liver; this becomes connected, at its caudal end, with the right subcardinal vein, and it forms that part of the inferior vena cava which lies in the groove on the dorsal aspect of the right lobe of the liver.

The Umbilical Veins.—In the earliest stages of development there are three umbilical veins, the vena umbilicalis impar and the left and right lateral umbilical veins. The vena umbilicalis impar and the left lateral vein persist until birth, and a remnant of the latter is found, in the adult, as the ligamentum teres of the liver; the right lateral vein disappears entirely at an early stage of development.

The vena umbilicalis impar passes from the placenta to the caudal boundary of the umbilical orifice, where it terminates in the left and right lateral umbilical veins. Each of the latter unites, for a time, with the corresponding vitelline vein; then it becomes directly connected with the corresponding cornu of the sinus venosus of the heart, and still later with sinusoidal spaces of the liver. The right lateral umbilical vein has also a temporary secondary connexion with the right vitelline vein, but at an early period it undergoes atrophy and all parts of it completely disappear.

The left lateral umbilical vein, which is connected first with the left vitelline vein, next with the heart, still later with the liver, and finally with the left vitelline again, at the point where

the latter becomes the left vena advehens, persists until birth and, after the disappearance of the right lateral umbilical vein, it conveys the blood from the placenta to the liver, where part of the placental blood passes into the left vena advehens and so through the left vena revehens to the inferior vena cava, and part passes into the ductus venosus, by which it reaches that portion of the cephalic part of the right vena advehens which becomes the cephalic or upper end of the permanent inferior vena cava.

After birth when the placental circulation ceases the left lateral umbilical vein becomes the ligamentum teres of the liver.

The Ductus Venosus.—The ductus venosus is developed as the right lateral umbilical vein loses its direct connexion with the liver and becomes united to the left vena advehens. It is formed from the sinusoidal spaces of the rudimentary liver and connects the commencement of the left vena advehens with the cephalic part of the right vena revehens. It forms the more direct channel by which blood from the placenta is passed to the heart through that part of the right vena revehens which becomes the upper end of the inferior vena cava. After birth it is converted into the fibrous ligamentum venosum, which connects the left branch of the portal vein with the upper end of the inferior vena cava.

The Anterior Cardinal Veins.—The anterior cardinal veins are the veins by which the blood is returned to the heart from the head and neck and, ultimately, that from the upper extremities, although the primitive veins of the upper extremities are, in the first place, tributaries of the posterior cardinal veins.

FIG. 834.—SCHEMA OF THE DEVELOPMENT OF THE PRIMITIVE CEREBRAL VEINS AND CRANIAL BLOOD SINUSES. A, side view; B, dorsal view. Stage I. (After Mall, modified.)

Each anterior cardinal vein may be separated into two parts—the intra-cranial and the extra-cranial. From the intra-cranial portions and their associated tributaries and anastomoses are developed some of the cranial blood sinuses and their tributaries; and from the extra-cranial portions and their anastomoses are formed the internal jugular veins, the innominate veins, the upper or cephalic parts of the superior vena cava and the left superior intercostal vein.

FIG. 835.—SCHEMA OF THE DEVELOPMENT OF THE PRIMITIVE CEREBRAL VEIN AND THE CRANIAL BLOOD SINUSES. A, dorsal view; B, side view. Stage II. (After Mall, modified.)

The intra-cranial portion of each anterior cardinal vein is called the *vena capitis medialis*, because it lies to the medial side of the otic vesicle and the fifth cerebral nerve. The cerebral extremities of the veins of opposite sides are associated with the developing cerebral hemispheres,

and each receives tributaries from the corresponding hemisphere and from the optic vesicle of the same side.

After a short time an anastomosing channel appears which connects the intra-cranial part of each anterior cardinal vein with the extra-cranial part. This channel is called the *vena capitis*

FIG. 836.—SCHEMA OF THE DEVELOPMENT OF THE PRIMITIVE CEREBRAL VEINS AND THE CRANIAL BLOOD SINUSES. Stage III. A, dorsal view; B, side view. (After Mall, modified.)

lateralis. It arises from the intra-cranial portion of the anterior cardinal vein, immediately caudal (posterior) to the semilunar ganglion of the trigeminal nerve; passes lateral to the otic vesicle, and leaves the cranium with the facial nerve. The caudal part of the intra-cranial portion of the anterior cardinal vein, which lies medial to the otic vesicle, then disappears. The part of the anterior cardinal vein which lies medial to the semilunar ganglion persists, and, up to the point where the vein from the optic vesicle joins it, it becomes the cavernous sinus. The remainder of the intra-cranial part of the anterior cardinal vein, which receives numerous tributaries from the cerebral hemisphere, then becomes the **primitive anterior cerebral vein**, and the vein from the optic vesicle becomes the **ophthalmic vein**.

In the meantime, however, two outgrowths are projected dorsally from the *vena capitis* **lateralis**, one from its junction with the intra-cranial part, and the other from its junction with the extra-cranial part of the anterior cardinal vein. The anterior of the two lies anterior to the otic vesicle, and passes towards the cerebellar part of the hind-brain and is known as the **primitive middle cerebral vein**. The other lies posterior or caudal to the otic vesicle and passes towards the caudal part of the hind-brain; it is called the **primitive posterior cerebral vein**. Subsequent to the formation of the primitive middle and posterior cerebral veins the lateral cerebral vein disappears.

After the condition above described is evolved, the tributaries which join each anterior cerebral vein become connected together, along the dorsal border of the hemisphere of the cerebrum by a longitudinal anastomosis which is the forerunner of the **superior sagittal sinus**. The superior sagittal sinus is therefore primitively double, but the right and left lateral halves soon fuse together to form a single median vessel. In the meantime, however, the tributaries which connect each half of the sagittal sinus with the corresponding

FIG. 837.—SCHEMA OF DEVELOPMENT OF THE PRIMITIVE CEREBRAL VEINS AND THE BLOOD SINUSES OF THE CRANIUM. Side view. Stage IV. (After Mall, modified.)

anterior cerebral vein atrophy in the middle parts of their lengths. The upper portions then become the **superior cerebral veins**, which terminate in the superior sagittal sinus, and the lower portions become the inferior cerebral veins. These open into the primitive anterior cerebral vein which lies in the lateral fissure of the hemisphere and becomes the medial cerebral vein of the adult. Very commonly one of the intercommunicating tributaries persists in the whole of its length and so becomes the **great anastomotomic vein** (Trolard).

The dorsal longitudinal anastomosis extends caudally on each side, beyond the fusion by which the median unpaired sagittal sinus is formed, and connects the sagittal sinus with the tributaries of

FIG. 838.—SCHEMA OF THE DEVELOPMENT OF THE PRIMITIVE CEREBRAL VEINS AND THE CRANIAL BLOOD SINUSES. Stage IV. Dorsal view. (After Mall, modified.)

the primitive middle and the posterior cerebral veins. This portion of the anastomosis becomes displaced caudally and laterally by the extending cerebral hemispheres, and it becomes converted, on each side, into the horizontal part of the **transverse sinus**, the sigmoid part of the transverse sinus being formed from the primitive posterior cerebral vein. At the same time the primitive middle cerebral vein becomes the superior petrosal sinus; and the inferior petrosal sinus is formed as a new structure which lies in the position of the original vena capitis medialis, but does not appear to be formed from it.

The extra-cranial parts of the anterior cardinal veins become connected together, in the upper or cephalic part of the thoracic region, by a transverse anastomosis which becomes the greater part of the left innominate vein. A short distance cephalwards of this transverse connexion, the primitive vein of the upper limb ultimately opens into the anterior cardinal vein. The portion of the anterior cardinal vein of the right side, which lies between the entrance of the limb vein and the transverse anastomosis, becomes the **right innominate vein** (Fig. 839), and the corresponding part on the left side forms the commencement of the **left innominate vein**.

The part of the extra-cranial portion of the entrance of the limb vein forms the **internal jugular vein**; and the part of the right anterior cardinal vein which lies caudalwards of the transverse anastomosis becomes the upper or cephalic part of the **superior vena cava**, whilst the corresponding portion of the left vein is converted into the upper part of the **left superior intercostal vein** (Fig. 839).

The **external jugular vein** is a new formation which receives for a time the cephalic vein of the upper extremity; but the cephalic vein, which is a secondary vessel, is eventually transposed to the axillary vein, which is a part of the primitive upper limb vein.

The Posterior Cardinal Veins, the Subcardinal Veins, and the Inferior Vena Cava.—The posterior cardinal veins appear later than the anterior cardinal veins and they terminate cephalwards in the ducts of Cuvier. They lie dorsal to the Wolffian bodies and they become connected with each other, dorsal to the descending aorta, by numerous transverse anastomoses.

The subcardinal veins appear later than the posterior cardinals. They lie along the ventral borders of the Wolffian bodies and they are connected not only by dorso-ventral anastomoses with the posterior cardinal veins, but also by transverse anastomoses with each other. The majority of both sets of anastomosing vessels ultimately disappear, but two remain; one which joins the right subcardinal to the right posterior cardinal, at the level of the right renal vein; and one which connects the subcardinal veins together, across the ventral surface of the aorta, at the same level.

After a time an anastomosis is formed between the right subcardinal vein and the cephalic end of the right vena revehens, dorsal to the liver, by the caudal outgrowth of an anastomosing offset from the right vena revehens. As soon as the anastomosis is completed the blood from the caudal portion of the body and from the lower limbs is short circuited to the heart, and extensive changes occur in the primitive posterior cardinal veins, into which in the meantime the veins from the lower extremities have opened.

The Posterior Cardinal Veins.—The right posterior cardinal vein, cephalwards of the right renal vein, becomes the vena azygos. Between the right renal vein and the entrance of the lower limb vein it forms the caudal or lower part of the **inferior vena cava** and the **right common iliac vein**; the remainder of the right posterior cardinal vein becomes the **right hypogastric vein**.

Two of the transverse anastomoses between the posterior cardinal veins form the transverse parts of the **hemiazygos** and **accessory hemiazygos veins**; others become converted into those parts of the **left lumbar veins** which lie dorsal to the aorta, and one, which lies opposite the fifth lumbar somite, becomes the greater part of the **left common iliac vein**.

Portions of the left posterior cardinal vein remain as the left hypogastric vein, the hemiazygos and the accessory hemiazygos veins and the lower part of the left superior intercostal vein.

The tributaries of the right posterior cardinal vein become the right intercostal, subcostal, and the right lumbar veins. The right renal vein is also one of its tributaries. The tributaries of the left posterior cardinal become the left intercostal and subcostal veins, and they form those

FIG. 839.—DIAGRAM OF THE COURSE OF THE FŒTAL CIRCULATION.

parts of the **left lumbar veins** which lie to the left of the vertebral column, and the corresponding part of the **left renal vein** (Fig. 839).

The Subcardinal Veins.—The only important parts of the subcardinal system which remain in the adult are a portion of the right subcardinal vein, one of its anastomoses with the right posterior cardinal vein, and a transverse anastomosis between the subcardinal veins. The last forms the part of the left renal vein which crosses the front of the abdominal part of the aorta, and the first two form that part of the inferior vena cava which extends from the liver to the entrance of the renal veins.

The Inferior Vena Cava.—It follows, from what has been said, that the inferior vena cava is

a composite vessel derived from five sources: (1) the cephalic end of the right vitelline vein; (2) a caudal outgrowth from the cephalic part of the right vitelline vein; (3) a portion of the right subcardinal vein; (4) an anastomosis between the right subcardinal vein and the right posterior cardinal vein; and (5) a portion of the right posterior cardinal vein.

The Veins of the Extremities.—The primitive veins of the extremities are superficial veins which run along the corresponding borders of the two limbs, *i.e.* the ulnar border of the upper and the fibular border of the lower limb.

The **primitive vein** of the upper extremity, which becomes the **basilic vein**, the **axillary vein**, and the **subclavian vein** in different regions, opens at first into the posterior cardinal vein, afterwards into the duct of Cuvier, and finally into the anterior cardinal vein.

The **cephalic vein** of the upper extremity appears at a later period and, in the first instance, joins the external jugular vein, the primitive termination being occasionally retained in adult life. At a later period its terminal extremity is transferred to the axillary vein.

The **deep veins** which accompany the arteries are the latest venous formations of the extremities.

The primitive vein in the lower extremity becomes the **small saphenous vein**, which is continued proximally, as the **inferior gluteal vein**, to that part of the posterior cardinal vein which later becomes the hypogastric vein. The **great saphenous vein** and the **femoral vein** appear later and are continued to the posterior cardinal vein as the **external iliac vein**. After the external iliac vein joins the posterior cardinal vein the part of the latter vessel which lies caudal to the point of union is called the hypogastric vein.

THE DEVELOPMENT OF THE LYMPH VASCULAR SYSTEM.

Very little is known regarding the origin of the vessels of the lymph vascular system in man, but during recent years numerous investigations have been made with the object of discovering the various phases of the development of the lymph vascular system in other mammals; some of the main points are however still subjects of dispute.

It is generally admitted that the terminal parts of the great lymph vessels, that is, the terminal part of the thoracic duct and the right lymphatic duct, are derived from venous channels, which, for a time, lose their connexion with the larger veins and become modified into terminal lymph sacs which obtained a secondary union with the great veins at the root of the neck; but regarding the origin of the thoracic duct and the cisterna chyli and the peripheral lymph vessels there is, as yet, no agreement. According to Florence Sabin, and those who agree with her, the peripheral lymph vessels are outgrowths from a series of lymph sacs of which the two cervical, a retro-peritoneal, a cisterna chyli, and two posterior sacs, lying along the inferior gluteal veins, are recognised in human embryos of about 24 mm. length. The origin of these sacs, in the human embryos, has not been proved, but it appears probable that the cervical sacs are derived as in other mammals from venous capillary vessels. There is no agreement, however, concerning the origin of the other sacs, for whilst, on the one hand, Florence Sabin appears to believe that they have an origin like that of the jugular lymph sacs and that the thoracic duct is developed in the same manner, Huntington, on the other hand, believes that, with the exception of the jugular or cervical lymph sacs, all the other lymph vessels, including the thoracic duct, are developed neither as outgrowths from lymph sacs nor by the modification of venous capillaries, but by the formation of endothelial lined spaces in the mesodermal tissues. The spaces are at first entirely closed but afterwards attain union with each other and with the terminal lymph vessels.

According to the view upheld by Florence Sabin and her supporters, the lymph vessels are outgrowths of lymph spaces derived from the venous system, and are, therefore, lined with endothelium which is genetically the same as that in the veins. According to Huntington this is not the case; for his observations lead him to believe that the endothelium of the lymph vessels is formed, *in situ*, from the mesodermal cells, and it has, therefore, no direct genetic connexion with the endothelium of the veins, which is derived from the original angioblast. The evidence brought forward by the supporters of the opposite views is interesting and instructive upon many points, and the balance at present appears to be in favour of Huntington's contention.

The Development of Lymph Glands.—Lymph glands are developed from plexuses of lymph vessels. The transformation is brought about by the aggregation of numerous lymphocytes in the connective tissue strands of the plexuses and the transformation of the lumina of the vessels into the peripheral and central portions of the lymph sinus. The stroma, the capsule, and the proper substance of a lymph gland are therefore formed from the fibro-cellular reticulum of the lymphatic plexus, and the cavity of the lymph sinus is formed from the lumina of lymph capillaries. The rudimentary lymph glands possess blood vascular as well as lymphatic capillary networks, and if the blood vascular network preponderates over the lymph vascular the developing gland has a reddish appearance and is known as a *hæmal gland*. Such glands are found in man (Schäfer) as well as in other mammals, and it would appear from the recent observations of S. v. Schumaker that hæmal glands are merely rudimentary forms of true lymph glands (*Arch. f. mikr. Anat.* H. 2., 1912).

MORPHOLOGY OF THE VASCULAR SYSTEM.

In conformity with the general plan of the vertebrate body, the vascular system is essentially segmental in character. This is obvious, even in the adult, in the intercostal and lumbar vessels. It is distinguishable, though less obvious, in the vessels of the head and neck and of the pelvis.

The segmental arteries and veins form a series of bilaterally symmetrical vessels, each of which is united to the vessels of adjacent segments by intersegmental channels, which anastomose with one another, through the portions of the segmental vessels which they connect together, and thus form longitudinal trunks. The longitudinal trunks are mainly, though not exclusively, intersegmental. From them the main stem vessels of the individual are formed, and from or to these latter the segmental vessels appear to proceed as branches or tributaries.

In the course of development the longitudinal trunks become the most important trunks in the individual, and they are formed before the segmental vessels make their appearance.

THE SEGMENTAL ARTERIES AND THEIR ANASTOMOSES.

The main longitudinal trunks are the primitive aortæ. The descending aorta is formed, in the

greater part of its extent, by the fusion of the dorsal parts of

the primitive aortæ, and from it the intersegmental, lateral, and ventral arteries arise in pairs.

In a typical segment of the body of the embryo there are three arteries on each side. One arises from the dorsal surface of the primitive dorsal aorta, *i.e.* from the dorsal longitudinal trunk, and runs laterally and ventrally in the tissues developed from the somatic mesoderm; it is distributed to the body wall, including the vertebral column and its contents, and is termed a **somatic intersegmental artery**. A second vessel arises from the side of the primitive dorsal aorta; it is distributed to the structures developed from the intermediate cell mass, *viz.*, the suprarenal gland, the kidney, and the ovary or the testis, and it is accordingly termed a **lateral or an intermediate visceral artery**. The third artery, which is known as the **splanchnic artery**, springs from the ventral surface of the aorta. It runs in the tissues developed from the splanchnic

mesoderm, and supplies the wall of the alimentary canal.

The **somatic intersegmental arteries** form, in the early embryo, a regular series of paired vessels throughout the cervical, thoracic, lumbar, and sacral regions. It is, however, only in the

thoracic and lumbar regions that their original characters are retained. The paired vessels pass dorsally, by the sides of the vertebræ, and divide into dorsal and ventral branches which accompany the corresponding anterior and posterior divisions of the spinal nerves.

The **ventral branches** run ventro-laterally between the ribs, in the thoracic region, and in corresponding positions in the lumbar region, and together with the stems they form the main parts or trunks of the vessels in the thoracic and lumbar regions. They are connected together, near their commencements, by a series of pre-costal anastomoses which pass in front of the necks of the ribs, and they are also connected together, near their terminations, by ventral anastomosing channels which run, in the thoracic region, behind the costal cartilages, and in the lumbar region behind or in the substance of the rectus abdominis muscle. Each ventral branch gives off a lateral offset which is distributed like the lateral cutaneous branch of a spinal nerve, and together with the stem of the intersegmental artery it forms the trunk of an intercostal or lumbar artery in the adult.

The **dorsal branches**, which are present before the ventral branches, run dorsally between the transverse processes of the vertebræ, and form the posterior branches of the intercostal arteries and the dorsal branches of the lumbar arteries of the adult; they are connected, behind the necks of the ribs, by post-costal anastomoses, and again, behind the transverse processes of the vertebræ, by post-transverse anastomosing channels. Moreover, each dorsal branch, as it passes by the corresponding intervertebral foramen, gives off a spinal offset which enters the spinal canal, along the corresponding nerve-root, and divides into a dorsal, a ventral, and a neural branch. The

FIG. 842.—DIAGRAM SHOWING THE ARRANGEMENT AND COMMUNICATIONS OF THE SEGMENTAL AND INTERSEGMENTAL ARTERIES AT AN EARLY STAGE OF DEVELOPMENT.

C, Cœlum; IN, Intestine.

dorsal branches of these spinal arteries are connected together along the ventral surfaces of the laminae by pre-laminar anastomoses, and the ventral branches are united on the dorsal surfaces of the vertebral bodies (or centra) with their fellows above and below by post-central anastomoses; they are also united with their fellows of the opposite side by transverse communicating channels. The neural branches of the spinal arteries divide similarly into dorsal and ventral branches; the dorsal branches of each side are connected together by post-neural anastomoses, which form the posterior spinal arteries; and the ventral branches unite, in the median line, both with their fellows above and below and with those of the opposite side, forming a single longitudinal pre-neural trunk, the anterior spinal artery.

In the thoracic and lumbar regions of the body the somatic segmental arteries persist, and form the intercostal and lumbar arteries. These vessels spring from the dorsal aspect of the descending aorta, usually in pairs. The corresponding vessels of opposite sides, however, occasionally fuse together at their origins, simultaneously with the fusion of the dorsal longitudinal trunks to form the descending aorta, and then the arteries of opposite sides arise by common stems.

The pre-costal anastomoses between the ventral branches of the somatic segmental arteries are only represented in the thoracic region by the superior intercostal arteries; in the lumbar region they disappear entirely. The anastomoses between the anterior ends of the ventral

branches of the somatic segmental arteries persist as the internal mammary and superior and inferior epigastric arteries.

The lateral offsets of the ventral branches are represented by the cutaneous arteries which accompany the lateral cutaneous branches of the spinal nerves, and the lateral branch of the seventh somatic intersegmental artery forms the greater part of the arterial stem of the upper limb.

The post-costal and post-transverse anastomoses usually disappear in the thoracic and lumbar regions, but the post-costal anastomoses occasionally persist in the upper thoracic region, and take part in the formation of the vertebral artery, which in such cases arises from the first or second intercostal artery. In some carnivores the post-costal longitudinal vessels persist in the upper thoracic region, and form, on each side, a trunk which is connected with the first aortic intercostal, and which supplies the first five intercostal spaces.

The pre-laminar, the post-central, and the pre- and post-neural anastomoses persist, the latter two aiding in the formation of the thoracic and lumbar portions of the anterior and posterior spinal arteries respectively.

It is in the cervical region, however, that the most interesting changes occur. The first six pairs of somatic intersegmental arteries lose their connexions with the dorsal roots of the aortic arches, *i.e.*, in other words, with the longitudinal anastomosing channels in this region. The seventh pair, however, persist in their entirety; and from them are formed, on the right side, a portion of the subclavian trunk, and on the left side the whole of the subclavian stem from its commencement up to the origin of the vertebral artery. On each side the ventral branch of the seventh intersegmental artery forms

and enlarged lateral offset of the ventral branch of the seventh somatic intersegmental artery, which is continued into the upper limb, caudal or postaxial to the shoulder girdle. The thyro-cervical trunk and the superior intercostal artery, both branches of the subclavian artery, are

that portion of the subclavian artery which lies between the origins of the vertebral and internal mammary arteries, and also the trunk of the internal mammary artery as far as the upper border of the first costal cartilage. The remainder of the internal mammary artery represents the ventral longitudinal anastomoses between the ventral branches of the seventh and the following somatic intersegmental arteries. The continuation of the subclavian artery, beyond the inner margin of the first rib, is the persistent

persistent pre-costal anastomoses, and the ascending cervical artery belongs to the same series of vessels. The vertebral artery, which appears as a branch of the subclavian in the adult, is, morphologically, somewhat complex. The first part represents the dorsal branch of the seventh somatic intersegmental artery; the second part, that passing through the cervical transverse processes, consists of the persistent post-costal anastomoses between the dorsal branches of the first seven intersegmental arteries; a third part, that lying on the arch of the atlas, is the spinal branch of the first somatic intersegmental artery and its neural continuation; whilst finally the upper part of the vertebral artery, the part in the cranial cavity, appears to represent a prolongation of the pre-neural anastomoses, which still farther upwards are probably represented by the basilar artery. As already stated, the post-costal anastomoses below the seventh intersegmental artery occasionally persist, and in such cases the vertebral may lose its connexion with the subclavian, and spring from one or other of the posterior branches of the upper intercostal arteries.

The profunda cervicis artery is to be regarded as a remnant of the post-transverse longitudinal anastomoses.

The origin of the seventh somatic intersegmental artery from the dorsal longitudinal trunk is, at first, some distance caudal to the sixth aortic arch, but, simultaneously with the elongation of the neck and the retraction of the heart into the thoracic region, it is shifted cephalwards until it is opposite the dorsal end of the fourth aortic arch.

The middle sacral artery is formed by the fusion of two vessels, each of which springs from the dorsal surface of the aorta. It is regarded as the direct continuation of the descending aorta.

The **lateral or intermediate visceral arteries** supply the organs derived from the intermediate cell mass. They form a somewhat irregular series of vessels in the adult, but presumably in the primitive condition there was a pair in each segment of the body; many of these disappear, however, and the series is only represented in the adult by the suprarenal, the right renal, part of the left renal, and the testicular or ovarian arteries—possibly, also, by some of the branches of the hypogastric arteries.

The **splanchnic arteries** arise in the embryo from the ventral aspects of the primitive dorsal aortæ, and are not strictly either segmental or intersegmental in arrangement. They are distributed to the walls of the alimentary canal. Each anastomoses with its immediate neighbours on the dorsal wall and the ventral walls of the gut.

After the fusion of the dorsal longitudinal trunks to form the descending aorta, the roots of each pair of the splanchnic arteries fuse into a common stem, or either the right or left artery altogether disappears, whilst at a later period the majority of the splanchnic arteries lose their direct connexion with the descending aorta; those which retain their connexion are the celiac artery and the superior and inferior mesenteric arteries.

The bronchial and œsophageal arteries are later formations. They appear to correspond morphologically with the more primitive splanchnic arteries, but the developmental history is not known.

The left gastric branch of the celiac artery, as it passes from its origin to the small curvature of the stomach, represents a right splanchnic artery; the remainder of the left gastric artery and the right gastric branch of the hepatic are remnants of the ventral anastomoses between the splanchnic arteries cephalwards of the umbilicus.

The splenic artery is a branch given off from a splanchnic artery to an organ developed in the mesogastrium, and the hepatic is a branch from the ventral splanchnic anastomoses to the hepatic diverticulum from the wall of the duodenal portion of the fore-gut.

The superior and inferior mesenteric arteries represent at their origins splanchnic branches, and in the remainder of their extent they represent the dorsal anastomoses on the gut wall.

THE AORTA, PULMONARY ARTERY, AND OTHER CHIEF STEM VESSELS.

The heart and the majority of the great arterial trunks of the body, including the aorta, the innominate, part of the right subclavian, the common, external, and greater parts of the internal carotids, and the pulmonary arteries, are all modified portions either of the primitive aortæ or of the aortic arches. The developmental changes, which result in the formation of the vessels named, are described in the preceding chapter, and the morphology of these vessels is obviously the same as that of the trunks from which they are derived.

It will be sufficient, therefore, to point out that the primitive aortæ may be regarded as the greatly enlarged pre-central or pre-vertebral longitudinal anastomoses between the successive intersegmental arteries of each side; obviously, therefore, each primitive aorta, like the rest of the longitudinal anastomoses, consists chiefly of segmental elements. The origins of the intersegmental vessels enter into its formation only in so far as they connect the segmental vessels together, and so complete the longitudinal anastomoses.

The first cephalic aortic arches are simple portions of the primitive aortæ. The other aortic arches have possibly a different morphological significance, but their exact nature is not definitely settled.

The second, third, fourth, fifth, and sixth cephalic aortic arches of each side are developed in the undivided mesoderm of the head region, caudal to the first arch. They spring from the part of the primitive aorta which, after the head fold is formed, lies on the ventral aspect of the fore-gut, and they extend, at the side of the pharyngeal part of the fore-gut, to the dorsal aorta. Thus, in some respects they may be looked upon as segmental vessels. In addition to the vessels already mentioned, there are given off from the ventral aortæ and the aortic arches a series of branches which supply ventral and lateral diverticula from the alimentary canal; these are represented in the adult by the superior thyroid, the thyroidea ima.

Iliac Arteries and their Branches.—The common iliac arteries are formed from the secondary roots of the umbilical arteries, and their exact morphological position is uncertain. The true morphological position of the hypogastric arteries is not yet defined. They also are parts of the secondary roots of the umbilical arteries, and they give off both somatic and splanchnic branches; therefore they do not correspond either with somatic intersegmental or with splanchnic arteries. The branches of the hypogastric artery are arranged in two groups—(1) a visceral set which supplies the walls of the hind-gut and the genital organs, and (2) a parietal set which is distributed to the body wall and to the hind-limbs. The branches distributed to the gut probably represent the splanchnic vessels, more or less homologous with ordinary splanchnic branches of the primitive aortæ, and the parietal branches are possibly the homologues of intersegmental arteries.

THE LIMB ARTERIES.

In all probability the vessels of both the upper and the lower limbs are derived originally from several somatic intersegmental arteries, the majority of which, however, have atrophied. The upper limb is supplied in man by the lateral offset from the ventral branch of the seventh somatic segmental artery. It passes into the extremity caudal to the shoulder girdle, courses through the arm, enters the cubital fossa, and is continued through the forearm, in the early stages, as the volar interosseous artery, which terminates in the deep part of the palm, in the deep volar arch. At a later period, phylogenetically, a median artery appears as a branch of the parent stem, and it terminates in a superficial volar arch; still later the radial and ulnar branches are formed. The latter grow rapidly, soon exceeding in size the parent stem, and they terminate in the superficial and deep volar arches. The interosseous and median arteries decrease, and generally lose their direct connexions with the volar arches. The dorsal interosseous artery is also a secondary branch from the parent stem, and the digital arteries are offsets from the volar arterial arches.

The chief arteries of the lower extremities spring directly from the secondary roots of the umbilical arteries, and may be looked upon as being essentially intersegmental; whether they represent the whole or only parts of typical somatic intersegmental arteries, however, is not clear.

The arteries of the lower limbs certainly show no very obvious indications of division into dorsal and ventral branches, though such indications are not entirely wanting. In their comparative absence it is supposed that the dorsal branches have been either suppressed or incorporated with the common stems; that similarly the ventral branches and their lateral offsets are indistinguishably fused, and that probably both are represented in a limb artery.

The original stem vessel of the lower limb is the inferior glutæal artery, which is continued distally, caudal to the pelvic girdle, into the popliteal and peroneal arteries, and so to the plantar arch. Subsequently the external iliac artery is given off from the secondary root of the umbilical artery, dorsal to the origin of the inferior glutæal, and, passing into the limb cephalward of the pelvic girdle, it becomes the femoral artery. This vessel ultimately unites with the proximal part of the popliteal artery, and after this communication is established the distal part of the inferior glutæal atrophies and loses its connexion with the popliteal, which henceforth appears to be the direct continuation of the femoral trunk; therefore, whilst the main artery of the upper limb is formed by the prolongation of the lateral branch of one segmental artery, the corresponding vessel of the lower extremity is developed from representatives of, probably, two somatic segmental arteries, the external iliac and femoral trunks being the representatives of one, whilst the popliteal and its continuation, the peroneal, are parts of another.

The first main artery of the leg, phylogenetically, is the peroneal, which is continued into the plantar arch; after a time, however, the posterior and anterior tibial branches are given off from the stem, over which, as a rule, they soon preponderate in size, and they terminate in the plantar arch, whilst the parent trunk diminishes and loses its direct connexion with the arch.

The peroneal artery corresponds in position and development with the common interosseous trunk and the volar interosseous artery in the forearm. The posterior tibial apparently corresponds with the median artery; it develops in a similar way, and has similar relations to homologous nerves, the tibial nerve representing the combined median and ulnar nerves of the upper extremity.

The anterior tibial artery represents the dorsal interosseous, whilst the radial and ulnar arteries of the upper extremity are not represented in the lower limb.

MORPHOLOGY OF THE VEINS.

Two dorsal longitudinal vessels, one on each side, connect the successive intersegmental veins together. They do not, however, in any part of their course, fuse together to form a single vessel comparable to the descending aorta.

Of these dorsal longitudinal vessels, that on the right side greatly enlarges, and from it the main stem vessels which return blood from the body walls, the head and neck, and the limbs, are almost entirely formed. The left dorsal longitudinal vessel remains relatively small—in parts, indeed, it altogether disappears—and the blood conveyed to it by the corresponding inter-

segmental veins is transmitted, across the median plane, to the chief functional stem by later developed and superadded transverse communicating channels, which are formed between the more primitive longitudinal anastomoses.

The primitive dorsal longitudinal anastomosing channels include on each side—(1) the anterior cardinal vein, (2) the posterior cardinal vein, and (3) the duct of Cuvier; the last-named vessel, which opens into the sinus venosus of the primitive heart, is, originally, part of the anterior cardinal vein; it becomes enlarged and receives a special name after the union of the posterior with the anterior cardinal vein.

The cardinal veins return blood not only from the limbs and body wall, but they are also, in the early stages, the only vessels by which blood is returned from the derivatives of the intermediate cell tract, *i.e.* the kidneys, the genital glands, and the suprarenal glands. At a later period other longitudinal anastomoses, called the subcardinal veins, appear, and into these a large part of the blood from the derivatives of the intermediate cell tract is poured. It is from these vessels, and from the transverse communications which are established between the cardinal and subcardinal veins of opposite sides, that the chief veins of the head and neck and the body are formed; there is in addition, however, a later-formed vessel, the upper part of the inferior vena cava, which is developed independently of the veins previously mentioned. Moreover, it must not be forgotten that the veins of the extremities are, like the extremities themselves, secondary structures, and that they are developed at a later period than the veins of the trunk, with which, however, they ultimately communicate.

In the light of these facts the morphology of the chief veins of the head and neck, the trunk and limbs may now be considered.

The cavernous sinuses are remnants of the anterior cardinal veins. The other blood sinuses of the cranium are either secondarily formed vessels, or anastomoses between the tributaries of the anterior cardinal veins, or anastomoses between those tributaries and other newly formed veins.

The internal jugular veins are also portions of the anterior cardinal veins.

The right innominate vein is a part of the right anterior cardinal vein. A small part of the left innominate vein is formed from the left anterior cardinal vein, the greater part is derived from a transverse anastomosis between the two anterior cardinal veins.

Other remnants of the anterior cardinal veins are the upper parts of the superior vena cava and left superior intercostal vein.

The basilic vein and its prolongations, the axillary vein and the subclavian vein, are derived from the ulnar or post-axial primitive veins of the upper extremities. The external jugular vein is a secondary formation, and the cephalic vein is the radial or pre-axial vein of the upper extremity which opens first into the external jugular vein and at a later period into the axillary vein.

The superior vena cava represents the lower part of the anterior cardinal vein and the right duct of Cuvier, and the oblique vein of the left atrium represents the left duct of Cuvier.

The azygos vein is the upper or cephalic part of the right posterior cardinal vein, and the vertical parts of the hemiazygos and accessory hemiazygos veins are remnants of the left posterior cardinal vein, whilst the transverse portions of the hemiazygos and accessory hemiazygos veins represent transverse anastomoses between the posterior cardinal veins.

The inferior vena cava is a compound structure representing parts of five different structures. Its upper end is the transformed cephalic end of the right vitelline vein. The portion posterior to the liver is a secondary outgrowth from the right vitelline vein. The part between the liver and the right renal vein represents a part of the right subcardinal vein and an anastomosis between it and the posterior cardinal vein, and the remainder is a portion of the right posterior cardinal vein.

The right common iliac vein is a part of the right posterior cardinal vein, but the left is a compound structure. Its lower part probably represents a portion of the left posterior cardinal vein, but the greater part is a persistent transverse anastomosis between the posterior cardinal veins.

The hypogastric veins are remnants of the posterior cardinal veins.

The popliteal and the inferior gluteal veins are remnants of the primitive fibular vein of the lower limb, and the external iliac vein is the trunk formed by the union of the tibial and the deep veins of the lower limb which are secondary formations.

Visceral Veins.—The portal vein represents portions of both vitelline veins and of the middle anastomosis between them.

The right gastric vein is a splanchnic ventral longitudinal anastomosing vein. The left gastric vein is partly a ventral and partly a dorsal splanchnic longitudinal anastomosis, and the superior and inferior mesenteric veins are dorsal splanchnic longitudinal venous anastomoses, the splenic vein being merely a tributary from a lymphoid organ developed in the dorsal meso-gastrium.

The anterior facial vein is a combination of somatic and splanchnic veins of several segments, and the internal maxillary vein is probably of similar nature. The thyroid and bronchial veins return blood from organs developed from diverticula from the walls of the alimentary canal; they are, therefore, more or less modified splanchnic veins; so also apparently are the vesical and the middle and inferior hæmorrhoidal veins.

The cardiac veins are simply “*vasa vasorum*,” and they belong therefore to the splanchnic group of vessels, but it is impossible to say whether they are segmental or intersegmental. The coronary sinus into which they open is a portion of the sinus venosus of the heart, and therefore of an originally segmental vessel.

The hepatic veins are parts of the primitive vitelline veins; and the pulmonary veins are splanchnic veins returning blood from a diverticula of the gut.

It is noteworthy that some parts of the splanchnic venous system, *i.e.* the portal vein and the coronary sinus, are portions of the most primitive vascular system, and that others,—the thyroid, bronchial, mesenteric, vesical, and hæmorrhoidal veins—appear to belong to a somewhat secondary group of splanchnic veins of combined segmental and intersegmental character; moreover, some of the secondary group of veins open into the primary splanchnic veins, *e.g.* the superior and inferior mesenteric into the portal vein; some open into the dorsal longitudinal anastomosing veins, *e.g.* the vesical and hæmorrhoidal veins open into the cardinal veins, which are intersegmental anastomoses; others again open into the internal jugular, which is part of the anterior cardinal vein.

Veins of the Limbs.—The veins of the limbs, like the arteries, were probably at one time intersegmental in character, but we have no indisputable proof that this was the case. Looked at from an embryological standpoint, the most primitive limb veins are a superficial distal arch and a post-axial trunk vein in each extremity; at a later period digital veins are connected with the distal arch, and a pre-axial trunk is formed. In the upper extremity the distal arch and its tributaries remain as the dorsal venous arch and the digital veins, and the post-axial vein becomes the basilic, axillary, and subclavian veins. The pre-axial vein of the upper extremity is represented in the adult by the cephalic vein; the latter vessel originally terminated in the external jugular vein, above the clavicle, the union with the axillary portion of the post-axial vessel being a secondary condition; the primary condition is, however, frequently retained in man, and is constant in many monkeys. The anastomosis between the pre-axial and post-axial veins in the region of the elbow, and the connexion of the anastomosing channels, is brought about by newly-formed vessels of secondary character.

The distal arch in the lower extremity and the tributaries connected with it remain in the adult as the dorsal venous arch of the foot and the digital veins. The post-axial vein becomes the small saphenous vein, which was originally continued proximally as the popliteal and inferior gluteal veins to the hypogastric portion of the posterior cardinal vein.

The pre-axial vein of the lower limb becomes the great saphenous vein, which is continued proximally to the cardinal portion of the left common iliac vein as the proximal part of the femoral and the external iliac veins.

The *venæ comites* of the arteries in both the upper and lower extremities are secondarily developed vessels which become connected with the upper portions of the pre-axial venous trunks.

ABNORMALITIES AND VARIATIONS OF THE VASCULAR SYSTEM.

Abnormalities are of special interest to the anatomist because of their morphological significance, and the vascular system is, perhaps more than any other, rich in such abnormalities, many of which are of great practical importance.

With the exception of those irregularities which are directly due to the effect of morbid conditions and external influences, all abnormalities are the result of modifications of normal developmental processes. The exceptions referred to are, however, very numerous; thus disease and external influences may lead to the obliteration of vessels, a condition which is invariably associated with the enlargement of collateral vessels, and it will be obvious that abnormalities so produced may occur in almost any situation.

Abnormalities which are determined by, or are dependent upon, modifications of the usual developmental processes are of greater interest. In the human subject they are generally due either to the retention of conditions which, normally, are only transitory in ontogenetic development, or to the acquirement of conditions which, though not as a rule present at any time in man, occur normally in some animals.

There are, in addition, other variations from the normal, such as the division of the axillary artery into radial and ulnar branches; the higher or lower division of the brachial artery; the formation of "*vasa aberrantia*," *e.g.* of long slender vessels connecting the axillary or brachial to the radial, ulnar, or interosseous arteries; the altered position of certain vessels, *e.g.* the transference of the subclavian artery to the front of the scalenus anterior, or of the ulnar artery to the front of the superficial flexor muscles; all of which, though undoubtedly due to alterations of ordinary developmental processes, still do not represent any known conditions met with, either temporarily or permanently, in man or in other animals. Their occurrence cannot at present be adequately explained, and their retention in the adult is entirely dependent upon their utility.

To the first and the last of these different groups of abnormalities it is not necessary to refer further, whilst with regard to the rest it will be sufficient to indicate those of greatest importance. They can only, however, be fully understood and explained on the basis of a comprehensive knowledge of the development and morphology of the vascular system, to the chapters on which the reader is referred.

ABNORMALITIES OF THE HEART.

The heart may be transposed from the left to the right side of the body, a condition which is usually associated with general transposition of the viscera, and with the presence of a right instead of a left aortic arch.

The external form of the heart does not as a rule vary much, but occasionally the apex is slightly bifid, a character it normally possesses at an early stage of its development, and which is retained in the adult in many cetaceans and sirenians. The internal conformation of the heart deviates from the normal much more frequently; more particularly is this the case with regard to the septa which separate the right from the left chambers. The interatrial septum may be entirely absent, as in fishes; it may be fenestrated and incomplete, as in some amphibians; or the foramen ovale may remain patent, as in amphibians and reptiles.

The interventricular septum may be absent, as in fishes and amphibians, or incomplete, as in reptiles; when incomplete, it is usually the "pars membranacea septi" which is deficient, but perforations are occasionally found in the muscular portion.

The communication between the infundibular part of the right ventricle and the body of the ventricle may be constricted or the infundibular part may be entirely cut off from the remainder of the cavity.

ABNORMALITIES OF ARTERIES.

The pulmonary artery and the aorta may arise by a common stem, as in fishes and some amphibians, and the common stem may spring either from the right or the left ventricle, or from both. In these cases the truncus arteriosus has remained undivided, and the normal position of the interventricular septum in relation to the lower orifice of the aortic bulb has been altered.

Again, owing to malposition of the aortic septum, the pulmonary artery may spring from the left ventricle and the aorta from the right ventricle. In some cases the root of the pulmonary artery is obliterated, and the blood passes to the lungs along the patent ductus arteriosus.

Occasionally the arch of the aorta is on the right side instead of the left, a condition which is normal in birds. More rarely there are two permanent aortic arches, right and left, as in reptiles; the œsophagus and trachea in these cases are enclosed in a vascular collar, the two arches unite dorsally, and the beginning of the descending aorta is double. Quite independent of this condition, however, the two primitive dorsal aortæ sometimes fail, either altogether or partially, to unite together, and the descending aorta is accordingly represented, to a corresponding extent, by two tubes. A more common, though still rare, form of double aorta is that due to the persistence, in whole or in part, of the septum formed by the fused walls of the primitive dorsal aortæ from which the descending aorta is developed.

The length of the descending aorta is determined largely by the extent to which fusion of the two primitive aortæ takes place. Accordingly, when this deviates from the normal, the termination of the descending aorta is at a correspondingly higher or lower level than usual, and resulting from this the lengths of the common iliac arteries are almost invariably proportionately modified. The bifurcation of the aorta may be as low as the fifth lumbar vertebra; less frequently it is higher than usual; it is rare, however, to find it as high as the third, and still more rare to find it at the level of the second, lumbar vertebra.

The aorta, instead of bifurcating into two common iliac arteries, may terminate in a common iliac artery on one side and a hypogastric artery on the opposite side, the external iliac artery on the irregular side arising, at a higher level, as a branch of the aortic stem. This arrangement approaches the condition met with in carnivores and many other mammals, in which the aorta bifurcates into two hypogastric arteries, the external iliacs arising from the aorta at a higher level as lateral branches; it is probably due either to a fusion of the secondary roots of the umbilical arteries of opposite sides.

THE BRANCHES OF THE AORTA.

The coronary or cardiac arteries may arise by a single stem. When arising separately both may spring from the same aortic sinus; or again, their interventricular and circumflex branches may arise as distinct vessels from a single aortic sinus. This variability is not very remarkable, seeing that the arteries in question are merely enlarged "vasa vasorum" raised to a position of special importance by the development of the heart.

The branches of the arch of the aorta are sometimes increased and sometimes decreased in number.

The highest number recorded is six, viz., right subclavian, right vertebral, right common carotid, left common carotid, left vertebral, and left subclavian. Apparently this condition is the result of the absorption into the arch of the innominate artery and of the roots of the subclavian arteries, to points beyond the origins of the vertebrae. By variations of this process of absorption other combinations may be produced; thus, instead of the roots of the subclavian arteries being absorbed, the right common carotid and innominate arteries may alone be absorbed, in which case the five following branches spring separately from the arch of the aorta: right subclavian, right external carotid, right internal carotid, left common carotid, and left subclavian. The trunk most commonly absorbed is the initial part of the left subclavian; the

number of branches then arising from the arch of the aorta is four, the additional vessel being the left vertebral, which arises between the left common carotid and the left subclavian. Occasionally the usual three branches from the arch are increased to four by the formation of a new vessel, the "thyreoidea ima." This may be placed between the innominate and left carotid trunks, in which case it represents a persistent ventral visceral branch from the ventral root of the fourth left aortic arch; in other cases the thyreoidea ima springs from the innominate artery and represents a ventral visceral branch of the ventral root of the fourth *right arch*. Very rarely the right vertebral artery arises separately, and forms a fourth branch of the arch of the aorta, the rest of the branches being normal. This condition cannot be accounted for by any modification of the ordinary developmental processes. It may possibly be due to the persistence of an irregular or unimportant anastomosis between the ventral root of an aortic arch and the seventh somatic segmental artery.

Decrease in the number of branches from the arch of the aorta is most frequently due to fusion of the ventral roots of the fourth aortic arches, the result being that a stem is formed common to the right subclavian and the right and left common carotid arteries; whilst the left subclavian, arising separately, is the only other branch which springs from the arch of the aorta.

If the fusion of the ventral roots proceeds further and includes those of the third arches, the result, as regards the branches given off from the arch of the aorta, is the same, viz., there is a common stem for the right subclavian and both carotids, and a separate left subclavian trunk; but the common stem now gives off the right subclavian artery, and then continues as a single vessel for some distance before it divides into the two common carotids, of which the left crosses in front of the trachea. This arrangement is common in many quadrumana and in some other mammals.

It is only in rare cases when the number of branches from the arch of the aorta is reduced to two, that these consist of a right subclavian artery and of a single stem common to the two carotids and the left subclavian arteries. In such cases, however, the right common carotid crosses in front of the trachea, and the variation is one of practical importance. This does not appear to exist as a normal condition in any mammal. Probably it is due to fusion of the ventral roots of the fourth aortic arches, with absorption of the left fourth arch and the left subclavian into the stem so formed, whilst the right subclavian is relatively displaced. The two common carotids may arise by a common stem, and the left subclavian arise separately from the arch of the aorta, whilst the right subclavian springs from the descending aorta. This arrangement probably results from the disappearance of the fourth right arch, the fusion of the ventral roots of the fourth arches of opposite sides and the persistence of the dorsal roots of the right fourth and sixth arches.

Sometimes two innominate arteries, right and left, replace the usual three branches of the arch of the aorta. This is the normal arrangement in bats, moles and hedgehogs. It is obviously the result of the disappearance of that portion of the arch which intervenes between the left carotid and left subclavian arteries, and the consequent fusion of these two vessels.

In a similar way may be explained the rarer condition in which the three ordinary branches of the arch arise by one single stem, which divides into right and left innominate arteries. In most ruminants, in the horse and in the tapir, this arrangement is constant.

It will be evident that other combinations and modifications may be met with in the branches of the arch of the aorta as the result of fusions and absorption.

The **right subclavian** or the right vertebral may spring from the commencement of the descending aorta.

The **bronchial arteries** obviously correspond to splanchnic arteries and their continuations to diverticula from the walls of the gut; therefore the usual origin of the right bronchial artery from the first right aortic intercostal artery must result from the persistence of an anastomosis between a splanchnic artery and the first part of a somatic intersegmental artery; the origin of the right from the upper left bronchial artery, which sometimes occurs, is due to the fusion of the roots of two splanchnic arteries. The occasional origin of a bronchial vessel from an internal mammary artery can result only from the persistence and enlargement of an anastomosis between a splanchnic artery and the ventral branch of a somatic segmental artery. The origin of a bronchial branch from a subclavian artery may have the same or a different significance on opposite sides of the body. A bronchial artery arising from the left subclavian artery corresponds with the origin of the right bronchial artery from the first aortic intercostal artery; it is due to the persistence of an anastomosis between a splanchnic artery and the root of a somatic intersegmental artery; and the origin of a bronchial artery from a right subclavian artery may be due to a similar cause. It may, on the other hand, be due to the enlargement of an anastomosis between a splanchnic branch of the descending aorta and a splanchnic branch of the fourth right aortic arch. When, as occasionally happens, the bronchial artery arises from the inferior thyroid, it is due to the persistence and enlargement of an anastomosis between splanchnic arteries.

Intercostal Arteries.—Variations of the intercostal arteries are not very common, but they are significant and interesting. Corresponding vessels of opposite sides may arise from a common stem which has been formed by the fusion of the roots of two somatic intersegmental arteries after or simultaneously with the fusion of the primitive dorsal aortæ. The number of intercostal arteries may be reduced, one artery supplying two or more intercostal spaces; in these cases the roots of origin of some of the somatic intersegmental arteries in the thoracic region have disappeared, and the precostal anastomoses between their ventral branches have persisted.

Occasionally the number of the aortic intercostal arteries is increased, an additional artery

being given to the second intercostal space, which is usually supplied by the superior intercostal artery; this is brought about by the persistence of the root of the tenth somatic intersegmental artery and the disappearance of the precostal anastomosis between the ventral branches of the ninth and tenth somatic intersegmental arteries. Very rarely the first aortic intercostal artery sends a branch upwards between the necks of the ribs and the transverse processes of the upper thoracic region; this branch supplies the upper intercostal spaces, the superior intercostal artery being small or absent, and it terminates by becoming the profunda cervicis artery. It is due to the persistence of the postcostal anastomoses in the upper thoracic region, and is a repetition of a condition regularly present in some carnivores.

There are no very important variations of the œsophageal, pericardial, and mediastinal arteries.

Lumbar Arteries.—Variations of the lumbar arteries are very similar to those of the intercostal arteries, and they are due to similar causes. The lumbar arteries of opposite sides may arise by common stems from the back of the aorta; and the last pair of lumbar arteries may arise in common with the middle sacral artery. Further, a lumbar artery may have its area of distribution extended into the adjacent segment.

The **inferior phrenic arteries** are very variable; they may arise by a common trunk either from the celiac artery or from the aorta; they may arise separately either from the aorta or from the celiac artery and more commonly from the latter vessel; or again, one may spring from the aorta or celiac artery, and the other from the coronary, renal, or even from the superior mesenteric artery.

The **middle sacral artery** usually springs from the back of the aorta above its bifurcation; it may be considerably above, or more rarely it may spring directly from the bifurcation. Not infrequently it arises from the last lumbar artery or from a stem common to the two last lumbar arteries, and occasionally it arises from a common or internal iliac artery. Sometimes it gives off the last pair of lumbar arteries, and, in a few cases, an accessory, renal, or a hæmorrhoidal branch arises from it. The vessel is not always present, it may be double, entirely or in part, and it may bifurcate at its termination.

The **renal arteries** frequently deviate from the normal arrangement. The arteries of opposite sides may spring from a common stem, or there may be two or more renal arteries on one or both sides. The accessory arteries are more common on the left than on the right side, and an accessory artery arising below the ordinary vessel is more common than one arising above it.

Accessory renal arteries may be derived not only from the aorta, but also from the common iliac or hypogastric arteries; they have been described as arising also from the inferior phrenic, spermatic, lumbar, or middle sacral arteries, and even from the external iliac artery. As the kidney is developed in the region of the first sacral vertebra, and afterwards ascends to its permanent position, it is not surprising that it occasionally receives arteries from the main stem of more than one of the segments of the body through which it has passed, and it is usually found that the lower the position of the kidney in the abdomen the more likely it is to receive its arteries from the lower part of the aorta or from the common iliac arteries. The accessory renal arteries which spring from the inferior phrenic, the spermatic, and lumbar arteries can only be the result of the persistence and enlargement of anastomosing channels between the renal and either another intermediate-visceral, or a somatic artery.

The **testicular or ovarian arteries** may be double on one or both sides; the arteries of opposite sides may spring from a common trunk, or they may rise from the renal or suprarenal arteries. The right artery may pass behind instead of in front of the inferior vena cava. The spermatic and ovarian arteries arise from the upper lumbar portion of the aorta, because the testes and ovaries are developed in and obtain their arterial supply in that region, and the vessels are elongated as the testes and ovaries descend to their permanent positions. The occurrence of two spermatic arteries on one side is probably an indication that the testis was developed in at least two segments of the body, and the origin of a spermatic artery from a renal or suprarenal artery is due to the obliteration of the root of the original vessel and the enlargement of an anastomosis between the intermediate visceral arteries of adjacent segments.

The **celiac artery** may be absent, its branches arising separately from the aorta or from some other source. Sometimes it gives off only two branches, usually the left gastric and splenic, and occasionally it gives four branches, the additional branch being either a second left gastric artery or a separate gastro-duodenal artery.

The **hepatic artery** may spring directly from the aorta or from the superior mesenteric artery, and the left hepatic artery arises occasionally from the left gastric artery. Accessory hepatic arteries are not uncommon, and they originate either from the left gastric, superior mesenteric, renal, or inferior mesenteric artery.

The **left gastric artery** is occasionally double; it may spring directly from the aorta, and it may give off the left hepatic or an accessory hepatic artery.

The **splenic artery** may arise from the middle colic, from the left hepatic, or from the superior or inferior mesenteric artery.

The **superior mesenteric artery** may be double, and it may supply the whole of the alimentary canal from the second part of the duodenum to the end of the rectum, the inferior mesenteric artery being absent. In addition to its ordinary branches it may give off a hepatic, a splenic, a pancreatic, a gastric, a gastro-epiploic or a gastro-duodenal branch. Very rarely it gives off an omphalo-mesenteric branch, which passes to the region of the umbilicus and becomes connected with capillary vessels in the falciform ligament of the liver.

The **inferior mesenteric artery** may give hepatic, renal, or middle colic branches; occasionally it is absent, being replaced by branches of the superior mesenteric, and sometimes, as in ruminants and some rodents, its left colic branch does not anastomose with the middle colic artery.

All these variations of the unpaired visceral branches of the abdominal aorta are merely due to modifications of the usual processes by which the vessels are developed.

The hepatic, splenic, and left gastric arteries may arise directly from the aorta, a condition which is due to the retention of a greater number of the splanchnic arteries than usual. A double superior mesenteric artery results from the persistence of both the right and left splanchnic vessels from which the superior mesenteric artery is formed, these remaining separate instead of fusing together. All the other variations are the results of the obliteration of the usual channels, combined with the enlargement of anastomoses which exist both between the splanchnic arteries of adjacent segments and between the splanchnic and intermediate visceral arteries.

THE ARTERIES OF THE HEAD AND NECK.

Innominate Artery.—From what has already been said with reference to the branches of the arch of the aorta, it will be noted that the innominate artery may be absent. On the other hand there may be two innominate arteries, a right and a left, each ending in corresponding common carotid and subclavian trunks, and the two vessels may themselves arise by a common stem.

The branches given off by the innominate artery may be increased in number, or the innominate may vary from the normal only as regards length. As a consequence of such modifications in length, the origins of the right common carotid and right subclavian arteries may be situated at a higher or lower level than usual, whilst, in the absence of the innominate artery, both these branches may arise directly from the aorta.

Common Carotid Arteries.—When the right common carotid artery arises separately from the arch of the aorta, it may be the first, or, much more rarely, the second branch. In the former case the fourth right aortic arch has been obliterated, and the right subclavian artery springs from the descending aorta; in the latter case either the innominate stem has been absorbed into the arch of the aorta, or the ventral root of the fourth right aortic arch has fused with part of an elongated fourth left arch.

Whether arising as the first or second branch, the origin may be to the left of the median plane, and the trunk may pass in front of the trachea, or behind the œsophagus, before it ascends into the neck.

The left common carotid artery varies, as regards its origin, much more frequently than the right vessel; not uncommonly, and apparently because of the fusion of the ventral roots of the fourth aortic arches, it arises from a stem common to it and to the right common carotid and right subclavian arteries.

Both common carotids may vary as regards their termination. They may divide at a higher or lower level than usual, the former more commonly than the latter; whilst in a few exceptional cases the common carotid does not divide, but is continued directly into the internal carotid, and from this the branches usually given off by the external carotid are derived.

This arrangement is probably due to obliteration of the ventral roots of the first and second aortic arches, the arches persisting and being divided into the branches which generally arise from their ventral extremities.

Usually the common carotids give off no branches, but not infrequently one or more of the branches of the external carotids arise from them.

The **external carotid artery** may be absent, or it may, in rare cases, arise directly from the arch of the aorta. The number of its branches may be diminished either by fusion of their roots or by transference to the internal or common carotid arteries. On the other hand, the number of its branches may be increased; thus, the sterno-mastoid artery, the hyoid branch usually given off by the superior thyroid artery, or the ascending palatine branch of the external maxillary, may arise from it. Sometimes the branches may arise in the usual way, but may deviate from the course generally taken; more particularly is this the case with the internal maxillary artery, which may pass either between the heads, or entirely lateral or medial to both heads of the external pterygoid muscle.

The **internal carotid artery** is rarely absent. Occasionally it springs from the arch of the aorta, and in its course through the neck it may vary somewhat in length and in tortuosity. One or more of the branches usually derived from the external carotid artery may arise from it, and it sometimes gives off a large meningeal branch to the posterior fossa of the skull. Its posterior communicating branch may replace the posterior cerebral artery; on the other hand, the upper part of the internal carotid may be absent, and the posterior communicating artery may become the middle cerebral artery. The anterior cerebral branch of the internal carotid may be absent, or rather it may arise from the corresponding artery of the opposite side; or there may be three anterior cerebral arteries, the third arising from the anterior communicating artery which connects the two anterior cerebrals together. The ophthalmic artery, as it traverses the orbit, may pass either above or below the optic nerve. It is occasionally replaced by a branch of the middle meningeal artery.

The **vertebral artery** may have a double origin—one from the subclavian, and one from the inferior thyroid artery or from the aorta.

The right vertebral may arise from the common carotid or from the arch of the aorta. Occasionally it springs from the descending aorta, an arrangement associated with the persistence of the dorsal roots of the fourth and fifth right arches.

The left vertebral artery not infrequently springs from the arch of the aorta, arising between the left common carotid and left subclavian arteries; this is evidently due to the absorption of the stem of the seventh segmental artery into the aortic arch. Very exceptionally the left vertebral is a branch of an intercostal artery.

In its course upwards either vertebral artery may enter the vertebrarterial foramen of any of the lower six cervical vertebra.

The cases in which it does not enter one of the lowest of these are apparently associated with its formation in part from the precostal instead of from the postcostal anastomosing channels.

The artery may enter the vertebral canal with the second instead of with the first cervical nerve, or, after leaving the foramen in the transverse process of the third vertebra, it may divide into two branches, one of which accompanies the second and the other the first cervical nerve; the two branches unite together again in the vertebral canal to form a single trunk.

Sometimes, though rarely, it gives off superior intercostal and inferior thyreoid branches. The upper end of one of the vertebrales is sometimes very small, or it may be entirely wanting; in the latter case the basilar artery is formed by the direct continuation of the opposite vertebral.

The **basilar artery** may be double in part or the whole of its extent, or its cavity may be divided by a more or less complete septum. It may terminate in one instead of two posterior cerebral arteries, the missing vessel being supplied by the enlargement of the posterior communicating branch of the internal carotid.

THE ARTERIES OF THE UPPER LIMB.

Subclavian Arteries.—The variations, so far as regards the origins of the subclavian arteries, have already been mentioned (p. 1051). Other interesting modifications are met with in respect of its position and branches.

The subclavian artery may reach as high as 25 or 37 mm. (1-1½ in.) above the clavicle, though as a rule it does not reach higher than 19 mm. above that bone. On the other hand, it may not rise even to the level of the upper border of the clavicle. These differences appear to be associated with the descent of the clavicle and sternum, which occurs as age increases.

The artery may pass in front of or through the scalenus anterior instead of behind it, or the vein may accompany it behind the muscle.

The branches of the subclavian artery may be modified with reference to their points of origin; thus, those of the first part may be further medial or lateral than usual, the transverse scapular or some other branch of the thyreo-cervical trunk may arise separately from the third part of the subclavian, and not uncommonly the descending branch of the transverse cervical artery is a branch of this part. The abnormalities of the vertebral branch have already been described; those of the thyreo-cervical trunk and its branches are numerous but not important.

The **internal mammary artery**, usually a branch of the first part of the subclavian, is very variable as regards its origin. It may arise from the second or third parts, or from the thyreo-cervical, or it may spring from the aorta, or from the innominate or axillary arteries. All these variations are due to obliteration of the normal origin and the opening up of anastomoses. The internal mammary artery sometimes descends in front of the cartilages of one or more of the lower true ribs; and occasionally it gives off a large lateral branch (a. *mammaria lateralis*) which descends on the inner side of the chest wall, close to the mid-axillary line,—a point of importance in paracentesis.

A few cases have also been noticed in which a bronchial artery has arisen from the internal mammary.

The **superior intercostal branch** of the costo-cervical trunk may be absent, and the profunda cervicis branch may arise directly from the subclavian trunk. The superior intercostal is sometimes formed from a postcostal instead of a precostal primitive channel. In such cases it passes between the necks of the ribs and the transverse processes of the vertebrae instead of, as usual, in front of the necks of the ribs.

The **axillary artery** does not vary much as regards its origin or course. Its relations may be modified by the existence of a muscular or tendinous "axillary arch," which, passing from the latissimus dorsi to the pectoralis major, crosses the distal part of the artery superficially; and a further interesting modification is associated with an anomalous arrangement of its branches. Occasionally the sub-scapular, circumflex, and profunda and superior ulnar collateral arteries arise from the axillary by a common stem. In these cases the chief branches of the brachial plexus are grouped round the common stem instead of round the main trunk. This is due to the persistence of a different part of the original vascular plexus.

Sometimes the axillary artery divides into the radial and ulnar arteries, and more rarely the interosseous artery may spring from it.

Obviously there is no brachial artery when the radial and ulnar arteries are formed by the division of the axillary; its place is taken by the two abnormal vessels which, as a rule, are separated by the median nerve as they run through the arm; the radial is usually more superficial than the ulnar, and crosses laterally in front of it at the bend of the elbow.

The **brachial artery** is rarely prolonged beyond its usual point of bifurcation; not uncommonly, however, it bifurcates at a more proximal level. Of the two terminal branches of the brachial, one may divide into radial and interosseous, the other forming the ulnar; or one may divide into

radial and ulnar, whilst the other is the interosseous artery. Occasionally the brachial artery terminates by dividing into three branches—viz., the radial, the ulnar, and the interosseous. In any case, the branch which gives origin to or becomes the interosseous was, in all probability, the original trunk.

Division of the brachial artery at a more proximal level than usual occurs most commonly in the proximal third of the arm, and least commonly in the distal third; the resulting trunks are often united near the bend of the elbow by a more or less oblique anastomosis.

In cases of proximal division of the brachial artery the radial branch may pierce the deep fascia of the arm near the bend of the elbow, and passes distally in the forearm immediately deep to the skin; in other cases the radial runs deeper, and passes behind the tendon of the biceps. The ulnar branch sometimes runs, on the medial intermuscular septum, towards the medial epicondyle, and then laterally towards the middle of the bend of the elbow, under a band of fascia from which the proximal fibres of the pronator teres arise, or round the supracondylar process of the humerus if it is present. More commonly the ulnar branch runs distally towards the medial epicondyle, and crosses superficial to the flexor muscles or deep to the palmaris longus; and in a few cases it is subcutaneous. In rare cases the ulnar artery accompanies the ulnar nerve behind the medial epicondyle; in these cases it has obviously been formed by enlargement of the ordinary superior ulnar collateral and dorsal ulnar recurrent arteries.

Instead of following its usual course along the brachialis muscle, the brachial artery may accompany the median nerve behind a supracondylar or epicondylar process, or ligament, as in many carnivores; it may pass in front of the median nerve instead of behind it. It may give off a "vas aberrans" or a median artery, and any of its ordinary branches may be absent.

The vas aberrans given off from the brachial artery usually ends in the radial artery, sometimes in the radial recurrent, and rarely in the ulnar artery.

The **ulnar artery** may be absent, being replaced by the median artery or the interosseous artery, and it may terminate in the deep instead of in the superficial volar arch. It rarely arises more distally than usual, and when it arises at a more proximal point it most commonly passes superficial to the muscles which spring from the medial epicondyle. Moreover, in these cases it frequently has no interosseous branch, the latter vessel springing from the radial artery, and in all probability variations of this description are produced by the ulnar artery taking origin from the main trunk, which is represented by the radio-interosseous vessel, at a more proximal level than usual. Even when it commences in the usual way the ulnar artery may pass superficial to the muscles arising from the medial epicondyle, and in these cases its interosseous and recurrent branches spring from the radial artery.

The volar and dorsal interosseous arteries may arise separately from the ulnar instead of by a common interosseous trunk. The recurrent branches of the ulnar may spring from the interosseous, and the interosseous itself may be a branch of the radial.

The small median artery, the companion artery of the median nerve, usually a branch of the volar interosseous, may spring from the axillary, brachial, or ulnar arteries; it may be much larger than usual, and it may terminate either by breaking up into digital branches, or by joining one or more digital branches of the superficial volar arch or the arch itself.

The **radial artery** may be absent, its place being taken by branches of the ulnar or interosseous arteries; it may arise from the axillary, or, more proximal than usual, from the brachial. It may terminate in muscular branches in the volar part of the forearm, or as the superficial volar, or in carpal branches; the distal portion of the artery, in these cases, is usually replaced by branches of the ulnar or interosseous arteries. Occasionally the radial divides some distance proximal to the wrist into two terminal branches, one of which gives off the carpal branches, and becomes the superficial volar, whilst the other crosses superficial to the extensor tendons and passes to the dorsum of the wrist.

The radial artery may run a superficial course, or, and especially when it commences at a more distal level than usual, it may pass deep to the pronator teres and the radial origin of the flexor digitorum sublimis. In some cases it passes to the dorsum of the wrist across the brachioradialis, and in others it lies superficial, instead of deep to, the extensor tendons of the thumb.

Its branches may be diminished or increased in number. The radial recurrent may spring from the brachial or ulnar arteries, or may be represented by several branches from the proximal part of the radial. The dorsal artery of the index digit may be large, and may replace the princeps pollicis and the volaris indicis radialis. On the contrary, the dorsal carpal artery and dorsal digital branches of the radial may be small, or the former may be replaced by branches of the metacarpal arteries, and the latter by the proximal perforating branches of the deep volar arch.

The **princeps pollicis** and **volaris indicis radialis** arteries may be absent, their places being taken either by branches of the superficial volar arch or by the dorsalis indicis radialis artery.

The **superficial volar arch** is sometimes absent; its branches are then given off from the deep arch. On the other hand, it may be larger than normal, and it may be completed on the radial side by the volaris indicis radialis, the princeps pollicis, or the comes nervi mediani arteries.

The **deep volar arch** is much more rarely absent than the superficial arch. When absent its branches are supplied by the superficial arch, the proximal perforating arteries, or the volar carpal arch.

THE ILIAC ARTERIES AND THEIR BRANCHES.

The **common iliac artery** may be longer or shorter than usual, a modification which is largely, though not altogether, determined by the point at which the bifurcation of the aorta

takes place. If exceptionally long, it is usually tortuous. In rare cases in man the artery is absent. It occasionally gives off the middle or a lateral sacral artery, and ilio-lumbar, spermatic, or accessory renal branches may arise from it.

The **hypogastric artery** varies as regards length. It is usually longer, and arises at a higher level when the common iliac is short. In rare cases it has been found to arise from the aorta without the intervention of a common iliac. Frequently it does not, even in appearance, end in anterior and posterior divisions, but obviously forms a single trunk, as in the fœtus, from which the several branches are given off.

The visceral branches vary much in number and size, and the middle hæmorrhoidal may not be present, its place being taken by branches from the vesical arteries. A renal branch sometimes arises from the hypogastric artery.

The ilio-lumbar branch may arise from the common iliac instead of from the hypogastric artery; the superior glutæal and inferior glutæal arteries may arise by a common stem, or the superior glutæal may be absent, and its place taken by a branch from the femoral artery; the inferior glutæal artery may, as in the fœtus, constitute the main artery of the lower limb, and run distally to become continuous with the popliteal artery. Probably the *arteria comitans nervi ischiadici* represents the original continuity of these two vessels. Occasionally the lateral sacral arteries do not arise from the hypogastric trunks.

In some instances the **obturator artery** arises from the inferior epigastric artery instead of from the hypogastric. The condition is apparently due to obliteration of the usual origin of the obturator artery and to the subsequent enlargement of the anastomosing pubic branches of the obturator and inferior epigastric arteries. The course of the abnormal obturator artery is of importance. From its origin it descends, into the pelvis minor, on the medial side of the external iliac vein, and in the majority of cases on the lateral side of the crural ring, but in three-tenths of the cases, and more frequently in males than in females, it descends on the medial side of the ring.

The obturator artery sometimes gives off an accessory pudendal branch which passes along the side of the prostate, pierces the urogenital diaphragm, and terminates by dividing into the profunda artery of the penis and the dorsal artery of the penis. When this occurs the internal pudendal artery is small, and it terminates in the artery to the bulb. Occasionally the accessory pudic arises from the external pudendal artery in the pelvis, or from one of the vesical arteries.

The **external iliac artery** may be much smaller than usual, especially if the inferior glutæal artery persists as the main vessel of the lower limb. It may give off two deep circumflex iliac branches, a dorsal artery of the penis, a medial circumflex artery of the thigh, or a *vas aberrans*, and its deep circumflex iliac and inferior epigastric branches may arise at higher or lower levels than usual.

THE ARTERIES OF THE LOWER LIMB.

The **femoral artery** is small, and ends in the profunda and circumflex branches, when the inferior glutæal artery forms the principal vessel of the lower limb. The profunda branch, which arises usually from the lateral side of the femoral trunk, about 37 mm. ($1\frac{1}{2}$ in.) distal to the inguinal ligament, may commence at a more proximal or a more distal level, and from the back or the medial side of the femoral trunk. In rare cases when the profunda arises from a more proximal level than usual it may cross anterior to the femoral vein, above the entrance of the great saphenous vein, after which it passes distally and laterally posterior to the femoral vessels (Johnston, *Anat. Anz.*, Bd., 42, 1912). Absence of the profunda has been noted, and in these cases the branches usually given off by it spring directly from the femoral artery.

The femoral artery may be double for a portion of its extent, or it may be joined by a *vas aberrans* given off from the external iliac artery. In addition to its ordinary branches, it may furnish one or both of the circumflex arteries of the thigh, and sometimes it gives off, near the origin of the profunda, a great saphenous artery, such as exists normally in many mammals. This vessel runs distally through femoral trigone and the adductor canal, and accompanies the saphenous nerve to the medial side of the foot.

The deep circumflex iliac, the obturator, and the inferior epigastric arteries are occasionally given off from the femoral.

The **popliteal artery** may exceptionally form the direct continuation of the inferior glutæal artery. It sometimes divides at a more proximal or more distal level than usual, and the division may be into either two or three branches; if three terminal branches are present, they are the anterior and posterior tibial and the peroneal arteries, and if only two, either the anterior and posterior tibial, or the anterior tibial and the peroneal arteries.

Occasionally the artery is double for a short portion of its course, and it has been found to cross first posterior to the medial head of the gastrocnemius to the medial side of the knee, and then anterior to the medial head of the gastrocnemius to regain the popliteal fossa. The number of its branches may be reduced, or they may be increased by the addition of a *vas aberrans* which connects it with the posterior tibial artery. Its superficial sural branch may enlarge to form a well-marked small saphenous artery.

The **posterior tibial artery** may be small or altogether absent, its place being taken by branches of the peroneal artery; again, it may be longer or shorter than usual, in conformity with the more proximal or more distal division of the popliteal trunk. The peroneal artery is large, if either the anterior or the posterior tibial artery is small. The perforating branch of the peroneal is almost invariably large when the anterior tibial artery is small; in some cases,

indeed, it replaces the whole of the dorsalis pedis continuation of the latter vessel; in others, however, only the lateral tarsal and arcuate branches are so replaced. The peroneal sometimes arises from a stem common to it and the anterior tibial artery.

The **anterior tibial artery** may be absent, its place being taken by branches of the posterior tibial and peroneal arteries. It is longer than normal when the popliteal artery divides at a more proximal level than usual, and in these cases it may pass either posterior or anterior to the popliteus muscle. Occasionally the anterior tibial artery and its dorsalis pedis continuation are larger than normal, and the terminal part of the dorsalis pedis takes the place, more or less completely, of the lateral plantar artery.

The **medial plantar artery** is sometimes very small, and it may be absent; its place is taken by branches of the dorsalis pedis or lateral plantar arteries. The **lateral plantar artery** also may be small or absent, the plantar arch being formed entirely by the dorsalis pedis.

ABNORMALITIES OF VEINS.

Abnormalities or variations of veins are as frequently met with as those of arteries, and they are due to similar causes.

THE SUPERIOR VENA CAVA.

The **superior vena cava** may develop on the left side instead of on the right. This peculiarity is due to the persistence of the left duct of Cuvier instead of that on the right side, and it is associated with absence of the coronary sinus, which is replaced by the lower part of the left superior vena cava. An exceptional case is recorded in which the opening of the coronary sinus into the heart was obliterated, and the cardiac veins terminated in a trunk which passed upwards to the left innominate vein. This trunk was obviously formed by enlargement of the left duct of Cuvier and the lower part of the left anterior cardinal vein. Not very uncommonly, as the result of the persistence of both ducts of Cuvier, there are two superior venæ cavæ, the transverse anastomosis which usually forms the left innominate vein being small or entirely absent. In these cases the left innominate vein descends in the left part of the superior mediastinum, crosses the aortic arch, is joined by the left superior intercostal vein, and becomes the left superior vena cava; which descends anterior to the root of the left lung, and terminates in the lower and back part of the right atrium. It receives the great cardiac vein, and, turning to the back of the heart, replaces the coronary sinus. This arrangement is normal in many mammals. Occasionally in man the left superior vena cava terminates in the left atrium, and the coronary sinus, which represents a part of the sinus venosus, has been seen to have a similar ending; both these abnormal endings must be the result of malposition of the interatrial septum.

The **vena azygos** may be formed on the left side; it then arches over the root of the left lung, and terminates in the left end of the coronary sinus. This is the normal arrangement in some mammals, and it is due to the persistence of the left posterior cardinal vein and the left duct of Cuvier.

Occasionally the azygos vein is the only vessel by which blood is returned to the heart from the lower limbs and the lower parts of the body walls. In such cases that portion of the inferior vena cava which usually extends from the right renal vein to the heart is absent and the azygos vein is the direct continuation of the inferior vena cava. This condition probably results from the absence of those parts of the inferior vena cava which are usually formed from the right vitelline and the right subcardinal veins, and to the enlargement of the whole of the suprapelvic portion of the right posterior cardinal vein.

The **hemiazygos** and the **accessory hemiazygos veins** may be absent. In these cases each left intercostal vein opens separately into the vena azygos. On the other hand the hemiazygos and the accessory hemiazygos veins may form a continuous trunk which may open by a transverse anastomosis into the azygos vein, or it may join the left innominate vein. When the hemiazygos and the accessory hemiazygos veins form a single trunk, which receives the left intercostal veins and opens into the left innominate vein, the condition is due to the persistence of the whole of the thoracic part of the left posterior cardinal vein and of the lower part of the left anterior cardinal vein.

Cases also occur in which the thoracic part of the posterior cardinal vein is represented by three instead of two stems, either the hemiazygos or the accessory hemiazygos vein being represented by two vessels.

The **internal jugular vein** may be either smaller or larger than normal. In either case compensatory changes in size occur in the transverse sinus and internal jugular vein of the opposite side, or in the external and anterior jugular veins of the same side.

The **external jugular vein** is sometimes absent, or it may be smaller than usual; in both cases either the anterior or the internal jugular vein is enlarged. In some of the cases in which the external jugular vein is small it receives no communication from the posterior facial vein, but is merely the continuation of the posterior auricular vein. On the other hand, it may be enlarged, and receive the whole of the posterior facial vein.

The **anterior jugular vein** may be absent, or it may be unusually large, especially in the lower part of its extent, and after it has received an occasional tributary from the common facial vein.

The **posterior facial vein** may terminate entirely in the common facial vein, or in the external or the internal jugular vein. It may be very small, and occasionally it is absent.

Variations of the **cranial blood sinuses** are not numerous. One transverse sinus may be absent or very small, when, as a rule, that of the opposite side is enlarged. The inferior sagittal, the occipital, or the speno-parietal sinuses may be absent, and there may be an additional petro-squamous tributary to the transverse sinus. The petro-squamous sinus, when present, is the remains of a sinus which crossed the temporal bone, passed through the post-condyloid foramen and terminated in the lateral cerebral vein. In the human adult, in rare cases, it pierces the skull behind the condyle of the mandible, and terminates in the posterior facial vein. This is the normal arrangement in some mammals.

THE VEINS OF THE UPPER EXTREMITY.

The **superficial veins** of the forearm are extremely variable; any of them may be absent, but most commonly it is the median or the cephalic vein which is wanting. The median cephalic and the cephalic veins may be small or absent, and, on the other hand, the cephalic vein may be larger than usual. Moreover the cephalic vein may end in the external jugular vein, its original termination; or it may be connected with the external jugular vein by an anastomosing channel which sometimes passes over the clavicle and sometimes through that bone.

The basilic vein is sometimes larger and sometimes smaller than usual, and it may pierce the fascia of the arm at a more proximal or at a more distal level than usual.

The **venæ comites** of the arteries of the upper extremity generally terminate at the lower border of the subscapularis, where they join the axillary vein, but they may end above or below the position of their usual termination.

The **subclavian vein** sometimes passes behind instead of in front of the scalenus anterior muscle, and it has been seen passing between the clavicle and the subclavius muscle.

THE INFERIOR VENA CAVA.

The lower part of the inferior vena cava is sometimes absent, in which case the common iliac veins ascend, one on the right and the other on the left of the aorta, to the level of the second lumbar vertebra, where the left common iliac vein receives the left renal vein, and then crosses in front of or behind the aorta to fuse with the corresponding vein of the right side; in such cases, therefore, the inferior vena cava commences at the level of the second lumbar vertebra, and it represents only the upper and last-formed part of the ordinary vessel; the common iliac veins, each of which receives the lumbar veins of its own side, are exceptionally long, and they may or may not be united at the pelvic brim by a small transverse anastomosing channel. Cases of this kind are sometimes described as partial doubling of the inferior vena cava.

Occasionally the inferior vena cava does not terminate in the right atrium, but is continuous with the vena azygos, which is much enlarged, all the inferior caval blood being then carried to the superior vena cava. In these cases the hepatic veins open directly into the right atrium without communicating with the inferior vena cava.

The lower part of the inferior vena cava sometimes lies to the left instead of to the right of the aorta; this condition is associated with a long right common iliac vein, which crosses obliquely from right to left to join the shorter left common iliac vein. After receiving the left renal vein the misplaced inferior vena cava crosses in front of the aorta, reaching the right side at the level of the second or first lumbar vertebra. In other cases, however, the left inferior vena cava continues upwards through the left crus of the diaphragm, usurping the place of a greater or smaller part of the hemiazygos vein; having entered the thorax, it may cross to the opposite side and terminate in the vena azygos, or it may continue upwards on the same side, and after arching over the root of the left lung, descend behind the left atrium to terminate in the right atrium in the situation of the coronary sinus. In this group of cases also the hepatic veins open separately into the right atrium.

The inferior vena cava may lie ventral instead of dorsal to the right internal spermatic artery, in which case the lower part of the vessel has been derived from the subcardinal vein instead of from the posterior cardinal vein. (Johnston, *Journ. of Anat. and Phys.* xlvii. 1913.)

The tributaries of the inferior vena cava are also subject to variation. Additional renal, spermatic, ovarian, or suprarenal veins may be present. Two or three lumbar veins of one or both sides may unite into a common trunk which terminates in the inferior vena cava, and the hepatic veins may open separately, or after fusing into a common trunk, into the right atrium near the opening of the inferior vena cava.

No explanation of the variations of the inferior vena cava and its tributaries is necessary, beyond the statement that they are due to persistence of portions of the cardinal and subcardinal veins which usually disappear, and to the persistence of transverse anastomoses and tributaries which usually atrophy, or to modifications of those which ordinarily take part in the formation of the inferior vena caval system.

The **left common iliac vein** is short and the right long when the inferior vena cava lies on the left side. The common iliac veins may be absent, the hypogastric veins uniting to form the commencement of the inferior vena cava, into which the external iliac veins open as lateral tributaries.

THE VEINS OF THE LOWER EXTREMITY.

The **great saphenous vein** is not subject to much variation, but the **small saphenous vein** may terminate by joining the great saphenous, or, after piercing the deep fascia in the distal part of the thigh, it may ascend and join the inferior gluteal vein or one of the tributaries of the profunda vein.

The **venæ comites** are generally described as terminating in the lower extremity, at the distal part of the popliteal fossa, but they may ascend as far as the femoral trigone; as a matter of fact, one or more small additional veins usually accompany the popliteal and femoral arteries, although as a rule there is only one large popliteal and one large femoral vein.

In a few cases the popliteal vein does not pierce the distal part of the adductor magnus, but ascends behind that muscle and becomes continuous with the profunda vein, the femoral artery being unaccompanied by any large vein during its passage through the adductor canal.

ABNORMALITIES OF THE LYMPHATICS.

Variations of the glands and smaller vessels of the lymphatic system are so common that they can hardly be regarded as abnormalities; variations of the larger vessels, however, are comparatively rare. This is especially the case with respect to the two terminal trunks, the thoracic duct and the right lymphatic duct, the abnormalities of which are interesting and important.

When the arch of the aorta is on the right side instead of on the left side, the thoracic duct terminates usually in the right innominate vein, in which case it receives the tributaries which usually open into the right lymphatic duct, whilst the corresponding area on the left side is drained by lymphatics terminating in a left lymphatic duct which opens into the commencement of the left innominate vein. A similar arrangement of the terminal lymphatic trunks sometimes occurs even when the arch of the aorta is in its normal position on the left side. In either case the thoracic duct may commence in the usual way, and after reaching the level of the fifth thoracic vertebra continue upwards on the right side, instead of crossing to the left side of the vertebral column; more rarely it commences on the left side and crosses over to the right at a higher level.

In one case in which the thoracic duct opened into the right innominate vein, instead of the left, no trace of a lymphatic duct was discovered on the left side.

Occasionally the thoracic duct commences and terminates in the usual manner, but crosses the vertebral column immediately after its origin and ascends on the left side.

Not uncommonly there is no distinct cisterna chyli, in which case the terminal lymphatic vessels of the abdomen merely unite to form a larger vessel which does not present any obvious dilatation, and from which the thoracic duct is continued. The terminal lymphatic trunk may open into the internal jugular vein, previous to its junction with the subclavian, instead of into the commencement of the innominate vein.

Occasionally the thoracic duct is double, either in the whole or in part of its extent, and sometimes it breaks up into a plexus of vessels which may reunite into a single trunk in the upper part of the thorax. Both the thoracic duct and the right lymphatic duct may, before terminating, divide into branches which, though sometimes reuniting on each side into a single trunk, not infrequently open separately into the great veins at the root of the neck.

As a rule the thoracic duct joins the commencement of the left innominate vein, but it may end in the internal jugular, vertebral, or subclavian veins of the left side; whilst very rarely, it opens into the vena azygos.

THE RESPIRATORY SYSTEM.

THE ORGANS OF RESPIRATION AND VOICE.

By the late D. J. CUNNINGHAM, F.R.S.,
Professor of Anatomy, University of Edinburgh.

Revised by RICHARD J. A. BERRY, F.R.C.S.,
Professor of Anatomy, University of Melbourne.

THE organs of respiration are the larynx and trachea, which, together, constitute a median air-passage; the two bronchi or branches into which the inferior end of the trachea divides; and the two lungs to which the bronchi conduct the air. In connexion with the lungs there are also the pleural membranes—two serous sacs which line the portions of the thoracic cavity which contain the lungs, and at the same time give a thin coating to those organs.

The larynx opens above into the inferior or caudal part of the pharynx, and the air which passes in and out from the air-passages likewise traverses the pharynx, the nasal cavity, and also the oral cavity if the mouth be open. This connexion between the digestive and respiratory systems is explained by the fact that the respiratory apparatus is secondarily developed, as an outgrowth, from the ventral aspect of the primitive fore-gut of the embryo. In most mammals the superior or cranial aperture of the larynx opens into the part of the pharynx which lies dorsal to the nasal cavities. In man, however, the superior opening of the larynx is placed below, that is inferior or caudal to, the communication between the mouth and pharynx, and both nasal and oral breathing may be carried on with very nearly equal ease.

LARYNX.

The larynx or organ of voice is the upper part of the air-passage, specially modified for the production of voice. Above it opens into the pharynx, whilst below its cavity becomes continuous with the lumen of the trachea or windpipe.

Position and Relations of the Larynx.—In the natural position of the neck, and whilst the organ is at rest, the larynx is placed on the ventral side of the bodies of the fourth, fifth, and sixth cervical vertebrae. Its highest point, represented by the tip of the epiglottis, extends to the inferior border of the body of the third cervical vertebra, whilst its lowest limit (the inferior border of the cricoid cartilage) usually corresponds to the inferior border of the body of the sixth cervical vertebra. From the vertebral column the larynx is separated, not only by the prevertebral muscles and the prevertebral fascia, but also by the dorsal wall of the pharynx—indeed the dorsal surface of the larynx forms the inferior part of the ventral wall of the pharynx, and is covered by the lining mucous membrane of that section of the alimentary canal. 3-6

The larynx lies below the hyoid bone and the tongue, and in the interval between the great vessels of the neck. It forms a more or less marked projection on the ventral side of the neck, and, in the median plane, it approaches very closely to the surface, being merely covered by skin and the two layers of fascia. Laterally

it is more deeply placed. Thus, it is overlapped by the sterno-cleido-mastoid muscle, and is covered by the two strata of thin ribbon-like muscles which are attached to the thyroid cartilage and the hyoid bone; and it is hidden, to some extent, by the upper prolongations of the lateral lobes of the thyroid gland.

The position of the larynx is influenced by movements of the head and neck. Thus it is elevated or raised when the head moves dorsally, and depressed when the chin is carried downwards towards the chest. Again, if the finger is placed upon it during deglutition, it will be noted that the larynx moves to a very considerable extent. The pharyngeal muscles attached to it, and more especially the stylo-pharyngeal muscles, are chiefly responsible for bringing about these movements. During singing, changes in the position of the larynx may also be noted, a high note being accompanied by a slight upward movement, and a low note by a similarly slight downward movement of the organ.

The position of the larynx is not the same at all periods of development and growth. In the fœtus, shortly before birth, it lies much nearer the head, and its inferior border corresponds to the inferior border of the fourth cervical vertebra. Its permanent position is not reached until the period of puberty is attained (Symington). This downward movement of the larynx has been stated to be due to the rapid and striking growth of the facial part of the skull (Symington). It is very doubtful, however, if the facial growth has any influence in this direction. In the anthropoid ape, in which the face forms a much greater part of the skull than in man, and in which, in the transition from the infantile to the adult condition, the facial growth is even more striking than it is in man, the larynx occupies a relatively higher position in the neck. In the early stages of growth all the thoracic viscera undergo a gradual subsidence. The larynx in its downward movements follows these. Indeed, it cannot do otherwise, seeing that the bifurcation of the trachea between infancy and puberty moves downwards towards the caudal end of the body more than the depth of one thoracic vertebra.

General Construction of the Larynx.—The wall of the larynx is constructed upon a somewhat complicated plan. There is a framework composed of several cartilages. These are connected together, at certain points, by distinct joints and also by elastic membranes. Two elastic cords, which stretch in a ventro-dorsal direction from the ventral to the dorsal wall of the larynx, form the groundwork of the vocal folds (O.T. true vocal cords). Numerous muscles also are present. These operate upon the cartilages of the larynx, and thereby not only bring about changes in the relative position of the vocal folds, but also produce different degrees of tension of these folds. The cavity of the larynx is lined with mucous membrane, under which, in certain localities, are collected masses of mucous glands.

CARTILAGINES LARYNGIS.

Three single cartilages and three pairs of cartilages enter into the construction of the laryngeal wall. They are named as follows:—

Single cartilages	{ Thyroid. Cricoid. Epiglottis.	Paired cartilages	{ Arytænoids. Corniculate cartilages (Santorini). Cuneiform cartilages.

Cartilago Thyroidea.—The **thyroid cartilage**, the largest of the laryngeal cartilages, is formed of two quadrilateral plates termed the *laminæ*, which meet ventrally at an angle, and become fused along the median plane. Dorsally the laminæ diverge from each other, and enclose a wide angular space which is open dorsally. The *ventral borders* of the laminæ are fused only in their inferior parts. Above they are separated by a deep, narrow V-shaped median notch, called the *incisura thyroidea* or **thyroid notch**. In the adult male the angle formed by the meeting of the ventral borders of the two laminæ, especially in its upper part, is very projecting, and with the margins of the thyroid notch, which lies above, constitutes a marked subcutaneous prominence in the neck, which receives the name of the **prominentia laryngea** (O.T. **Adam's Apple**).

The angle which is formed by the meeting of the two laminae of the thyroid cartilage varies to some extent in different individuals of the same sex, and shows marked differences in the two sexes and at different periods of life. In the adult male the average angle is said to be 90° ; in the adult female it is 120° ; whilst in the infant the laminae meet in the form of a gentle curve, convex ventrally.

The dorsal border of each lamina of the thyroid cartilage is thick and rounded, and is prolonged beyond the superior and inferior borders in the form of two slender cylindrical processes, termed cornua. The superior cornu is longer than the inferior cornu. It is directed upwards, towards the head, with a slight dorso-medial inclination, and ends in a rounded extremity, which is joined to the tip of the great cornu of the hyoid bone by the lateral hyo-thyroid ligament. The inferior cornu is shorter and stouter than the superior cornu. As it proceeds downwards it curves slightly towards the median plane, and upon the medial face of its extremity it shows a circular flat facet, by means of which it articulates with a similar facet on the lateral aspect of the cricoid cartilage.

The superior border of each lamina is for the most part slightly convex, and ventrally it dips suddenly to become continuous with the margin of the thyroid notch. Dorsally, where it joins the superior cornu, it exhibits a shallow notch or concavity. The inferior border is almost straight, but it is marked off by a projection, termed the inferior thyroid tubercle, into a short dorsal part, which shows a shallow concavity close to the inferior cornu and a longer part which lies ventral to the tubercle, and is also concave, but to a less degree.

FIG. 846.—PROFILE VIEW OF THE CARTILAGES AND LIGAMENTS OF THE LARYNX.

FIG. 845.—VENTRAL ASPECT OF THE CARTILAGES AND LIGAMENTS OF THE LARYNX.

The lateral surface of each lamina is divided into two unequal areas by the *linea obliqua*. This line begins above at the superior thyroid tubercle, a prominence situated immediately below the superior border, and a short distance ventral to the root of the superior cornu. From this the oblique line proceeds forwards and downwards to end in the inferior tubercle on the inferior border of the lamina. The area which lies dorsal to the oblique line is much smaller than that which lies on its ventral side. It is covered by the inferior constrictor muscle of the pharynx. The larger ventral area is for the most part covered by the thyro-hyoid muscle. To the oblique line are attached the sterno-thyroid and thyro-hyoid muscles. The medial surface of the lamina of the thyroid cartilage is smooth and slightly concave.

Cartilago Cricoidea.—The cricoid cartilage is shaped like a signet-ring. Dorsally there is a broad, thick plate, somewhat quadrilateral in form, termed the *lamina*; whilst ventrally and laterally the circumference of the ring is completed by a curved band, called the *arch*. The

lumen of the ring enclosed by these parts is circular below, but the upper part of the ring is compressed laterally, so that the lumen becomes elliptical. The upper border of the lamina presents a faintly marked median notch. On either side of this there is an oval facet which looks more laterally than upwards; it articulates with the base of the arytenoid cartilage. The dorsal surface of the lamina is divided by an elevated median ridge into two depressed areas which give attachment to the posterior crico-arytenoid muscles. The ventral part of the arch of the cricoid is in the form of a narrow band, but as it proceeds dorsally towards the lamina its upper border rises rapidly, and in consequence the arch becomes much broader. The *inferior border* of the cricoid is nearly straight, although it frequently presents a median ventral projection and two lateral projections. It is joined to the first ring of the trachea by an elastic membrane—the crico-tracheal ligament. On the *lateral surface* of the cricoid cartilage, at the place where the arch joins the lamina, a vertical ridge runs downwards from the arytenoid

articular facet. On this, a short distance from the inferior border of the cartilage, a prominent circular articular facet is visible, for articulation with the inferior cornu of the thyroid cartilage (Fig. 848, p. 1067). The *medial surface* of the cricoid cartilage is smooth, and is lined with mucous membrane.

The narrow band-like part of the arch of the cricoid cartilage lies below the inferior border of the thyroid cartilage, whilst the lamina is received into the interval between the dorsal portions of the laminae of the thyroid cartilage.

Cartilagine Arytænoideæ. —

The arytenoid cartilages are placed one on either side of the median plane, and rest upon the upper border of the lamina of the cricoid cartilage, in the interval between the dorsal portions of the laminae of the thyroid cartilage. Each presents a somewhat pyramidal form, the pointed apex of which is directed upwards, and at the same time curves dorsally and medially.

FIG. 847.—DORSAL ASPECT OF THE CARTILAGES AND LIGAMENTS OF THE LARYNX.

It supports the corniculate cartilage (Santorini). Of the three surfaces, the medial one faces the corresponding surface of the opposite cartilage, from which it is separated by a narrow interval; another looks dorsally; whilst the third is directed laterally and ventrally. The *medial surface*, which is the smallest of the three, is triangular in outline. It is narrow, vertical, and even, and is clothed with the lining mucous membrane of the larynx. The *dorsal surface* is smooth and concave in the cranio-caudal direction; it lodges and gives attachment to the arytenoideus transversus muscle. The *ventro-lateral surface* is the most extensive of the three (Fig. 848, p. 1067). Its middle part is marked by a deep depression in which is lodged a mass of mucous glands. Upon this surface of the arytenoid cartilage the vocalis and thyro-arytenoid muscles are inserted, whilst a small tubercle a short distance above the base gives attachment to the ventricular ligament—the feeble supporting ligament of the ventricular fold (O.T. false vocal cord). The three surfaces of the arytenoid cartilages are separated from each other by a ventral, a dorsal, and a lateral border. The *lateral border* is the longest, and it pursues, as it is traced from the apex to the base, a sinuous course. Reaching the base of the cartilage, it is prolonged laterally

and dorsally in the form of a stout prominent angle or process, termed the **processus muscularis**. Into the ventral side of this process is inserted the crico-arytænoideus lateralis muscle; whilst into its dorsal aspect the crico-arytænoideus dorsalis (posterior) muscle is inserted. A small nodule of yellow elastic cartilage, called the **sesamoid cartilage**, is frequently found on the lateral border of the arytenoid cartilage, where it is held in position by the investing perichondrium. The *ventral border* of the arytenoid is vertical, and at the base of the cartilage is prolonged ventrally into a small sharp-pointed process called the **processus vocalis**, which receives this name because it gives attachment to the vocal ligament or supporting band of the vocal fold (O.T. true vocal cord). The base of the arytenoid cartilage presents on its inferior surface, particularly in the region of the processus muscularis, an elongated concave facet for articulation with the facet on the superior border of the lamina of the cricoid cartilage.

Cartilagine Corniculatæ (Santorini).—The corniculate cartilages are two minute conical nodules of yellow elastic cartilage which surmount the apices of the arytenoids, and prolong the upper curved ends of these cartilages in a dorso-medial direction. Each corniculate cartilage is enclosed within the dorsal part of the corresponding ary-epiglottic fold of mucous membrane.

Cartilagine Cuneiformes (Wrisbergi).—The cuneiform cartilages are not always present. They are two minute rod-shaped pieces of yellow elastic cartilage, each of which occupies a place in the corresponding ary-epiglottic fold immediately ventral to the arytenoid cartilage and the corniculate cartilage of Santorini. On the superficial surface of each a collection of mucous glands is present, and this tends to make the cartilage stand out in relief under the mucous membrane.

Cartilago Epiglottica.—The epiglottis is supported by a thin, leaf-like lamina of yellow fibro-cartilage, the **epiglottic cartilage**, which is placed dorsal to the root of the tongue and the body of the hyoid bone, and ventral to the aperture of the larynx. When divested of the mucous membrane, which covers it dorsally and also to some extent ventrally, the epiglottic cartilage is seen to present the outline of a bicycle-saddle, and to be indented by pits and pierced by numerous perforations. In the pits, glands are lodged, whilst through the foramina, blood-vessels and, in some cases, nerves pass. The *broad end* of the epiglottic cartilage is directed upwards, and is free. Its *margins* are, to a large extent, enclosed within the ary-epiglottic fold. The *ventral surface* is free only in its upper part. This part is covered with mucous membrane, and looks towards the pharyngeal part of the tongue. The *dorsal surface* is covered throughout its whole extent with the lining mucous membrane of the laryngeal cavity. The *inferior pointed extremity* is carried downwards in the form of a strong fibrous band, termed the thyreo-epiglottic ligament.

Ossification of the Cartilages of the Larynx.—The thyreoid and cricoid cartilages and the greater part of the arytenoid cartilages are composed of the hyaline variety of cartilage. The apical parts, and also the vocal processes of the arytenoid cartilages, the corniculate cartilages of Santorini, the cuneiform cartilages, and the epiglottis, are formed of yellow fibro-cartilage, and at no period of life do they exhibit any tendency towards ossific change. The thyreoid, cricoid, and basal portions of the arytenoids, as life advances, become more or less completely transformed into bone. In males over twenty years of age, and in females over twenty-two years of age, the process will usually be found to have begun (Chievitz). It is impossible, however, by an examination of the laryngeal cartilages, to form an estimate of the age of the individual, although in old age it is usual to find the thyreoid, cricoid, and the hyaline parts of the arytenoids completely ossified. It would appear that the process is somewhat slower in the female than in the male. The thyreoid is the first to show the change; then, but almost at the same time, the cricoid; and lastly, a few years later, the arytenoids.

ARTICULATIONS, LIGAMENTS, AND MEMBRANES OF THE LARYNX.

Crico-thyreoid Joints.—These are diarthrodial joints, and are formed by the apposition of the circular facets on the tips of the inferior cornua of the thyreoid cartilage with the elevated circular facets on the sides of the cricoid cartilage. An articular capsule surrounds each articulation, and this is lined with a

synovial layer (*stratum synoviale*). On the dorsal aspect of the joint a strengthening band is present in the capsule. The movements which take place at the crico-thyroid joints are of a twofold character, viz., gliding and rotatory. In the first case the thyroid facets glide upon the cricoid surfaces in different directions. The rotatory movement is one in which the thyroid cartilage rotates to a slight extent around a transverse axis which passes through the centres of the two joints.

Crico-arytænoid Joints.—These also are diarthrodial articulations. In each case there is a joint cavity surrounded by an articular capsule, which is lined with a synovial layer. The cricoid articular surface is convex, whilst that of the arytaenoid is concave; both are elongated or elliptical in form, and they are applied to each other so that the long axis of the one intersects or crosses that of the other at an acute angle. In no position of the joint do the two surfaces accurately coincide—a portion of the cricoid facet is always left uncovered. The capsule of the joint is strengthened dorsally by a band which is inserted into the dorso-medial part of the base of the arytaenoid cartilage, and plays a somewhat important part in the mechanism of the joint; it effectually arrests excessive ventral movement of the arytaenoid cartilage.

The movements which take place at the crico-arytænoid joints are of a twofold kind, viz., gliding and rotatory. The ordinary position of the arytaenoid during easy, quiet breathing is one in which it rests upon the lateral part of the cricoid facet. By a gliding movement it can move upon the cricoid facet, and advance towards the median plane and its fellow of the opposite side. The gliding movements, therefore, are of such a character that the two arytaenoid cartilages approach or retreat from each other and from the median plane. In the rotatory movement the arytaenoid cartilage revolves around a vertical axis. By this movement the vocal process is swung laterally or medially, so as to open or close the rima glottidis.

The joint between the arytaenoid and the corniculate cartilage (*Santorini*) may either partake of the nature of an amphiarthrosis or of a diarthrosis. The tips of the two corniculate cartilages can generally be made out to be connected to the upper border of the lamina of the cricoid cartilage by a delicate Y-shaped band of connective tissue termed the *ligamentum corniculopharyngeum*.

Hyothyroid Membrane.—This is a broad membranous and somewhat elastic sheet which occupies the interval between the hyoid bone and the thyroid cartilage. It is not equally strong throughout. It presents a central thick portion and cord-like right and left dorsal margins, whilst in the intervals between these it is thin and weak (Figs. 845 and 846, p. 1063). The central thickened part, or the *ligamentum hyothyroideum medium*, is largely composed of elastic fibres. Below it is attached to the margins of the thyroid notch, whilst above it is fixed to the dorsal part of the upper border of the body of the hyoid bone. The upper part of its ventral surface, therefore, is placed dorsal to the dorsal hollowed-out surface of the body of the hyoid bone; a synovial bursa of variable extent is placed between them, and in certain movements of the head and larynx the upper border of the thyroid cartilage moves towards the head on the dorsal side of the hyoid bone. On either side of the strong central part the hyothyroid membrane is thin and loose, and is here attached below to the upper border of the thyroid cartilage, and above to the medial aspect of the great cornu of the hyoid bone. It is pierced by the internal ramus of the superior laryngeal nerve and by the superior laryngeal vessels. The dorsal border of the hyothyroid membrane on each side is thickened, round, and cord-like, and is chiefly composed of elastic fibres; it is termed the *ligamentum hyothyroideum laterale*, and extends from the tip of the great cornu of the hyoid bone to the extremity of the upper cornu of the thyroid cartilage. In this ligament there is usually developed a small oval cartilaginous or bony nodule, which receives the name of the *cartilago triticea*. The deep surface of the lateral part of the hyothyroid membrane is covered with the pharyngeal mucous membrane, and its central part lies ventral to the epiglottis, but separated from it by a mass of adipose tissue (Fig. 851, p. 1070).

Conus Elasticus.—The *conus elasticus*, formerly known as the crico-thyroid membrane, is a very important structure, which it is convenient to consider in three

parts, viz., one median and two lateral, all of which are directly continuous with each other, and differ only in the nature of their upper connexions. The **median part** (crico-thyroid ligament) of the conus elasticus is strong, tense, and elastic. It is triangular in shape, and is attached by its broad base to the upper border of the arch of the cricoid cartilage, whilst its apex is fixed to the medial part of the lower border of the thyroid cartilage (Fig. 845, p. 1063). It is pierced by minute apertures, and is crossed superficially by the crico-thyroid branch of the superior thyroid artery. The median part of the conus elasticus, therefore, closes, ventrally, the interval between the cricoid and thyroid cartilages. The **lateral part** on each side presents very different connexions. It is not attached to the inferior border of the thyroid cartilage, but slopes upwards and medially on the inner side of the thyroid lamina, and thus diminishes materially the transverse or frontal width of the cavity of the larynx. Its attachments are very definite. *Inferiorly* it is fixed to the superior border of the cricoid cartilage immediately subjacent to the lining mucous membrane of the larynx; *above* it is directly continuous with the vocal ligament or supporting band of the vocal fold. This ligament, indeed, may be looked upon as constituting the superior thickened free border of the lateral part of the conus elasticus. *Ventrally* the lateral part of the conus elasticus is attached to the inferior half of the medial surface of the lamina of the thyroid cartilage, close to the angle, and *dorsally* to the inferior border of the processus vocalis of the arytenoid cartilage. In contact with the *outer surface* of the lateral part of the conus elasticus, and separating it from the thyroid lamina, are the lateral crico-arytenoid muscles; the *inner surface* is clothed with the lining mucous membrane of the larynx.

FIG. 848.—DISSECTION TO SHOW THE CONUS ELASTICUS. The right lamina of the thyroid cartilage has been removed.

Ligamentum Vocale.—The vocal ligament (O.T. inferior thyreo-arytenoid lig.) is formed in connexion with the superior border of the conus elasticus, and constitutes the supporting ligament of the vocal fold (O.T. true vocal cord). It is attached *ventrally*, close to its fellow of the opposite side, to the middle of the angular depression between the two laminae of the thyroid cartilage. From this it stretches *dorsally*, and becomes incorporated with the tip and superior border of the processus vocalis, which projects ventrally from the base of the arytenoid cartilage. The vocal ligament is composed of yellow elastic fibres, and embedded in its ventral extremity there is frequently a minute nodule of elastic cartilage. Its medial border is sharp and free, and is clothed with mucous membrane, which in this position is very thin and tightly bound down to the ligament.

Ligamentum Ventriculare.—The ventricular ligament supports the ventricular fold (O.T. false vocal cord). It is weak and indefinite, but somewhat longer than the vocal ligament. *Ventrally* it is attached to the angular depression between the two laminae of the thyroid cartilage, above the vocal ligament and close to the attachment of the thyreo-epiglottic ligament; it extends *dorsally* to be fixed to a tubercle on the ventro-lateral surface of the arytenoid cartilage, a short distance above the processus vocalis. It is composed of connective tissue and elastic fibres which are continuous with the fibrous tissue in the ary-epiglottic fold.

Epiglottic Ligaments.—The epiglottis is bound by ligaments to the base of the tongue, to the wall of the pharynx, to the hyoid bone, and to the thyroid cartilage. The **glosso-epiglottic fold** is a prominent median fold of mucous membrane which proceeds from the middle of the ventral free surface of the epiglottis to the root of the tongue. The **pharyngo-epiglottic folds** are similar

elevations of mucous membrane which proceed from the lateral margins of the epiglottis to the lateral walls of the pharynx at the side of the tongue. Between the two layers of mucous membrane which form each of these folds is a certain amount of elastic tissue. By the three folds the depression between the root of the tongue and the epiglottis is marked off into two fossæ, termed the **epiglottic valleculæ**. From the lateral margins of the epiglottis there also pass off the **pllicæ aryepiglotticæ** to the aryænoïds.

The **ligamentum hyoepiglotticum** is a short, broad elastic band, somewhat broken up by adipose tissue, which connects the ventral surface of the epiglottic cartilage to the upper border of the hyoid bone (Fig. 853, p. 1073). The **ligamentum thyreoepiglotticum** is strong and thick (Fig. 855, p. 1075). Composed mainly of elastic tissue, it proceeds downwards from the inferior pointed extremity of the epiglottic cartilage, and is attached to the angular depression between the two laminae of the thyroid cartilage below the median notch.

A triangular interval is left between the ventral surface of the epiglottis and the hyo-thyroid membrane. This is imperfectly closed above by the hyo-epiglottic ligament, and contains a pad of soft fat (Fig. 851, p. 1070).

CAVUM LARYNGIS.

The **cavity of the larynx** is smaller than might be expected from an inspection of its exterior. On looking into its interior through the laryngeal aperture it is seen to be subdivided into three portions by two pairs of elevated folds of mucous membrane, which extend ventro-dorsally (antero-posteriorly), and project medially from each lateral wall of the cavity. The upper pair of folds are the **ventricular folds** (O.T. **false vocal cords**); the lower, more definite pair, are the **vocal folds** (O.T.

true vocal cords) (Fig. 849). The latter are the chief agents in the production of the voice, and the larynx is so constructed that changes in their relative position and in their degree of tension are brought about by the action of the muscles and the recoil of the elastic ligaments.

Aditus Laryngis.—

The **laryngeal aperture** is a large obliquely placed opening which slopes rapidly in a dorsal and downwards direction and looks upwards and dorsally into the laryngeal part of the pharynx. Somewhat triangular in outline, the basal part of the aperture, placed superiorly and ventrally, is formed by the

FIG. 849.—ADITUS LARYNGIS, EXPOSED BY THE REMOVAL OF THE DORSAL WALL OF THE LARYNX.

free border of the epiglottis. The opening rapidly narrows as it runs downwards, and it ends in the interval between the two aryænoïd cartilages. The sides of the aperture are formed by two sharp and prominent folds of mucous membrane called the **ary-epiglottic folds** which stretch between the lateral margins of the epiglottis ventrally and the aryænoïd cartilages dorsally. The two layers of mucous membrane which compose the ary-epiglottic folds, enclose between them some connective tissue, muscular fibres belonging to the ary-epiglottic muscles, and in their dorsal parts the cuneiform and corniculate cartilages, which latter surmount

the arytaenoid cartilages. These small nodules of cartilage raise the dorsal part of the ary-epiglottic fold in the form of two rounded eminences, termed respectively the *tuberculum cuneiforme* [Wrisbergi] and the *tuberculum corniculatum* [Santorini].

On either side of the laryngeal opening there is, in the pharynx, a small recess directed downwards which presents a wide entrance, but rapidly narrows towards the bottom. It is termed the *recessus piriformis*, and is of importance to the surgeon, because foreign bodies introduced into the pharynx are liable to be caught in this little pocket. On the medial side the recessus piriformis is bounded by the arytaenoid cartilage and the ary-epiglottic fold, whilst on the lateral side it is limited by the inner surface of the laminae of the thyroid cartilage, clothed with the pharyngeal mucous membrane.

Vestibulum Laryngis.—The vestibule of the larynx is the uppermost compartment of the cavity of the larynx. It extends from the laryngeal aperture to the ventricular folds. In its inferior part it exhibits a marked lateral compression. Its width, therefore, diminishes in the vertical direction, whilst, owing to the obliquity of the laryngeal aperture, its depth rapidly diminishes ventro-dorsally. *Ventrally* it is bounded by the dorsal surface of the epiglottis, clothed with mucous membrane. This wall passes obliquely from its superior end in an inferior ventral direction, and becomes narrower as it approaches the ventral or anterior ends of the ventricular folds. The superior part of the dorsal surface of the epiglottis is convex, owing to the manner in which the upper margin is curved ventrally towards the tongue; caudal to this there is a slight concavity, and still more caudally a marked bulging or convexity, over the superior part of the thyreo-epiglottic ligament. This swelling is called the *tuberculum epiglotticum*, and it forms a conspicuous object in laryngoscopic examination of the larynx. Each *lateral wall* of the vestibule of the larynx is formed by the medial surface of the corresponding ary-epiglottic fold. For the most part it is smooth and slightly concave, and it diminishes considerably in vertical depth as it passes dorsally. In its dorsal part the mucous membrane stands out in two elongated vertical elevations, placed one dorsal to the other (Fig. 849, p. 1068). The more ventral elevation is formed by the subjacent cuneiform cartilage with the mass of glands associated with it; the more dorsal elevation is produced by the upper part of the arytaenoid cartilage and the corniculate cartilage (Santorini). A shallow groove (philtrum ventriculi of Merkel) passes downwards between these rounded elevations, and terminates below by running into the interval between the ventricular and vocal cords. The ventral elevation ends below in the dorsal extremity of the ventricular fold; the arytaenoid or dorsal elevation, in its inferior part, bends round the dorsal end of the ventricle of the larynx and becomes lost in the vocal fold. The *dorsal wall* of the laryngeal vestibule is narrow, and corresponds to the interval between the upper parts of the two arytaenoid cartilages. Its width, to a large extent, depends on the position of these cartilages, and when they are placed near each other the mucous membrane which covers this wall is thrown into longitudinal folds.

The **middle compartment of the larynx** is much the smallest of the three. It is bounded above by the ventricular fold and below by the vocal folds, whilst it communicates between these folds with the vestibule on the one hand and the inferior compartment on the other.

FIG. 850.—FRONTAL SECTION THROUGH THE LARYNX TO SHOW ITS COMPARTMENTS.

The **ventricular folds** (O.T. false vocal cords) are two prominent folds of mucous membrane which extend ventro-dorsally on the lateral walls of the laryngeal cavity. Ventrally they reach the angle between the two laminae of the thyroid cartilage, but dorsally they do not extend so far as the dorsal wall of the larynx. They come to an end at the inferior extremity of the elongated swelling produced by the cuneiform cartilage. The ventricular fold is soft and somewhat flaccid, and presents a free border which is slightly arched—the concavity looking downwards. Within the fold of mucous membrane which forms this fold are contained: (1) the feeble ventricular ligament; (2) numerous glands which are chiefly aggregated in its middle part; and (3) a few muscle fibres.

FIG. 851.—SECTION THROUGH LARYNX IN THE MEDIAN PLANE TO SHOW THE OUTER WALL OF THE RIGHT HALF.

the mucous membrane which is stretched over it is very thin and firmly bound down to the subjacent ligament. In colour it is pale, almost pearly white, whilst dorsally the point of the processus vocalis of the arytenoid, which stands out clearly in relief, presents a yellowish tinge. In cross-section the vocal fold is prismatic in form, and its free border looks upwards as well as medially.

The vocal folds are the agents by means of which the voice is produced. The ventricular folds are of little importance in this respect; indeed, they can in great part be destroyed and no appreciable difference in the voice result.

Rima Glottidis.—This name is applied to the elongated fissure by means of which the middle compartment of the larynx communicates with the lower compartment. It is placed somewhat below the middle of the laryngeal cavity, of which it constitutes the narrowest part. Ventrally it corresponds to the interval between the vocal folds; dorsally it corresponds to the interval between the bases and vocal processes of the arytenoid cartilages. It is composed, therefore, of two distinct parts: (1) a narrow ventral portion, between the vocal folds, involving

The interval between the ventricular folds is sometimes termed the *rima vestibuli* (O.T. false glottis), and is considerably wider than the interval between the two vocal folds, which is called the *rima glottidis*. It follows from this that when the cavity of the larynx is examined from above the four folds are distinctly visible, but when examined from below the vocal folds alone can be seen.

The vocal folds (O.T. true vocal cords), placed below the ventricular folds, extend from the angle between the laminae of the thyroid cartilage ventrally, to the vocal processes of the arytenoid cartilages dorsally. The vocal fold is sharp and prominent, and

FIG. 852.—DIAGRAM OF RIMA GLOTTIDIS.

A. During ordinary easy breathing. B. Widely opened.

It is composed, therefore, of two distinct parts: (1) a narrow ventral portion, between the vocal folds, involving

more than half of its length, and called the *pars intermembranacea* of the rima glottidis; (2) a broader, shorter portion, between the arytaenoid cartilages, and termed the *pars intercartilaginea*. By changes in the position of the arytaenoid cartilages the form of the rima glottidis undergoes constant alterations. In ordinary easy breathing it is somewhat lanceolate in outline. The *pars intermembranacea* presents under these conditions the form of an elongated triangle with the base directed dorsally, and corresponding to an imaginary line drawn between the points of the vocal processes of the arytaenoid cartilages, whilst the *pars intercartilaginea* is somewhat quadrangular. When the glottis is opened widely the broadest part of the fissure is at the extremities of the vocal processes of the arytaenoids, and here the side of the rima glottidis presents a marked angle. The two vocal folds, on the other hand, may be approximated to each other so closely, as in singing a high note, that the *pars intermembranacea* is reduced to a linear chink.

The length of the rima glottidis differs very considerably in the two sexes, and upon this depends the different character of the voice in the male and female. According to Moura, the following are the average measurements in the quiescent condition of the rima :—

Male—Length of entire rima glottidis, 23 mm.	{ <i>pars intermembranacea</i> , 15·5 mm.
	{ <i>pars intercartilaginea</i> , 7·5 mm.
Female—Length of entire rima glottidis, 17 mm.	{ <i>pars intermembranacea</i> , 11·5 mm.
	{ <i>pars intercartilaginea</i> , 5·5 mm.

By stretching the vocal folds, however, the length of the rima glottidis in the male may be increased to 27·5 mm., and in the female to 20 mm.

The position of the rima glottidis may be indicated on the surface by marking a point on the middle line of the neck 8·5 mm. below the thyroid notch in the male and 6·5 mm. in the female. This is the average position (Taguchi).

Ventriculus Laryngis (Morgagnii).—The lateral wall of the larynx, in the interval between the ventricular and the vocal folds, exhibits a marked pocket-like depression or recess called the **ventricle of the larynx**. The ventricle passes upwards so as to undermine somewhat the ventricular fold, and its mouth is somewhat narrower than its cavity. Ventrally it reaches to the angle between the laminae of the thyroid cartilage, whilst dorsally it ends at the ventral border of the arytaenoid cartilage.

Under cover of the ventral part of the ventricular fold a small slit-like aperture may be detected; this leads upwards from the laryngeal ventricle into a small diverticulum of mucous membrane, termed the **appendix ventriculi laryngis**, which passes upwards between the ventricular fold and the lamina of the thyroid cartilage. The laryngeal appendix is of variable extent, but as a rule it ends blindly at the level of the upper border of the thyroid cartilage.

Sometimes the appendix ventriculi laryngis extends much higher up, and may even reach the dorsal part of the great cornu of the hyoid bone. This is of interest when considered in connexion with the extensive laryngeal pouches of the anthropoid apes.

The **lowest compartment** of the cavity of the larynx leads caudally into the trachea. Above it is narrow and compressed laterally, but it gradually widens out until it becomes circular, in correspondence with the trachea, with which it is continuous. It is bounded by the sloping medial surfaces of the conus elasticus (O.T. crico-thyroid membrane) and by the medial aspect of the cricoid cartilage—both covered with smooth mucous membrane. In the operation of laryngotomy the opening is made through the crico-thyroid ligament in the ventral wall of the compartment.

Tunica Mucosa Laryngis.—The mucous membrane which lines the larynx is continuous above with the lining of the pharynx, and below with the mucous membrane of the trachea. Over the dorsal surface of the epiglottis it is closely adherent, but elsewhere, above the level of the vocal folds, it is loosely attached by submucous tissue which extends into the ary-epiglottic folds. As it passes over the vocal folds the mucous membrane is very thin, and is tightly bound down.

It is important to bear these facts in mind, because, in certain inflammatory conditions, the lax submucous tissue in the upper part of the larynx is liable to become infiltrated with fluid, pro-

ducing what is known as œdema glottidis. This may proceed so far as to cause occlusion of the upper part of the cavity. The close adhesion of the mucous membrane to the vocal folds, however, prevents the œdema extending beyond the level of the rima glottidis, and the surgeon is thus able to relieve the patient by making an opening through the ventral part of the conus elasticus into the cavity of the larynx.

Above the level of the rima glottidis the laryngeal mucous membrane is extremely sensitive, and when touched by a foreign body there is an immediate response in the shape of an explosive cough. In the lower compartment of the larynx the mucous membrane is lined with columnar ciliated epithelium. Over the vocal folds this is replaced by squamous epithelium. In the ventricle of the larynx and in the inferior part of the vestibule of the larynx the columnar ciliated epithelium again reappears. The upper part of the epiglottis and the upper parts of the lateral walls of the vestibule are covered with squamous epithelium similar to that present in the mouth and pharynx.

The mucous membrane of the larynx has a plentiful supply of acinose glands, and in only one place, viz., over the surface of the vocal folds, are these completely absent. For the most part the glands are aggregated in groups. The following are the localities in which these groups are especially noticeable: (1) On the dorsal surface of the epiglottis, many of the glands piercing the cartilage; (2) around the cuneiform cartilage, where they are chiefly responsible for the elongated elevation seen in this part of the wall of the vestibule; (3) in the ventricular folds and over the wall of the laryngeal vestibule and the appendix ventriculi laryngis.

MUSCULI LARYNGIS.

Of the several muscles attached to the cartilages of the larynx all do not physiologically belong to the larynx, as, for example, the inferior constrictor muscles of the pharynx, which, though attached to both cricoid and thyroid cartilages, belong to the muscles of the pharynx, as do also the stylo-pharyngeus muscles inserted in part into the thyroid cartilage.

The true physiological muscles of the larynx may be divided into two great groups, **extrinsic** and **intrinsic**. The extrinsic laryngeal muscles comprise all muscles passing to the os hyoideum, which is physiologically a part of the laryngeal apparatus, as well as the *m. sterno-thyreoideus*. They have already been described in the section on muscles.

The **intrinsic laryngeal muscles** are twenty-one in number, ten paired and one unpaired. They may be roughly classified physiologically as follows:—

- A. Constrictor muscles of the larynx, including the adductors of the vocal folds—
 - Mm. cricoarytænoidei laterales*. Paired.
 - Mm. thyreoarytænoidei*. Paired.
 - M. arytænoideus transversus*. Unpaired.
 - Mm. arytænoidei obliqui*. Paired.
 - Mm. aryepiglottici*. Paired.
- B. Dilator muscles of the larynx, including the abductors of the vocal folds—
 - Mm. cricoarytænoidei posteriores*. Paired.
 - Mm. thyreoepiglottici*. Paired.
- C. Muscles modifying the tension of the vocal cords—
 - Mm. cricothyreoidei*. Paired.
 - Mm. vocales*. Paired.
 - Mm. ventriculares*. Paired.
 - Mm. thyreoarytænoidei* (also constrictors). Paired.

The ***mm. cricoarytænoidei laterales*** are a pair of triangular muscles, each of which lies in the lateral wall of the larynx upon the conus elasticus and concealed by the lamina of the thyroid cartilage, the thyroid gland, and the infra-hyoid muscles.

Each muscle arises from the upper border and the lateral surface of the arch of the cricoid cartilage as far dorsally as the facet which supports the base of the arytenoid cartilage, and also from the lateral part of the conus elasticus.

From this origin the muscular fibres run dorsally and upwards, and converge to be inserted into the ventral surface of the processus muscularis of the arytaenoid cartilage. The muscle is not infrequently inseparable from the (external) thyreo-arytaenoid muscle.

By its action the lateral crico-arytaenoid muscle draws the processus muscularis of the arytaenoid cartilage ventrally and downwards, thus turning the processus vocalis of the same cartilage medially, and tending thereby to stretch the vocal fold and to approximate it to its fellow of the opposite side, thus assisting in closure of the rima glottidis. Its nerve supply is the anterior ventral branch of the inferior laryngeal nerve.

The Mm. Thyreoarytaenoidei (O.T. Thyreoarytaenoides Externus).—Each thyreo-arytaenoid muscle is a paired, thin, quadrangular muscle, which is only separable from the m. vocalis, with which it forms a common mass, by artificial means.

It lies in the lateral wall of the larynx immediately to the medial side of the lamina of the thyroid cartilage, and lateral to the appendix ventriculi laryngis, the m. vocalis, and the conus elasticus; its inferior border is in contact with the lateral crico-arytaenoid

FIG. 853.—DISSECTION OF THE MUSCLES OF THE LATERAL WALL OF THE LARYNX.

muscle, whilst its superior border extends farther upwards than the vocal fold, and is in contact with the inferior border of the thyreo-epiglotticus.

It arises from the inferior half of the medial surface of the lamina of the thyroid cartilage, close to its ventral angle, and also from the lateral part of the conus elasticus. The muscular fibres pass dorsally and upwards to be inserted into the lateral border and muscular process of the arytaenoid cartilage; some of the fibres, however, turn round this cartilage and become continuous with the arytaenoid obliquus. The upper fibres of the thyreo-arytaenoid vary very greatly in their development and arrangement.

By its action the muscle rotates the arytaenoid cartilage and draws it ventrally in such a way that its vocal process is carried ventrally and medially and the vocal fold is rendered somewhat flaccid. The muscle thus antagonises the crico-thyreoideus. The main action of the muscle must, however, be that of a constrictor of the supraglottic region of the larynx.

FIG. 854.—DISSECTION OF THE MUSCLES ON THE DORSAL ASPECT OF THE LARYNX.

The *nerve supply* is the anterior branch of the inferior laryngeal nerve.

The **m. arytenoideus transversus** is a thick, oblong, unpaired muscle which lies in the dorsal wall of the larynx and bridges across the interval between the two arytenoid cartilages. The ventral surface of the muscle is in contact with the dorsal concave surfaces of the arytenoid cartilages, and between them with the mucous membrane of the larynx. Its dorsal surface is partly concealed by the arytenoidei obliqui and by the submucous tissue of the pharynx. The inferior border extends to the lamina of the cricoid cartilage, and its upper border does not quite reach the apices of the arytenoid cartilages.

The **attachments** of the muscle are, on both sides, to the dorsal surface of the processus muscularis and the lateral edge of the arytenoid cartilages. All the fibres run in a frontal (coronal) direction, and some turn round the arytenoid cartilage to become continuous with the thyreo-arytenoideus. It is in this way that the latter muscle becomes a sphincter of the glottis.

By its **action** the arytenoideus transversus approximates the arytenoid cartilages, thereby tending to close the pars intercartilaginea of the rima glottidis. Its assistance in the sphincter action of the thyreo-arytenoideus has already been pointed out.

The muscle is *innervated* by the posterior or dorsal rami of the inferior laryngeal nerve of both sides.

The **mm. arytenoidei obliqui** are a pair of muscles which lie in the dorsal wall of the larynx, immediately dorsal to the arytenoideus transversus and ventral to the submucous tissue of the pharynx.

Each muscle consists of a bundle of muscular fibres which **arise** from the dorsal aspect of the processus muscularis of the corresponding arytenoid cartilage. From their origins the two fleshy slips proceed upwards and medially, and cross each other in the median plane like the two limbs of the letter X. Reaching the apex of the arytenoid cartilage of the opposite side, many, but not all, of the fibres are **inserted** there, but others receiving a fresh attachment *arise* from the apex of the arytenoid cartilage as the **m. aryepiglotticus**, and extend ventrally and upwards in a series of arches within the ary-epiglottic fold to terminate in the thyreo-epiglottic ligament and the lateral margin of the epiglottic cartilage; and as the muscle approaches the latter structure its fibres are joined by the fibres of the thyreo-epiglotticus. With its superior border are also commingled some fibres from the **m. stylo-pharyngeus**.

Action.—The arytenoideus obliquus and aryepiglotticus combined, act as a rudimentary sphincter muscle for the aditus and the vestibulum laryngis, that is for the superior aperture of the larynx, inasmuch as they extend from the base of one arytenoid cartilage to the arytenoid cartilage of the opposite side, and then on to the epiglottis within the ary-epiglottic fold.

The two muscular slips are *innervated* by the corresponding anterior rami of the inferior laryngeal nerves.

The **mm. cricoarytenoidei posteriores** are a pair of triangular muscles, each of which lies on the dorsal surface of the lamina of the cricoid cartilage, under cover of the tela submucosa of the pharynx. They **arise** by a broad origin from the medial and inferior part of the depression on the dorsal surface of the lamina of the cricoid cartilage at the side of the median ridge; from this origin its fibres converge upwards and laterally to be **inserted** into the dorsal surface and apex of the processus muscularis of the arytenoid cartilage. In pursuing their course from origin to insertion the muscular fibres display very different degrees of obliquity. The most superior fibres are short and nearly horizontal; the intermediate fibres are the longest and are very oblique; whilst the most inferior fibres are almost vertical in their direction.

By its **action** the crico-arytenoideus posterior draws the muscular processes of the arytenoid cartilages medially and dorsally, swings the vocal processes and the vocal folds laterally, and thereby opens the rima glottidis.

The muscle is *innervated* by the posterior ramus of the inferior laryngeal nerve.

The **mm. thyreoepiglottici** are a pair of thin, oblong, very variable muscles,

which lie in the lateral walls of the larynx. Each is bounded below by the thyreo-arytænoideus, medially by the thyreo-epiglottic ligament and the appendix ventriculi laryngis, and laterally by the lamina of the thyroid cartilage. It constitutes what was formerly described as the uppermost fibres of the thyreo-arytænoideus externus muscle.

Each thyreo-epiglotticus arises from the medial surface of the lamina of the thyroid cartilage, immediately above the origin of the thyreo-arytænoideus. From this origin the fibres run in arches upwards and dorsally to be inserted partly into the margin of the ary-epiglottic fold, and partly into the lateral margin of the epiglottis, being intermingled with the fibres of the ary-epiglotticus.

By its action the thyreo-epiglotticus widens the aditus and the vestibulum laryngis. Its innervation is derived from the ventral ramus of the inferior laryngeal nerve.

The **mm. cricothyroidei** are a pair of quadrangular muscles, broader and

FIG. 855.—THE CRICO-THYROID MUSCLE OF THE RIGHT SIDE.

FIG. 856.—FRONTAL SECTION OF THE LARYNX, SHOWING MUSCLES.

thicker above than below. They lie on the cricoid cartilage and bridge over the crico-thyroid interval, and are therefore the only intrinsic laryngeal muscles which are visible in an ordinary dissection of the neck. Each is covered laterally and in part by the thyroideus and the sterno-thyroid and the sterno-hyoid muscles. Between the two muscles of opposite sides there is an intermediate triangular area left in which the crico-thyroid ligament is visible.

Each crico - thyroideus arises from the lower border and lateral surface of the arch of the cricoid cartilage, and from this origin its fibres radiate dorsally and upwards to be inserted into the inferior border and medial surface of the lamina of the thyroid cartilage, as far as its inferior cornu, and also into the inferior cornu itself. As a general rule each muscle is divided into two parts, viz., (1) a **pars recta** composed of those fibres which are inserted into the lamina of the thyroid car-

tilage; and (2) a **pars obliqua** formed of those fibres which are inserted into the inferior cornu. The muscle is closely associated with the inferior constrictor

muscle of the pharynx, and sometimes shows a certain amount of continuity with it.

The general **action** of the crico-thyreoideus is to render the vocal fold tense, as is more fully set forth in the paragraph dealing with the actions of the intrinsic laryngeal muscles as a whole.

The *innervation* is derived from the external ramus of the superior laryngeal nerve.

The Mm. Vocales (O.T. Internal Thyreo-arytænoid Muscles).—The vocalis muscle of each side is a triangular, somewhat prismatic muscle, which forms with the thyreo-arytænoides a common muscular mass separable only with difficulty into its two constituent portions. The m. vocalis lies within the vocal fold closely applied to the lateral aspect of the ligamentum vocale, and receives its prismatic form from this adaptation. Of its three surfaces, the *medial* lies adjacent to the ligamentum vocale and the conus elasticus; the *upper* surface is bounded by the labium vocale and the entrance to the ventricle of the larynx; whilst the *lateral* surface is bounded by, and is in contact with, the thyreo-arytænoides.

The m. vocalis **arises** from the inferior part of the angular depression between the two laminae of the thyroid cartilage, and also from the corresponding vocal fold, whence the fibres run dorsally to be **inserted** into the lateral aspect of the vocal process and the depression on the ventro-lateral surface of the arytænoid cartilage. The greater thickness of the m. vocalis dorsally than ventrally is due to the fact that whilst all its fibres are attached dorsally to the arytænoid cartilage, only a certain proportion obtain attachment ventrally to the thyroid cartilage. The remainder are attached at irregular intervals to the lateral margin of the vocal fold itself.

It follows that the **action** of the muscle is to draw the vocal process of the arytænoid cartilage ventrally, thereby relaxing the vocal fold and ligament.

The *innervation* is derived from the anterior ramus of the inferior laryngeal nerve.

The **m. ventricularis** is composed of several bundles of fibres, visible under the microscope, which pass in a vertical direction from the lateral edge of the arytænoid cartilage to the lateral margin of the cartilage of the epiglottis. There are also intermingled with it fibres from the thyreo-arytænoides and aryepiglotticus.

Action of the Intrinsic Laryngeal Muscles.—By the action of the intrinsic laryngeal muscles the position and tension of the vocal folds are so influenced that, during the passage of air through the larynx, the tone and the pitch of the voice is determined. *Tension* of the vocal folds is produced by the contraction of the two **crico-thyroid muscles**. The straight portions of the muscles pull the inferior border of the thyroid cartilage downwards, whilst the oblique portions, through their insertion into the inferior cornua, draw the thyroid cartilage ventrally, thereby increasing the distance between the angle of the thyroid cartilage and the vocal processes of the arytænoid cartilages. When the crico-thyroid muscles cease to contract, the relaxation of the cords is brought about by the elasticity of the ligaments. The **thyreo-arytænoid muscles** must be regarded as antagonistic to the crico-thyroid muscles. When they contract they approximate the angle of the thyroid cartilage to the arytænoid cartilages, and still further relax the vocal folds; and when they cease to act the elasticity of the ligaments of the larynx again restores the state of equilibrium. They also act as constrictors of the supraglottic region of the larynx. The **vocales muscles**, by the attachments of their fibres into the vocal folds, may tighten portions of these folds, but their main action is relaxation of the vocal folds and ligaments.

The *width of the rima glottidis* is regulated by the **arytænoides transversus**, which draws together the two arytænoid cartilages, and this may be done so effectually that the medial surfaces of these cartilages come into contact; the pars intercartilaginea of the rima glottidis is thus completely closed. The crico-arytænoides lateralis and posterior also modify the width of the rima glottidis. When they act together they assist the arytænoides transversus in closing the glottis, but when they act independently they are antagonistic muscles. Thus the **crico-arytænoides posterior** draws the muscular processes of the arytænoid cartilages dorsally and medially, and swings the vocal processes and the vocal folds laterally, and thereby opens the rima. The

lateral crico-arytænoid muscles act in exactly the opposite manner. By drawing the muscular processes of the arytænoid cartilages ventrally and medially, they approximate the vocal processes and close the rima glottidis. The actions of the other muscles have been sufficiently described already.

Closure of the Larynx during Deglutition.—The muscles of the larynx have, however, another function to perform besides vocalisation and regulating the amount of air passing to and fro through the glottis. During deglutition it is requisite that the communication between the pharynx and larynx should be closed, to prevent the fluid or solid parts of the food entering the respiratory passages. In the process of closing the laryngeal entrance the epiglottis stands erect, whilst the dorsal wall formed by the arytænoids is carried ventrally, the arytænoid cartilages are closely approximated, glide ventrally, and are then inclined towards the epiglottis. The result of this is that the laryngeal opening is converted into a T-shaped fissure. The median limb of the T is formed by the interval between the closely applied arytænoid cartilages, whilst the cross limb, which lies ventrally, is bounded ventrally (anteriorly) by the epiglottis and dorsally by the aryepiglottic folds. The apices of the arytænoid cartilages, with the corniculate cartilages (Santorini), are pressed against the tubercle of the epiglottis, whilst the lateral margins of the epiglottis are pulled dorsally so as to make the transverse limb of the fissure distinctly concave in a dorsal direction. The muscles chiefly concerned in producing these movements are the thyreo-arytænoid and the transverse arytænoid muscles. These form a true sphincter vestibuli. The thyreo-epiglottic and aryepiglottic muscles also come into play. They pull upon the epiglottis so as to produce tight application of its tubercle to the arytenoid cartilages and the corniculate cartilages (Santorini), and they also curve its margins dorsally so as to increase its dorsal concavity.

Vessels and Nerves of the Larynx.—Two branches of the vagus nerve, viz., the superior laryngeal and the recurrent (laryngeal) nerves, supply the larynx. The superior laryngeal divides into the internal and external laryngeal branches. The external laryngeal nerve supplies the crico-thyroid muscle; whilst the internal laryngeal nerve enters the larynx by piercing the lateral part of the hyothyroid membrane to supply the laryngeal mucous membrane. The recurrent nerve reaches the larynx from the thoracic direction, and, by its terminal inferior laryngeal branch, supplies all the intrinsic laryngeal muscles with the exception of the crico-thyroid.

The superior laryngeal artery, a branch of the superior thyreoid, accompanies the internal laryngeal nerve; whilst the inferior laryngeal artery, which springs from the inferior thyreoid, accompanies the inferior laryngeal nerve. These two vessels ramify in the laryngeal wall and supply the mucous membrane, the glands, and muscles.

Growth-Alteration and Sexual Differences in the Larynx.—A considerable amount of variation may be noticed in the size of the larynx in different individuals. This is quite independent of stature, and explains to a great extent the difference in the pitch of the voice in different persons. But quite apart from these individual variations, there is a marked sexual difference in the size of the larynx. The male larynx is not only absolutely, but also relatively, larger than the female larynx in all its diameters, but more particularly in the ventro-dorsal diameter; and to a large extent the increase in that direction is produced by the strong development of the prominentia laryngea in the male. The greater ventro-dorsal diameter of the male larynx necessarily implies a greater length of the vocal folds and a lower or deeper tone of the voice in the male than in the female.

In a newly born child the larynx, in comparison with the rest of the body, is somewhat large (C. L. Merker), and it continues to grow slowly and uniformly up to the sixth year of childhood. At this period there is a cessation of growth until puberty is reached, and then a stage of active growth supervenes. Up to this time the larynx in both sexes is similar in its dimensions, and although the growth which now occurs affects both the male and the female larynx, it is much more rapid and much more accentuated in the male than in the female. As a result of this the voice of the male "breaks" and assumes its deep tone.

It is interesting to note that the growth activity of the larynx at puberty is intimately connected with the development of the sexual organs. In a male subject who has been castrated when young the larynx attains a size which exceeds that of the female only to a small degree, and the high pitch of the voice is retained.

Appearance of the Interior of the Larynx when examined by the Laryngoscope.

When the cavity of the larynx is illuminated and examined by laryngoscopic mirrors, the parts which surround the superior aperture of the larynx, as well as the interior of the organ, come into view. Not only this, but when the vocal folds are widely separated it is possible to inspect the interior of the trachea as far as its bifurcation.

In such an examination the arched upper border of the epiglottis is a conspicuous object, whilst, dorsal to this, the bulging on the ventral wall of the vestibule, formed by the tubercle of the epiglottis, may also be a feature of the picture. The median glosso-epiglottic fold with the epiglottic vallecula on either side of it, can also be inspected in the interval between the epiglottis and the base of the tongue. The sharp aryepiglottic folds are clearly visible, and in the dorsal portion of each of these can be seen the two prominent tubercles which are formed by the enclosed cuneiform and corniculate cartilages. Dorsal to these tubercles is the dorsal wall of the pharynx, whilst to their lateral side the deep piriform

FIG. 857.—CAVITY OF THE LARYNX, as seen by means of the laryngoscope.

A. Rima glottidis closed.

B. Rima glottidis widely opened.

recess may be seen. In the interior of the larynx the ventricular and the vocal folds are easily recognised, and the interval between the two, or, in other words, the entrance into the laryngeal ventricle, appears as a dark line on the lateral wall of the larynx. The ventricular folds are red and fleshy-looking; the vocal folds during phonation are tightly stretched and pearly white—the white colour being usually more apparent in the female than in the male. The outline and yellowish tinge of the vocal process at its attachment to the vocal fold, and the outline of the ventral part of the base of the arytenoid cartilage to a slight extent as well, can be made out in a successful laryngoscopic examination. The vocal folds during ordinary inspiration are seldom at rest, and with the laryngoscope their movements may be studied. It should be borne in mind that the picture afforded by the laryngoscope does not give a true idea of the level at which the different parts lie. The cavity appears greatly shortened, and its depth diminished.

TRACHEA.

The **trachea** or **windpipe** is a wide tube which is kept permanently patent by a series of cartilaginous rings embedded in its wall. These rings are deficient dorsally, and consequently the tube is not completely cylindrical: its dorsal wall is flattened. The trachea begins at the inferior border of the cricoid cartilage, opposite the inferior margin of the sixth cervical vertebra. From this it extends through the neck into the superior mediastinum of the thorax, and it ends at the level of the superior border of the fifth thoracic vertebra by dividing into the right and left bronchi. The length of the trachea in the male is from four to four and a half inches, and in the female from three and a half to four inches, but even in the same individual it varies considerably in length with the movements of the head and neck.

The inferior end of the trachea is fixed in position. This is a necessary provision to prevent dragging on the roots of the lung during movements of the head and neck. The remainder of the tube is surrounded by a quantity of loose areolar tissue, and possesses a considerable amount of mobility. Further, its wall is highly elastic, and thus when the head is thrown back the tube elongates through stretching, and when the chin is depressed its length is diminished by the recoil of its wall.

The trachea does not present an absolutely uniform calibre throughout its whole length. About its middle it exhibits a slight expansion or dilatation, and from this the calibre diminishes towards both extremities. Close to the bifurcation it is again slightly expanded (Braune and Stahel).

These differences in the calibre of the tube are determined by the surroundings of the trachea. The cervical part is narrowed owing to its being clasped by the thyroid gland. Further, a short distance above its bifurcation an impression, sometimes strongly marked, is usually seen on the left side of the trachea. This is due to the close contact of the aortic arch as it passes dorsally against this part of the tube. It is evident therefore that the second slight diminution in calibre which is described by Braune and Stahel is produced by the proximity of the aorta. Lejars gives the average ventro-dorsal diameter of the trachea in the living person as 11 mm., and the transverse diameter as 12.5 mm. In the dead subject the lumen of the tube is considerably greater.

The trachea adheres rigorously to the median plane except towards its termination, where it deviates very slightly to the right. As it passes downwards it recedes rapidly from the surface. This is due to its following the curvature of the vertebral column, from which it is separated by the œsophagus alone.

Relations of the Trachea.—In the study of the relations of the trachea it is convenient to consider it in the two stages of cervical and thoracic.

When the chin is held so that the face looks directly forwards the **cervical part** of the trachea measures from 2 to 2½ inches in length; but when the head is thrown dorsally or backwards the length is considerably increased. It is clasped by the thyroid gland, the isthmus of which is applied to its ventral surface, and covers the second, third, and fourth rings; while on each side the lateral lobe of the thyroid gland is applied to the lateral surface of the trachea and extends downwards to the fifth or sixth ring. On either side of the cervical part of the trachea is the common carotid artery, whilst the recurrent nerve passes upwards in the groove between the trachea and the œsophagus. Dorsally the trachea is in relation to the œsophagus, which intervenes between it and the bodies of the vertebræ and deviates somewhat to the left as it passes downwards.

In addition to the isthmus of the thyroid gland two thin muscular strata, composed of the sterno-hyoid and the sterno-thyroid muscles, as well as the deep

FIG. 858.—THE TRACHEA AND BRONCHI.

The thyroid gland is indicated by a dotted line and a purple tint.

cervical fascia and integument, separate the cervical part of the trachea from the surface. In the median plane of the neck there is a narrow diamond-shaped space between the medial margins of these muscles, within which the trachea is covered merely by the integuments and fasciæ. It is important to note that in the inferior

part of the neck the cervical fascia is in two layers—viz., a strong stratum applied to the ventral surface of the sterno-hyoid and sterno-thyroid muscles, and a weaker superficial layer stretching across between the two sterno-cleido-mastoid muscles. Dorsal to these muscular and fascial layers the inferior thyroid veins pass downwards on the ventral surface of the trachea, and sometimes the occasional thyroidea ima artery passes upwards on the ventral aspect of the tube. At the superior border of the manubrium sterni the innominate artery may be seen crossing the trachea obliquely.

The thoracic part of the trachea is situated in the dorsal part of the superior mediastinum, being separated from the bodies of the vertebræ by the œsophagus alone. Immediately above its bifurcation the deep cardiac plexus of nerves is placed on the ventral and lateral sides of the trachea. At the level of the fourth thoracic vertebra the aortic arch is very intimately related to it, lying first on the ventral side of the tube, and thereafter on its left side. The three great vessels which spring from the aortic arch are also placed in close proximity to the trachea. The innominate and the left common carotid arteries lie at first ventral to the trachea, and then gradually diverging as they proceed upwards, come to lie on either side of it—the innominate to the

right, and the left common carotid to the left. Ventral to these vessels are the left innominate vein and the remains of the thymus. On the right side the thoracic part of the trachea is in relation to the right vagus nerve, and is clothed by the right mediastinal pleura; on the left side are the left subclavian artery and the left recurrent nerve.

FIG. 859.—TRANSVERSE SECTIONS through the trachea and its immediate surroundings at the level of each of the upper five thoracic vertebræ.

Structure of the Wall of the Trachea.—The walls of the trachea and bronchi are composed of (1) a fibro-elastic membrane in which the cartilaginous rings are embedded; (2) within this, and on the dorsal aspect of the tube, a layer of muscular tissue, termed the *musculus trachealis*; and (3) the lining mucous membrane.

The **fibro-elastic membrane** is strong and dense, and, passing round the whole circumference of the tube, becomes continuous above with the perichondrium which invests the cricoid cartilage. Embedded in its substance are the series of **cartilaginous rings**. These vary in number from 15 to 20, and are composed of hyaline cartilage. They are horseshoe-shaped, the dorsal fourth of the circumference being deficient, so that dorsally each ring ends in two rounded extremities. The outer surface of the tracheal ring is flat and even, and does not project much beyond the level of the membrane in which

FIG. 860.—SAGITTAL SECTION THROUGH THE THORAX OF AN OLD MAN. The superior border of the manubrium sterni and the bifurcation of the trachea are lower than in the average adult.

it is embedded; the inner surface, however, is convex in the vertical direction, and consequently it bulges slightly into the lumen of the tube. The intervals between the rings are somewhat narrower than the rings themselves, and neighbouring rings frequently show a more or less complete fusion, whilst others present other irregularities, such as a tendency to bifurcate. The lowermost ring is specially adapted to the tracheal bifurcation. In the median plane, ventrally, it inclines downwards, and from this median peak a cartilaginous strip is carried backwards in the fork between the two bronchi.

The **m. trachealis** is a continuous layer of involuntary muscular tissue placed in the dorsal part of the wall of the trachea internal to the fibro-elastic membrane. The muscular bundles are arranged transversely, and are attached to the extremities of the rings, and also to the inner surfaces of the rings for a short distance beyond their extremities. In the intervals between the rings the transverse muscular bundles are attached to the fibro-elastic membrane. It is evident that, by its contraction, this muscle will reduce, in a marked degree, the lumen of the tube.

The **mucous membrane** is laid smoothly over the interior of the tube upon a layer of submucous areolar tissue. Lymph tissue enters largely into the composition of the tracheal mucous membrane, and its inner surface is lined with columnar ciliated epithelial cells. The action of the cilia exercises an important influence in producing an upward movement of the mucus which is present on the surface of the mucous membrane.

Numerous longitudinal bundles of elastic tissue are present in the dorsal wall of the trachea, more particularly in its inferior part, between the mucous membrane and the trachealis muscle.

In connexion with the mucous membrane there is a plentiful supply of **acinous mucous glands**. These are placed in the submucous tissue, and also, on the dorsal aspect of the tube, on the exterior of the trachealis as well as amidst its muscular bundles. They send their ducts to the surface of the mucous membrane, where they open by trumpet-shaped mouths.

BRONCHI.

The two chief **bronchi** proceed obliquely downwards and laterally from the termination of the trachea, each towards the hilus of the corresponding lung. Like the

FIG. 861.—DRAWING OF A STEREOSCOPIC SKIAGRAPH OF THE TRACHEA AND BRONCHI INJECTED WITH STARCH AND RED LEAD.

trachea, they are kept permanently patent by the presence of cartilaginous rings in their walls. These rings are deficient dorsally, so that the bronchi exhibit a flattened dorsal surface, in every respect similar to the trachea. The two bronchi differ from each other, not only in the relations which they present to surrounding structures, but also in length, in width, and in the direction which they pursue (Fig. 858, p. 1079).

The first collateral branch of the right bronchus (**ramus bronchialis eparterialis**) arises much nearer the trachea than the first branch of the left bronchus. This difference determines the length of the primary divisions of the trachea, and, although there is much variation in the matter, it may be said that, as a rule, the

left bronchus is at least twice as long as the right bronchus. According to Henle there are from six to eight rings in the right, and from nine to twelve rings in the left, bronchus. A marked difference is also noticeable in the calibre of the two tubes. The right bronchus is wider than the left in the proportion of 100 to 78·4 (Braune and Stahel), and this asymmetry is clearly due to the fact that the right lung is more bulky than the left. The right bronchus, as it passes towards the hilus of the right lung, takes a more vertical course than the left bronchus. It therefore lies more in the line of the trachea, and to this, as well as to its greater width, is due the greater tendency which foreign bodies exhibit, when introduced into the trachea, to drop into the right bronchus, in preference to the left. The average angle which the right bronchus forms with the median plane is $24^{\circ}8'$, whilst the angle formed by the left bronchus with the median plane is $45^{\circ}6'$. The more horizontal course of the left bronchus is probably determined by the marked projection of the heart to the left side of the median plane (Merkel).

Relations of the Bronchi.—Arching above the right bronchus, from behind forwards, is the vena azygos, whilst arching above the left bronchus, from before backwards, there is the arch of the aorta. Occupying the interval between the bronchi there is a cluster of bronchial lymph glands, and an irregular chain of similar glands is carried along each tube towards the hilus of the lung. On the dorsal aspect of each bronchus the vagus nerve breaks up into the plexus pulmonalis posterior, whilst the left bronchus, as it proceeds downwards and laterally, crosses the ventral surfaces of the œsophagus and descending thoracic aorta. The most interesting relation is, however, that presented on each side by the corresponding pulmonary artery. On the left side the pulmonary artery crosses ventral or anterior to the left bronchus on the superior side of its first collateral branch, and then turns round its lateral side to gain its dorsal aspect. All the left bronchial branches, therefore, are placed inferior to the left pulmonary artery, and are in consequence termed **hyparterial**. The right pulmonary artery, on the other hand, crosses ventral to the continuation of the right bronchus, inferior to its first collateral branch. This branch is therefore termed the **eparterial bronchus**, whilst all the others are classified as hyparterial.

Structure of the Walls of the Bronchi.—The walls of the bronchi present a structure similar to that seen in the trachea.

CAVUM THORACIS.

The **cavity of the thorax** is divided into two large lateral chambers, which contain the lungs, by a median partition termed the **mediastinal septum**, which extends from the vertebral column to the ventral thoracic wall. From the fact that each of these chambers is lined by an extensive and separate serous membrane called the **pleura**, they receive the name of the **pleural cavities**.

Septum Mediastinale.—The mediastinal septum is built up of several structures which lie in, or in close proximity to, the median plane. The more important of these are the heart, enveloped in its pericardium, the thoracic aorta, with the great vessels which spring from its arch, the pulmonary artery, and the great veins in the neighbourhood of the heart, the thymus or its remains, the trachea, œsophagus, and thoracic duct, and the vagi and phrenic nerves.

Cavum Pleuræ.—The pleural cavities, in which the two lungs lie, comprise much the larger part of the thoracic cavity. Each **pleural cavity** is bounded *inferiorly* by the corresponding cupola of the diaphragm; and as the right cupola rises to a higher level than the left, the right pleural cavity presents a smaller vertical depth than the left. *Ventrally*, the wall of each pleural chamber is formed by the costal cartilages and the sternum; *laterally*, by the bodies of the ribs and the intercostal muscles as far as the costal angles; *dorsally*, by the portions of the ribs, with the intervening intercostal muscles, which lie medial to the costal angles; and *medially*, by the bodies of the vertebræ and the mediastinal septum, which completely shuts off the one chamber from the other.

The mediastinal septum is not uniformly median in position. Owing to the

marked projection of the heart to the left side, and to the position of the thoracic aorta on the left side of the median plane, the left pleural chamber, although it is deeper than the right, is greatly reduced in width. The two pleural cavities, therefore, are very far from being symmetrical in form, and consequently the mediastinal septum tends to extend to the left of the median plane of the body.

Each pleural cavity is completely lined by a separate serous membrane termed the **pleura**. The portion of this membrane which clothes the mediastinum or intervening partition forms the lateral boundary of an area termed the **mediastinal** or **interpleural space**, within which the parts which build up the mediastinal septum are placed.

PLEURÆ.

The pleura of each side not only lines the corresponding pleural cavity, but at the pulmonary root, it is prolonged on to the lung so as to give it a complete investment. It is customary, therefore, to recognise a **pulmonary** or **investing part** (pleura pulmonalis) and a **parietal** or **lining part** (pleura parietalis). The inner surface of the pleura (*i.e.* that surface which is turned towards the interior of the cavity) is coated with squamous endothelium, and presents a smooth, glistening, and polished appearance; further, it is moistened by a small amount of serous fluid.

FIG. 862.—DIAGRAM SHOWING ARRANGEMENT OF PLEURAL SACS AS SEEN IN TRANSVERSE SECTION.

down to the very bottom, and thus completely separates the different lobes of the lungs from each other. The pulmonary pleura becomes continuous with the mediastinal pleura at the root of the lung, and also through the ligamentum pulmonale.

Pleura Parietalis.—Different names are applied to the parietal pleura as it lines the different parts of the wall of the cavity in which the lung lies. Thus there are the *costal pleura*, the *diaphragmatic pleura*, the *mediastinal pleura*, and the *cupula pleuræ*; but it must be borne in mind that these terms are merely used for convenience in description, and that the portions of the pleura so designated are all directly continuous with each other.

The **cupula pleuræ** or the cervical pleura rises into the root of the neck, through the superior aperture of the thorax, and forms a dome-shaped roof for the pleural cavity. Its highest point or summit reaches the level of the inferior border of the neck of the first rib; but owing to the great obliquity of the first costal arch, this point is placed from one to two inches above to the ventral or anterior extremity of the first rib, and from a half to one and a half inches above the clavicle. The cupula pleuræ is supported on the lateral side by the scalenus anterior and scalenus medius muscles, whilst the subclavian artery, arching laterally, lies in a groove on its medial and ventral aspects a short distance below its summit.

In consequence of this the surface of the lung covered by pulmonary pleura can glide on the wall of the cavity, lined as it is by parietal pleura, with the least possible degree of friction. In the pathological condition known as pleurisy the inner surface of the pleura becomes roughened by inflammatory exudation, and the so-called "friction sounds" are heard when the ear is applied to the chest.

Pleura Pulmonalis.—The pulmonary pleura is very thin, and is so firmly bound down to the surface of the lung that it cannot be detached without laceration of the pulmonary substance, and then only in small pieces. It dips into the fissures of the lungs, lines them

At a lower level the innominate and subclavian veins also lie upon its medial and ventral aspects.

The cupula pleuræ is strengthened and held in place by an aponeurotic expansion, first described by Sibson, which is spread over it, and is attached to the internal concave margin of the first rib. This fascia is derived from a small muscular slip which takes origin from the transverse process of the seventh cervical vertebra.

Pleura Costalis.—The costal pleura is the strongest and thickest part of the parietal pleura. It lines the internal surfaces of the costal arches and of the intervening intercostal muscles. Ventrally it reaches the sternum, whilst dorsally it passes from the ribs over the sides of the bodies of the vertebrae. It is easily detached from the parts which it covers, except as it passes from the heads of the ribs on to the vertebral column. Here it is somewhat tightly bound down.

Pleura Diaphragmatica.—The diaphragmatic pleura covers that portion of the thoracic surface of the diaphragm which lies to the lateral side of the base

of the pericardium, but it does not dip down to the bottom of the narrow interval between the thoracic wall and the diaphragm. In other words, a strip of the thoracic surface of the diaphragm adjoining its costal attachment is left uncovered.

Pleura Mediastinalis.—The mediastinal pleura extends from the dorsal surface of the ventral thoracic wall to the vertebral column, and clothes the side of the mediastinal septum, which intervenes between the two pleural cavities. It is continuous with the costal pleura of its own side, both ventrally and dorsally, along two lines which are respectively termed the sternal and vertebral lines of

FIG. 863.—DISSECTION OF A SUBJECT HARDENED BY FORMALIN INJECTION, to show the relations of the two pleural sacs, as viewed from the front. The anterior and diaphragmatic lines of pleural reflection are exhibited by black dotted lines, whilst the outlines of the lungs and their fissures are indicated by the blue lines.

pleural reflection; whilst inferiorly it becomes continuous with the diaphragmatic pleura, of its own side, at the base of the pericardium.

Above the root of the lung the mediastinal pleura passes directly from the sternum to the vertebral column. In this region the *left mediastinal pleura* is applied to the arch of the aorta and the phrenic and vagus nerves; to the left innominate vein, the left superior intercostal vein and the left common carotid and

left subclavian arteries; to the œsophagus and the thoracic duct. The *right mediastinal pleura*, on the other hand, is applied, above the root of the lung, to the superior part of the vena cava superior and the right innominate vein; to the innominate artery; to the vena azygos, as it hooks forwards above the bronchus; to the vagus and phrenic nerves; and to the right side of the trachea.

Opposite the root of the lung, as well as in the region below it, the mediastinal pleura clothes the corresponding aspect of the pericardium (*pleura pericardiaca*), and is somewhat firmly attached to it. As the phrenic nerve passes downwards upon the pericardium it likewise is covered over by the pleura. In the region corresponding to the superior part of the lateral aspect of the pericardium the mediastinal pleura is prolonged laterally, so as to form an investment for the root of the lung, and becomes continuous around the hilus of the lung with the pulmonary pleura. Below the root of the lung the two layers of pleura which invest it come into apposition with each other, and are prolonged downwards as a distinct fold, termed the *ligamentum pulmonale*. This fold stretches between the pericardium and the inferior part of the mediastinal surface of the lung, and ends inferiorly in a free border.

Dorsal to the root of the lung and the *ligamentum pulmonale* the mediastinal pleura on the *right side* passes over the œsophagus to the vertebral column, whilst on

FIG. 864.—LATERAL VIEW OF THE RIGHT PLEURAL SAC IN A SUBJECT HARDENED BY FORMALIN INJECTION. The blue lines indicate the outline of the right lung, and also the position of its fissures.

the *left side* it passes dorsally over the thoracic aorta, and to a small extent over the lower end of the œsophagus, in the region immediately adjoining the diaphragm, ventral to the thoracic aorta.

Lines of Pleural Reflection.—These are three in number—viz., the sternal, the vertebral, and the diaphragmatic. The pleural cavities are not symmetrical. The left is longer and narrower than the right, and it thus happens that the lines of pleural reflection do not accurately correspond on the two sides of the body. Further, although the

vertebral line of reflection is fairly constant, the other two reflection-lines are subject to marked variations in different subjects. Consequently the following description must be regarded as merely giving the average condition.

The **vertebral line of pleural reflection** is that along which the costal pleura is continued ventrally from the vertebral column to become the mediastinal pleura. On the *right side*, above the root of the lung, the pleura passes from the bodies of the vertebræ on to the right side of the trachea; whilst lower down, and dorsal to the pericardium, it passes from the vertebral bodies on to the œsophagus. On the *left side*, and above the arch of the aorta, the pleura along this line of reflection is carried from the vertebral column on to the œsophagus and thoracic duct; below that level it passes on to the thoracic aorta. In the superior part of the chest the right and left lines of reflection are placed well apart from each other, and about equidistant from the median plane. As they are traced downwards they approach more closely to each other and deviate to the left, so that whilst the reflection on the *right side* takes place from the ventral aspect of the vertebral bodies, on the *left side* it takes place from the left aspect of the vertebral column. This is due to the position of the thoracic aorta.

The **sternal line of pleural reflection** is that along which the costal pleura leaves the ventral thoracic wall to become the mediastinal pleura. The lines differ somewhat on the two sides, and in both cases show a tendency to deviate to the left (Fig. 863, p. 1085). In the vicinity of the manubrium sterni the two pleural sacs are separated from each other by an angular interval. The lines of reflection at the superior thoracic aperture or inlet correspond to the sterno-clavicular joints. From these points the lines, as they are traced downwards, converge behind the manubrium, until at last they meet at its inferior border. Here the two sacs come into contact with each other, and the lines of reflection coincide. From this they proceed downwards on the back of the body of the sternum, with a slight deviation to the left of the median plane, until a point immediately above the level of the sternal attachments of the fourth costal cartilages is reached, and here the two sacs part company. The line of reflection of the *right pleura* is continued downwards in a straight line to the xiphoid process, where the

FIG. 865.—LEFT PLEURAL SAC IN A SUBJECT HARDENED BY FORMALIN INJECTION, opened into by the removal of the costal part of the parietal pleura. The lung has also been removed so as to display the mediastinal pleura.

sternal reflection-line passes into the right diaphragmatic reflection-line. Opposite the sternal attachment of the fourth costal cartilage the reflection-line of the *left pleura* deviates laterally, and is continued downwards at a variable distance from the right pleura. A small triangular area of pericardium is thus left uncovered by pleura, and therefore in direct contact with the ventral chest-wall. Leaving the sternum, the reflection-line of the left pleura passes downwards, parallel and close to the left margin of the sternum, dorsal to the fourth intercostal space, the fifth costal cartilage and the

fifth intercostal space, to the sixth costal cartilage. Here it turns laterally and downwards, and passes into the diaphragmatic reflection-line of the left side.

From the back of the sternum the *right pleura* is reflected, in the superior part of the chest, on to the remains of the thymus, the right innominate vein and the vena cava superior, and, inferior to this, directly on to the ventral aspect of the pericardium. The *left pleura* is reflected from the back of the manubrium sterni on to the left innominate vein and the aortic arch, and, inferior to this, directly on to the ventral side of the pericardium.

The **diaphragmatic line of reflection** is that along which the pleura leaves the thoracic wall and is reflected on to the thoracic surface of the diaphragm. This reflection takes place along a curved line, which, except as it approaches the vertebral column, is placed a short distance above the inferior

FIG. 866.—DISSECTION OF THE PLEURAL SACS FROM BEHIND.

The blue lines indicate the outlines and the fissures of the lungs.

border of the thoracic wall. It differs somewhat on the two sides of the body.

On the *left side* the diaphragmatic line of reflection proceeds downwards along the ascending part of the sixth costal cartilage, crosses the ventral end of the sixth intercostal space and the descending part of the cartilage of the seventh rib (Fig. 865). Still continuing to pass downwards, it crosses the eighth costal arch at the junction between its cartilaginous and bony portions. This is a fairly constant relation on both sides of the body, and it should be noted that a vertical line—the mamillary line,—drawn downwards from the nipple of the breast, intersects the line of pleural reflection, close to the point where it presents this relation to the eighth costal arch. Beyond this point

the line of diaphragmatic reflection is carried downwards and laterally across the extremities of the bony portions of the ninth and tenth ribs. As it crosses the tenth rib, or, it may be, as it proceeds across the tenth intercostal space, the line of pleural reflection reaches its lowest point, and it is important to observe that this point lies in the mid-lateral line (*i.e.* in a vertical line drawn on the side of the chest, midway between vertebral column and sternum). From this, as it curves dorsally towards the vertebral column, it passes slightly upwards. Thus it cuts across the eleventh rib and reaches the twelfth rib. The relation which it presents to the twelfth rib varies in accordance with the length of that rib. When the last rib is not abnormally short the pleura clothes its medial half, and the line of reflection falls below this portion of the rib, so as to reach the vertebral column, midway between the capitulum of the last rib and the transverse process of the first lumbar vertebra (Fig. 866). Here, therefore, the line of diaphragmatic reflection falls below the inferior border of the thoracic wall; and this is a point of practical importance, because in operations upon the kidney the incision cannot be carried above the level of the transverse process of the first lumbar vertebra and the lateral lumbocostal arch without the risk of wounding the pleura. On the *right side* the line of diaphragmatic pleural reflection differs from that on the left chiefly ventrally (Fig. 864, p. 1086). Here it passes at a lower level, and proceeds laterally and downwards from the dorsum of the xiphoid process along the dorsal aspect of the seventh costal cartilage, and then behind the eighth costal arch, as a rule at the same point as on the left side, *viz.*, the junction of its cartilaginous and bony parts. From this on to the vertebral column the relations are so similar to those of the left side that a separate description is unnecessary.

It is commonly stated that the left pleural sac reaches a lower level than the right. In certain cases there is no doubt that it does, but this condition is by no means the rule. In those cases where the two pleural sacs do not reach the same level at their lowest points, it is sometimes the right and sometimes the left pleura which oversteps the mark.

As already stated, the lowest point which the pleura attains is usually found, on both sides, in the mid-lateral line where the diaphragmatic reflection-line crosses the tenth rib or the tenth intercostal space. This point can be very readily ascertained on the surface by drawing a horizontal line round the trunk at the level of the lowest part of the extremity of the spinous process of the first lumbar vertebra, and noting where it is intersected by the mid-lateral line. In the majority of cases the point of intersection will correspond with the lowest part of the pleural sac. Another horizontal line opposite the spine of the twelfth thoracic vertebra will give the level of the diaphragmatic pleural reflection in the mamillary line.¹

Along the line of the diaphragmatic reflection a strong fascia passes from the uncovered part of the diaphragm, and from the costal cartilages to the surface of the costal pleura, so as to hold it firmly in its place. It may be termed the **phrenicopleural fascia**.

MEDIASTINUM.

The term mediastinum is applied to the interval between the mediastinal portions of the two pleural sacs. *Ventrally* it is bounded by the sternum, and *dorsally* by the vertebral column. It is customary to subdivide this space in a purely arbitrary manner into four portions, termed respectively the superior or cranial, the ventral or anterior, the middle, and the dorsal or posterior part, according to the relations which they present to the pericardium.

The **superior mediastinum** is that part of the general area which lies above the level of the pericardium. Its boundaries are as follows:—*Ventrally*, the manubrium sterni, with the attached sterno-hyoid and sterno-thyroid muscles; *dorsally*, the bodies of the first four thoracic vertebrae; *below*, an imaginary and oblique plane, which extends from the inferior border of the manubrium sterni to the inferior border of the fourth thoracic vertebra; *laterally*, the mediastinal pleura.

Within the superior mediastinum are placed (1) the aortic arch and the three

¹ The above description represents the average results which have been obtained from the study of the pleura in a large number of subjects, eight of which were specially hardened by formalin or other re-agents for the purpose. For many of the dissections I have to thank my former assistant, Dr. H. St. J. Brooks, and for others I am indebted to Professor C. J. Patten of Sheffield.—D. J. C.

great arteries which spring from it; (2) the innominate veins and part of the vena cava superior; (3) the trachea, œsophagus, and thoracic duct; (4) the phrenic, vagi, and cardiac nerves, and the left recurrent nerve; (5) the thymus.

The **middle mediastinum** is the wide part of the area which contains the pericardium, and lies below the superior mediastinum. In addition to the pericardium and its contents the middle mediastinum contains the phrenic nerves and their accompanying vessels.

The **ventral mediastinum** is that part of the interpleural region which lies between the pericardium dorsally and the body of the sternum ventrally. In its superior

FIG. 867.—SAGITTAL SECTION THROUGH THE THORAX OF AN OLD MAN. The superior border of the manubrium sterni and the bifurcation of the trachea are lower than in the average adult.

part this region can hardly be said to exist, seeing that there the two pleural sacs come into contact with each other on the ventral aspect of the pericardium; but below the level of the sternal ends of the fourth costal cartilages the left pleura falls short of the right pleura, and an interval is apparent. The only contents to be noticed in the ventral mediastinum are a few lymph glands and some areolar tissue, in which ramify some lymph vessels, and some minute twigs from the internal mammary artery.

The **dorsal mediastinum** is that part of the interpleural region which is situated dorsal to the pericardium. It may be regarded as an inferior continuation of the more dorsal part of the superior mediastinum, and many of the structures in the one are prolonged into the other. The arbitrary superior limit of the dorsal mediastinum is the inferior border of the fourth thoracic vertebra. *Ventrally* it is bounded by the pericardium and the vertical part of the diaphragm. *Dorsally* it is limited by the bodies of the last eight thoracic vertebrae and on each lateral side by the mediastinal pleura. It contains the descending

thoracic aorta with the aortic intercostal arteries, the azygos and hemiazygos veins, the thoracic duct and the œsophagus, with the two vagi.

Structure of the Pleura.—The pleura on each side is a closed sac, and, like other serous membranes, is attached to the wall of the cavity which it lines and to the surface of the viscus which it covers. It is composed of a thin connective-tissue stratum, in which bundles of fibres cross each other in various directions, and intermixed with which there is a considerable quantity of elastic tissue. On the internal surface of this there is a continuous coating of thin endothelial cells placed edge to edge. The pleura so formed is attached to the parts which it lines and invests by a small amount of areolar tissue termed the **subserous layer**. In the case of the pulmonary pleura the subserous tissue is continuous with the areolar tissue in the substance of the lung, and this accounts for the tight manner in which the membrane is bound down.

The pleura is plentifully supplied with blood. This is conveyed to it by minute twigs from the intercostal arteries, the internal mammary artery, and the bronchial arteries. Lymph vessels are also particularly abundant in the pleura and in the subserous layer, and it is by these that excess of fluid is conveyed from its cavity. Many lymph vessels communicate directly with the cavity by means of excessively minute orifices termed **stomata**. Dybkowsky has shown that the lymph vessels and stomata of the pleura are not equally distributed throughout the membrane. Over the ribs and on the mediastinal pleura they are absent.

PULMONES.

The Lungs.—When healthy and sound each lung lies free within the corresponding pleural cavity, and is attached only by its root and the ligamentum pulmonale. It is uncommon, however, in the dissecting room, to meet with a perfectly healthy lung. Adhesions between the pulmonary and parietal layers of pleura, due to pleurisy, are generally present.

Like the cavities in which they are placed, the two lungs are not precisely alike. The right lung is slightly larger than the left, in the proportion of about 11 to 10. The right lung is also shorter and wider than the left lung. This difference is due partly to the great bulk of the right lobe of the liver, which forces the right cupola of the diaphragm to a higher level than the left cupola, and partly to the heart and pericardium projecting more to the left than to the right, thus diminishing the width of the left lung.

The lung is light, soft, and spongy in texture; when pressed between the finger and thumb it crepitates, and when placed in water it floats. The elasticity of the pulmonary tissue is very remarkable. A striking demonstration of this is afforded when the thoracic cavity is opened, and the atmospheric pressure acting upon the interior and exterior of the lung is equalised. Under these conditions the organ immediately collapses to about one-third of its original bulk, and it becomes impossible in such a specimen to study its proper form and dimensions.

The surface of the adult lung presents a mottled appearance. The ground colour is a light slate-blue, but scattered over this there are numerous dark patches of various sizes, and also fine dark intersecting lines. The coloration of the lung differs considerably at different periods of life. In early childhood the lung is rosy-pink, and the darker colour and the mottling of the surface, which appear later, are due to the pulmonary substance, and particularly its interstitial areolar tissue, becoming impregnated, more or less completely, with atmospheric dust and minute particles of soot.

At every breath foreign matter of this kind is inhaled, but only a small proportion of it reaches the lung tissue. The greater part of it becomes entangled in the mucus which coats the mucous membrane of the larger air-passages, and is gradually got rid of along with the mucus through the activity of the cilia attached to the lining epithelium. By the constant upward sweep of these a current towards the pharynx is established. The fine dust and soot particles which reach the finer recesses of the lungs, and ultimately the interstitial tissue, are partly conveyed away by the lymph vessels to the bronchial glands, which in consequence become, in many cases, quite black. The colour of the lung, therefore, depends, to some extent, upon the purity of the atmosphere which is inhaled, and it thus happens that in coal-miners the surface of the lung may be very nearly uniformly black.

The foetal lung differs in a marked degree from the lung of an individual who has breathed. After respiration is fully established, the lung soon comes to occupy almost the whole space allotted to it in the pleural cavity; in the foetus, on the other hand, the lung is packed away at the dorsal aspect, and occupies a relatively much smaller amount of space in the thoracic cavity. Further, it is firm to the touch, and sinks in water. It is only when air and an increased supply of blood are

FIG. 868.—DISSECTION OF THORAX AND ROOT OF THE NECK FROM THE FRONT TO SHOW THE RELATIONS OF THE LUNGS, PERICARDIUM, AND THYMUS.

introduced into the lung that it assumes the soft spongy and buoyant qualities which are characteristic of the adult lung.

Form of the Lungs.—The lungs are accurately adapted to the walls of the pleural chambers in which they are placed, and in the natural state they bear on the surface impressions and elevations which are an exact counterpart of the irregularities on the walls of the cavity in which they lie.

When care has been taken to harden it *in situ*, each lung presents for examination an apex, diaphragmatic, mediastinal, and costal surfaces, and ventral (anterior) and inferior borders.

The **apex pulmonis** is blunt and rounded, and rises above the level of the oblique first costal arch to the full height of the cupula pleuræ. It therefore protrudes above, through the superior aperture of the thorax, into the root of the

neck. The subclavian artery arches laterally on its medial and ventral aspects a short distance below its summit, and a groove, the *sulcus subclavius*, corresponding to the vessel, is apparent upon it. At a lower level on the apex pulmonis a shallower and wider groove upon its medial and ventral aspects marks the position of the innominate vein. Although these vessels impress the lung they are separated from it by the cupula pleuræ.

The diaphragmatic surface, or base of the lung, presents a semilunar outline, being curved around the base of the pericardium. It is adapted to the thoracic surface of the diaphragm, and is consequently deeply hollowed out. As the right cupola of the diaphragm passes further upwards than the left, the basal concavity of the right lung is deeper

FIG. 869.—THE TRACHEA, BRONCHI, AND LUNGS OF A CHILD, HARDENED BY FORMALIN INJECTION.

than that of the left lung. Laterally and dorsally, the diaphragmatic surface of each lung is limited by a thin salient margin, called the *inferior border* or margin, which extends downwards for some distance in a narrow pleural recess, the *sinus phrenicocostalis*, between the diaphragm and the chest-wall. This inferior border of the lung extends further downwards on the lateral side and dorsally than it does ventrally, but it falls considerably short of the bottom of the phrenicocostal sinus. Thus, after expiration, it reaches the inferior border of the sixth rib in the mamillary line; the eighth rib, in the axillary or mid-lateral line; whilst dorsally it proceeds medially

FIG. 870.—MEDIAL SURFACE OF A LEFT LUNG HARDENED *IN SITU*.

along a straight horizontal line so as to reach the vertebral column at the level of the extremity of the spine of the tenth thoracic vertebra. During respiration the thin inferior border moves freely in a vertical direction within the phrenico-

costal sinus, but even after the deepest breath it never reaches the extreme lower limit of this recess.

The diaphragmatic surfaces of the lungs establish important relations with certain of the viscera which occupy the costal zone of the abdominal cavity, the diaphragm alone intervening. Thus the diaphragmatic surface of the right lung rests upon the right lobe of the liver; whilst that of the left lung is in relation to the left lobe of the liver, the fundus of the stomach, the spleen, and in some cases to the left colic flexure.

The **costal surface** is extensive and convex. It is accurately adapted to that part of the wall of the pleural cavity which is formed by the costal arches and the intervening intercostal muscles, and it presents markings corresponding to these. Thus the imprint of the ribs appear as shallow oblique grooves, while the

intercostal spaces show as elongated intervening bulgings.

The **mediastinal surface** presents a smaller area than the costal surface. It is applied to the mediastinal septum, and presents markings in accordance with the inequalities upon this (Figs. 870 and 871). Thus it is deeply hollowed out in adaptation to the pericardium upon which it fits. This pericardial concavity comprises the greater part of the mediastinal surface, and owing to the greater projection of the heart to the left side, it is much deeper and more extensive in the left lung than in the right lung. Above and dorsal to the pericardial hollow is the hilus of the lung. This is a wedge-shaped depressed area, within which the blood-vessels, nerves, and

FIG. 871.—THE MEDIAL SURFACE OF A RIGHT LUNG HARDENED *IN SITU*.

lymph vessels, together with the bronchus, enter and leave the organ. Amidst these structures there are also some bronchial glands. The hilus is surrounded by the reflection of the pleura from the surface of the lung on to the pulmonary root. Dorsal to the hilus and pericardial area there is on each lung a narrow strip of the mediastinal surface of the lung which is in relation to the lateral wall of the dorsal mediastinum. On the *right lung* this part of the surface is depressed, and corresponds to the oesophagus; on the *left lung* it presents a broad longitudinal groove, which is produced by the contact of the lung with the thoracic aorta, and also, close to the base, a small flattened area ventral to this which is applied to the oesophagus where it pierces the diaphragm.

The portion of the mediastinal surface of the lung which lies above the hilus and pericardial hollow is applied to the lateral aspect of the superior mediastinum, and the markings are accordingly somewhat different on the two sides. On the left lung a broad deep groove, produced by the aortic arch, curves dorsally above the hilus, and becomes continuous with the aortic groove on the dorsal part of the mediastinal surface. From this a narrower, deeper, and

much more sharply marked groove runs upwards, and laterally over the apex pulmonis a short distance from the summit. This is the *sulcus subclavius*, and it contains the left subclavian artery when the lung is in place. Ventral to this a shallow wide groove, also leading to the ventral aspect of the apex, corresponds to the left innominate vein. In the *right lung* the hilus is also circumscribed above by a curved groove, but this is narrow and more distinctly curved than the aortic groove on the left side. It lodges the *vena azygos* as it turns ventrally to join the *vena cava superior*. From the ventral end of the *azygos sulcus* a wide shallow groove extends upward to the inferior part of the anterior aspect of the apex pulmonis. This is produced by the apposition of the lung with the *vena cava superior* and the right innominate vein. Close to the summit of the apex there is also, on its medial aspect, a *sulcus* for the superior end of the innominate artery.

In addition to the hilus, it must now be evident that the mediastinal surface of each lung presents three areas which correspond respectively with (1) the middle mediastinum (*i.e.* the pericardial hollow), (2) the dorsal mediastinum, and (3) the superior mediastinum; and that in each of these districts impressions corresponding to structures contained within these portions of the interpleural space may be noticed.

The **dorsal part** of the lung at the junction of the costal and mediastinal surfaces is thick, long, and rounded. It forms the most bulky part of the organ, and occupies the deep hollow in the thoracic cavity which is placed on either side of the vertebral column.

The **ventral border** or *margo anterior* of the lung is short, and exceedingly thin and sharp. It begins abruptly immediately below the groove on the apex for the innominate vein, and extends to the base, where it becomes continuous with the sharp inferior border. The thin ventral part of the lung is carried ventrally and medially, ventral to the pericardium, into the narrow pleural costo-mediastinal sinus, dorsal to the sternum and costal cartilages. The ventral border of the right lung fills up this recess completely, and in the upper part of the chest is separated from the corresponding border of the left lung only by the two layers of mediastinal pleura which are reflected from the sternum to the pericardium. The ventral border of the left lung, in its lower part, shows a marked deficiency or notch, the *incisura cardiaca*, corresponding to the apex of the heart, and where this exists the lung margin leaves a considerable portion of the pericardium uncovered, and fails to fill up completely the costo-mediastinal sinus of the pleural cavity. During respiration the ventral margin of the left lung at the *incisura cardiaca* advances and retreats to a small extent in this pleural sinus, ventral to the pericardium.

Fissures and Lobes of the Lung.—The *left lung* is divided into two lobes by a long deep fissure, the *incisura interlobaris*, which penetrates its substance to within a short distance of the hilus. On the upper and lower sides of the hilus this fissure cuts right through the lung and appears on the mediastinal surface. Viewed from the costal surface, it begins dorsally about two and a half inches below the apex, about the level of the vertebral end of the third rib, and is continued downwards and ventrally in a somewhat spiral direction to the diaphragmatic surface of the lung, which it reaches a short distance from its ventral end. The *lobus superior* lies above and ventral to this cleft. It is conical in form, with an oblique base, and the apex and the whole of the ventral border of the lung belong to it. The *lobus inferior* lies below and dorsal to the fissure. It is the more bulky of the two, and includes almost the entire diaphragmatic surface and the greater part of the thick dorsal part of the lung.

In the *right lung* there are two *incisuræ interlobares*, which subdivide it into three lobes. One of the *incisuræ interlobares* is very similar in its position and relations to the fissure in the left lung. It is directed, however, rather more vertically, and ends somewhat farther from the median plane. It separates the *lobus inferior* from the *lobus medius* and *lobus superior*. The second *incisura interlobaris* begins in the main fissure at the dorsal part of the lung, and proceeds ventrally, to end at the ventral border of the lung at the level of the fourth costal

cartilage. The middle lobe of the right lung is triangular or wedge-shaped in outline.

Variations.—Variations in the pulmonary fissures are fairly common. Thus, it sometimes happens that the middle lobe of the right lung is imperfectly cut off from the lobus superior. Supernumerary fissures also are not infrequent, and in this way the left lung may be cut into three lobes, and the right lung into four or even more lobes. The occurrence of the *lobus azygos* in the right lung is a variation of some interest, seeing that such a lobe is constant in certain mammals. It is a small accessory lobe, pyramidal in form, which makes its appearance on the lower part of the mediastinal surface of the right lung. In certain cases the *vena azygos* is enclosed within a fold of pleura, and is sunk so deeply in the pulmonary substance of the right lung that it marks off a small accessory lobe.

RADIX PULMONIS.

The term **root of the lung** is applied to a number of structures which enter and leave the lung at the hilus on its mediastinal surface. They are held together by an investment of pleura, and constitute a pedicle which attaches the lung to the mediastinal wall of the pleural cavity. The phrenic nerve passes downwards a short distance ventral to the pulmonary root, whilst the vagus nerve breaks up into the dorsal or posterior pulmonary plexus on its dorsal aspect under cover of the investing pleura. The delicate ventral or anterior pulmonary plexus is placed ventral to the root of the lung under cover of the pleura, whilst from the inferior border of the root of the lung the ligamentum pulmonale extends towards the diaphragm. These relations are common to the pulmonary root on both sides of the body, but there are others which are peculiar to each side. On the *right side* the *vena cava superior* lies ventral to the pulmonary root, whilst the *vena azygos* arches over its upper border. On the *left side* the *aorta* arches above the root of the lung, whilst the descending thoracic *aorta* passes dorsal to it.

Constituent Parts of the Pulmonary Root.—The large structures which enter into the formation of the pulmonary root are (1) the two pulmonary veins, (2) the pulmonary artery, (3) the bronchus. But in addition to these there are one or more small bronchial arteries and veins, the pulmonary nerves and the pulmonary lymph vessels, and some bronchial glands.

The **pulmonary nerves** come from the vagus nerve and also from the sympathetic system. They enter the lung and follow the air-tubes through the organ. The **bronchial arteries** are small vessels which carry blood for the supply of the lung-tissue. They arise from the aorta or from an intercostal artery, and vary in number from one to three for each lung. In the root of the lung they lie on the dorsal aspect of the bronchus, and they follow the air-tubes through the organ. Part of the blood conveyed to the lung by the bronchial arteries is returned by the pulmonary veins; the remainder is returned by special **bronchial veins** which open on the right side into the *vena azygos*, and on the left side into the *vena hemiazygos*.

The **lymph-vessels** of the lungs are numerous and well developed, and are divided into two groups, superficial and deep.

The **superficial lymph-vessels** form a network on the surface of the lung and eventually terminate by four or five vessels in the broncho-pulmonary glands of the hilus. It is usually stated that the superficial lymph vessels communicate freely with the deep. This, however, is denied by Miller, who maintains that anastomoses between the two systems of vessels are very rare. A specimen of secondary carcinoma of the lung in the Pathology Museum of the University of Melbourne shows a direct continuation of the disease through the lung-substance from the surface to the tubes by way of the lymph vessels, and would thus tend to disprove Miller's assertion.

The **deep lymph-vessels** are subdivided into bronchial accompanying the bronchi and vascular accompanying the blood-vessels. Both systems communicate freely together, and at the level of the hilus terminate in the broncho-pulmonary glands.

The pulmonary or broncho-pulmonary lymph-glands, found at the hilus, are usually numerous and variable in size. They are situated either just outside the lung or within the lung-substance itself.

From these broncho-pulmonary glands the lymph-flow is continued onward from the lung, partly directly into the thoracic duct, and partly by a more circuitous route as follows:—

From the broncho-pulmonary lymph-glands vessels pass on to the tracheo-bronchial glands situated at the angles produced by the bifurcation of the trachea into the two bronchi. Of these glands there are, therefore, three groups, an inferior and right and left superior. From these glands the lymph-flow is continued upwards through the tracheal lymph-glands lying on either side of the trachea into the deep cervical lymph-glands, and thence into the thoracic duct.

The **bronchus** in the root of the lung lies dorsal to the great pulmonary vessels.

The **pulmonary artery** occupies a different position on the two sides, in relation to the main or undivided part of the bronchus. On the right side it is placed below it, whilst on the left side it crosses the bronchus and occupies a higher level in the pulmonary root. The two **pulmonary veins** on both sides lie at a lower level in the root of the lung than the pulmonary artery and bronchus, whilst the superior of the two veins occupies a plane ventral to the pulmonary artery (Figs. 870 and 871).

Distribution of the Bronchial Tubes within the Lungs.—The two lungs are not symmetrical; the right lung is subdivided into three lobes, and the left lung is cleft into two lobes. The bronchi exhibit a corresponding want of symmetry. The *right bronchus*, as it approaches the pulmonary hilus, gives off two branches for the superior and middle lobes of the right lung respectively, and then the main stem of the tube enters the inferior lobe. The *left bronchus* sends off a large branch to the superior lobe of the left lung, and then sinks into the inferior lobe. The first branch of the right bronchus, for the superior lobe, leaves the main stem about one inch from the trachea. The first branch of the left bronchus, on the other hand, takes origin about twice that distance from the trachea.

The relation of the pulmonary artery to the bronchial subdivisions is different on the two sides. On the right side it turns dorsally to reach the dorsal aspect of the bronchus inferior to the first, and superior to the second, bronchial branch.

On the left side the pulmonary artery turns dorsally above the level of the first bronchial branch. On the right side, therefore, the first bronchial branch is placed above the pulmonary artery, and in consequence it is termed the **eparterial bronchial ramus**; all the others lie below the artery, and are termed **hyparterial bronchial rami**. On the left side there is no eparterial branch; they are all hyparterial.

When the main stem of the bronchus is followed into the inferior lobe of each lung, it is seen to travel downwards and dorsally in the pulmonary substance until it reaches the thin

FIG. 872.—DIAGRAM OF THE RELATIONS OF THE PULMONARY ARTERY TO THE BRONCHI.

dorsal part of the diaphragmatic surface of the lung which lies between the diaphragm and the thoracic wall, and there it ends. As it proceeds through the inferior lobe it gives off a series of large **ventral** and a series of smaller **dorsal branches**. As a rule these are three in number in each case, and the dorsal and ventral branches do not arise opposite to each other, but alternately, one from the dorsum, and then another, after a slight interval, from the ventral surface of the tube. The first hyparterial division on each side (*i.e.* the branch to the middle lobe of the right lung and the branch to the superior lobe of the left side) is generally regarded as the first member of the ventral group.

It was Aeby who first recognised the existence in each lung of a main or stem bronchus giving off a ventral and dorsal series of branches, and who drew the distinction between the eparterial and hyparterial bronchial rami. A consideration of these relations led this author to conclude that the eparterial bronchus and the superior lobe of the right lung have no morphological equivalents on the left side of the body. In other words, he was led to believe that the middle lobe of the right lung is the homologue of the superior lobe of the left lung. Hasse, who has also investigated the subject, endorsed this view, with certain modifications and additions; and the hypothesis, either in its original state as presented by Aeby, or as subsequently modified by Hasse, has been, until lately, very generally accepted by anatomists. More recent research,

however, has seriously affected the stability of this conclusion. Narath contends that the distinction between the eparterial bronchus of the right side and the hyparterial bronchi of both sides is not one of fundamental importance, and that a branch which arises from the first hyparterial bronchus on the left side and turns upwards into the apex of the left lung is the direct equivalent of the eparterial bronchus of the right side. This he terms the **apical bronchus**, and he believes that it represents the first dorsal branch of the left stem-bronchus. Huntington, in a very convincing paper, strongly supports the contention of Narath, and holds that, except "for purposes of topography, we should abandon the distinction between eparterial and hyparterial bronchi." With Narath he regards the eparterial bronchus as a secondary branch which has migrated in an upward direction on the main stem. According to Huntington, therefore, Aebys's proposition should be amended as follows :—

	Right side.			Left side.	
Superior	and	middle lobes	=	Superior lobe.	
Inferior	and	cardiac lobes	=	Inferior lobe.	

The cardiac lobe mentioned in this table is the occasional azygos lobe to which reference has already been made, and it is interesting to note that, whilst the lobe in question as a separate entity is rarely seen in the human lung, the bronchus which corresponds to it is always present in the pulmonary substance as an accessory branch, which proceeds from the main stem as it traverses the inferior lobe of the right side. It receives the name of the **cardiac bronchus**.

STRUCTURE OF THE LUNG.

The lung is constructed so that the blood which reaches it through the pulmonary artery is brought into the most intimate relation with the air which enters it through the trachea and bronchi. An interchange of materials between the blood and the air is thus rendered possible, and the object of respiration is attained. As a result of this interchange the dark, impure blood, which flows into the lung through the pulmonary artery, is rendered bright red and arterial.

Lobules of the Lung.—A thin layer of subpleural connective tissues lies subjacent to the continuous coating which the lung receives from the pulmonary pleura. From the deep surface of this subpleural layer fine septal processes penetrate into the substance of the lung, and these, with the connective tissue which enters at the hilus upon the vessels and bronchi, constitute a supporting framework for the organ. The lung is lobular, and on the surface the small polygonal areas which represent the lobules are indicated by the pigment present in the connective tissue septa which intervene between them. Although no pigment is present, the lobular character of the lung is particularly well marked in the foetus, and with a little care the surface lobules in the fetal lung can be separated from each other by gently tearing through the intervening connective tissue. The lobules thus isolated are piriform or pyramidal in form. The broad bases of these lobules abut against the subpleural layer, whilst each of the deep narrow ends receives a minute division from the bronchial system of tubes. The lobules which lie more deeply in the substance of the organ are not so large, and are irregularly polygonal in form.

The Lung Unit.—The unit of lung-structure is the lung-lobule. This comprises a terminal bronchus with its air-spaces, blood-vessels, lymph vessels, and nerves.

The terminal bronchus of the lung-unit is attained as follows :—The larger branches of the bronchi, as they traverse the lung, give off numerous divisions, which, by repeated branching, ultimately form a system of tubes which pervade the entire organ. At first the bronchial divisions come off at very acute angles, but as the finer ramifications are reached this character becomes much less apparent. The ramifications of these bronchi are termed *bronchioles*, which by subdivision give rise to the *respiratory bronchiole* of the lung-unit.

Within the lung unit the respiratory bronchiole gives off a series of terminal bronchi or *alveolar ducts*, each of which leads to a group of air-spaces termed *atria*. Each one of these atria communicates, in its turn, with a further and secondary series of air-spaces termed air-sacs or *alveolar saccules*, the walls of which are pouched out to form the very numerous *alveoli* or *air-cells* of the lung-unit.

Structure of the Bronchi.—When the large bronchi enter the lung they become cylindrical, and lose the flattening on the dorsal aspect which is characteristic of the primary bronchi outside the lung. They possess the same coats as are present in the case of the trachea and primary bronchi, but as the tubes become smaller by repeated divisions, these coats become correspondingly thinner and finer. Certain marked differences also in the manner in which the constituents of these coats are arranged become apparent.

In the **external fibro-cartilaginous coat** the cartilage is no longer present in the form of incomplete rings, but in irregular plates or flakes deposited at various points around

the wall. As the tubes diminish, these cartilaginous deposits show a corresponding reduction in size, until at last, in bronchi of 1 mm. diameter, they disappear altogether. The **glands** in relation to the tubes for the most part cease to exist about the same point. The **muscular** or **middle coat**, which in the trachea and primary bronchi is confined to the dorsal wall of the tube, forms a continuous layer of circularly arranged bundles in the bronchi as they ramify within the lung. Spasmodic contraction of the muscular coat gives rise to the serious symptoms which accompany asthmatic affections. The muscular fibres of the middle coat may be traced as far as the atria, on the walls of which they are present in considerable numbers. The **mucous lining** of the tubes becomes greatly thinned as it is followed into the smaller bronchioles. It contains a large number of longitudinally arranged elastic fibres, and is disposed in longitudinal folds, so that when the tube is cut across the lumen presents a stellate appearance. The mucous membrane is lined with ciliated columnar epithelium.

Structure of the Atria and Alveoli.—The walls of the atria and alveoli are exceedingly fine and delicate, but, nevertheless, constituents continuous with those observed in the three coats of a bronchus are found entering into their construction. The epithelium is reduced to a single layer. Further, it is no longer columnar and ciliated, but it has become flat and pavement-like. Two kinds of epithelial cells may be recognised—(1) a few small granular polygonal cells, arranged singly or in groups of two or three, (2) more numerous thin cells of large size and somewhat irregular in outline. Outside the epithelium is a delicate layer of faintly fibrillated connective tissue. This is strengthened by a network of elastic fibres, which is specially well marked around the mouths of the alveoli, and is also to some extent carried over the walls of the air-cells. Muscular fibres also are present on the walls of the atria, but it is questionable if any are prolonged over the air-cells.

Pulmonary Vessels.—The pulmonary artery, as it traverses the lung, divides with the bronchi, and closely accompanies these tubes. The resultant branches do not anastomose, and for the most part they lie above and dorsal to the corresponding bronchi. The fine terminal divisions of the artery join a dense capillary plexus which is spread over the alveoli or air-cells. This vascular network is so close that the meshes are barely wider than the capillaries which form them. In the partition between adjacent alveoli there is only one layer of the capillary network, and thus the blood flowing through these vessels is exposed on both aspects to the action of the air in the air-cells. The radicles of the pulmonary vein arise in, and carry the blood from, the pulmonary capillary plexus. Each afferent arteriole supplies the blood which flows through the capillaries spread over a number of neighbouring alveoli, and in like manner each afferent venous radicle drains an area corresponding to several adjoining air-cells. At first the veins run apart from the arteries, but after they have attained a certain size they join them and the bronchi. As a rule the pulmonary veins are placed on the inferior and ventral aspects of the corresponding bronchi.

DEVELOPMENT OF THE RESPIRATORY APPARATUS.

The larynx, trachea, bronchi, and lungs all arise as an outgrowth from the ventral aspect of the foregut. The first indication of a respiratory tract occurs in the human embryo early in the third week, on or about the fifteenth day of development, and when the embryo is but little more than 3 mm. in length. At this period a median longitudinal groove makes its appearance on the ventral wall of the foregut, extending thereon from the primitive pharynx well towards the primitive stomach, and deepening gradually as it passes caudalwards.

The cranial end of the respiratory tube becomes enlarged and forms the larynx, the intermediate portion forms the trachea, and the caudal end bifurcates in the floor of the groove into two tubes—the future bronchi were already indicated by slight bulgings before the two tubes divide—which grow caudalwards on either side of the heart, into a mesodermic mass, from which the connective tissue of the future lungs is ultimately developed. The respiratory tube is lined with entoderm continuous with the entodermal lining of the foregut.

The groove becomes deeper and constricted, its lateral margins approximate, and finally meet dorsally, and the groove separates off from the foregut as a distinct tube. This differentiation necessarily results in the production of two tubes or canals, a ventral one forming the respiratory tube, and a dorsal one the œsophagus. The separation of the two tubes commences at the caudal end and proceeds cranialwards towards the pharynx, into which both the œsophagus and the respiratory tube open.

The Larynx.—The rudiment of the larynx appears, at the cranial or pharyngeal end of the primitive respiratory tube, about the twenty-fifth day, and before the trachea separates off from the œsophagus in the form of two lateral swellings—the arytenoid swellings, which lie caudal to the fourth visceral pouches, and possibly represent rudimentary fifth branchial arches (Kallius). These arytenoid swellings are connected by a ventral median ridge which intervenes between the ventral ends of the third visceral arches. At this period the site of the future larynx is represented at the pharyngeal end of the respiratory tube by a U-shaped ridge which surrounds the tube cranially and laterally, and is known as the *furcula*.

The cranial or anterior portion of the *furcula* forms a median elevation from which the epiglottis is developed, whilst the lateral portions of the *furcula*—the arytenoid swellings—eventually form the ary-epiglottic folds. On the medial side of the latter, about the fourth month, a furrow marks the future site of the ventriculus laryngis [Morgagni], the margins of which later become the vocal folds.

About the eighth week the cartilaginous framework of the larynx is indicated by mesoblastic condensations of the connective tissue around the now slit-like rima glottidis; and at this period the rudimentary arytenoids, the cricoid and the cartilages of the trachea are all continuous laterally.

The *epiglottic cartilage* is developed, as stated, in the anterior portion of the *furcula*, and chondrifies relatively late. It may possibly represent a rudiment of the cartilage of the sixth branchial arch, and according to Göppert it is at first continuous dorsally with the cuneiform cartilages, which, therefore, are derivatives of the epiglottic cartilage.

The *thyroid cartilage* is laid down in the form of two separate lateral mesoblastic plates, in each of which chondrification proceeds from two centres, ventral and dorsal, which probably represent the cartilages of the fourth and fifth branchial arches. As development proceeds the sheets of cartilage formed from these centres fuse, and eventually extend ventrally to fuse with their fellows of the opposite side, in the median plane. Chondrification is completed comparatively late, and when incomplete it results in the formation of an abnormality—the thyroid foramen. The superior cornu of the thyroid cartilage is at first continuous with the greater cornu of the os hyoideum, and the remains of this cartilaginous connexion is seen in the presence of the cartilago triticea in the lateral hyothyroid ligament of the adult.

The pro-cartilaginous rudiments of the cricoid and arytenoid cartilages are at first continuous with each other, but later become differentiated by the appearance of separate cartilaginous centres for the arytenoids, and an incomplete ring, for a time deficient dorsally, for the cricoid. The cricoid thus resembles developmentally a tracheal ring, with which it probably corresponds morphologically. Chondrification proceeds in the cricoid by two centres, one on each lateral side. These centres unite ventrally, but dorsally fusion does not take place until much later, and is finally completed by an extension of chondrification from the lateral into the dorsal plate. The cricoid thus differs from the tracheal ring, in having its chondrification completed dorsally, whereas this never takes place in the tracheal ring.

The *arytenoid cartilages* are, as stated, at first continuous with the cricoid cartilage by fibrous tissue, but become eventually completely separated from it by the appearance of one chondrification centre for each arytenoid.

The *corniculate cartilages* (*Santorini*) are merely portions of the arytenoid cartilages separated off by segmentation; whilst the *cuneiform cartilages* (*Wrisbergi*) are, as previously stated, derivatives of the epiglottic cartilage.

The Trachea.—The trachea is developed from the intermediate portion of the median longitudinal groove. Originally, both this portion of the primitive respiratory tube and the œsophageal portion of the primitive alimentary canal were of equal length; but as development proceeds both tubes lengthen, the latter more rapidly than the former, so that eventually the lung rudiments no longer lie on the ventral and lateral sides of the primitive stomach, but come to lie on the cephalic side of that viscus, and are separated from each other by the œsophagus dorsally and the heart and pericardium ventrally. In this way, that is by unequal growth, it comes about that the trachea in the adult is shorter than the œsophagus, though originally both were of equal length.

The cartilaginous rings of the trachea are developed like the cricoid cartilage, with the difference that in the trachea the process of chondrification does not extend into their dorsal portions, and hence, in the adult, the C-shaped rings of the trachea are deficient dorsally—an arrangement which admirably adapts itself to the functional uses of both trachea and œsophagus.

The Lungs.—The lungs are developed from the two diverticula of the caudal end of the median longitudinal groove and the mesodermal tissue into which these grow. Originally single, this caudal end soon becomes bilobed and pouches out on each side into two lateral diverticula, which represent the primitive bronchi and lungs. From the first the right pulmonary diverticulum or vesicle is slightly the larger of the two. Both diverticula elongate, and almost immediately undergo a subdivision—the right into three vesicles, and the left into two vesicles—thus early indicating the three lobes of the right lung and the two lobes of the left lung. As the primitive respiratory tube lies in the median plane in the dorsal attachment of the septum transversum, the pulmonary diverticula grow laterally and dorsally into the dorsal parietal recesses, that is into the future pleural cavities, carrying before them a covering of mesoblast. From this mesoblast are derived the blood-vessels and other tissues which build up the lung, whilst the entodermal cells which form the lining membrane of the primitive respiratory tube eventually develop into the epithelial lining of the air-passages, and are embedded within the surrounding mesoderm. The main entodermal subdivisions continue to branch and re-branch, pushing their way into the pulmonary mesoblast, until the complete bronchial tree is formed.

The primary pulmonary diverticula increase in size and complexity as additional out-growths arise by the subdivision of the enlarged terminal part of each diverticulum. Their mode of subdivision is very characteristic, and from the first the various branches are bulbous or flask-shaped at their extremities. These bifurcate, and although at first the two main subdivisions appear, in each case, of equal importance, one grows out as the continuation of the main bronchial stem—the future hyparterial bronchus—whilst the other remains as a branch. When the ramification of the entodermal tubes into the lung-mesoderm is complete, the small terminal flask-shaped extremities of the various branches represent the atria of the lung.

This repeated bifurcation results, as just stated, in the formation of a main bronchus which traverses the entire length of the lung, and into which numerous secondary bronchi open. The latter, from the manner in which they arrange themselves around the main stem of the pulmonary artery, are divided into dorsal and ventral. These alternate with each other, and usually number four in each series; not infrequently the third dorsal bronchus fails to develop. In the left lung the first dorsal bronchus arises, not from the main tube as on the right side, but from the first ventral bronchus—an arrangement which probably results from the fusion on the left side of the superior and middle lobes of the left lung into one, namely, the so-called lobus superior of the adult left lung.

The secondary bronchi elongate, and give rise to the tertiary bronchi, and these in turn to lesser bronchi, and so on down to the terminal bronchi, with their atria, air-sacs, and air-cells of the lung-unit. At first the lung-unit is devoid of air-cells, but between the sixth month and full term the alveolar saccules and air-cells make their appearance on the alveolar ducts; and it is thus clear that the epithelial lining of the entire system of bronchial subdivisions and ramifications is derived originally from the entodermal lining of the primitive foregut. By the close of the fourth month of foetal life the columnar cells lining the trachea and bronchi have become ciliated.

At first the diverticula of the respiratory tube are surrounded by thick masses of mesoblastic tissue, but as development proceeds the latter fails to keep pace with the former, and hence the mesoblastic tissue becomes greatly reduced in amount and in thickness. Coincidentally, this mesoblast becomes vascularised, and thus rich plexuses of blood-vessels come to surround the terminal divisions of the epithelial tubes—an arrangement obviously adapted to the interchange of gases from air to blood and *vice versa*.

The rudiments of the developing lungs grow dorsally on each side of the œsophagus into the fissure-like portion of the cœlom which occupies the thoracic region. They push before them the endothelial lining of the cœlom, and thus come to acquire their covering of pulmonary pleura. By the development of the diaphragm and the pericardium the pleural portions of the cœlom become cut off from the peritoneal cavity and from each other.

THE DIGESTIVE SYSTEM.

REVISED AND LARGELY REWRITTEN

BY DAVID WATERSTON.

APPARATUS DIGESTORIUS.

The Digestive System.—The physical characters and the chemical composition of much of the food taken into the body are such that it cannot at once be utilised by the organism. Before it can be absorbed and used in nutrition it requires to be acted upon, both chemically and mechanically. The performance of these mechanical and chemical changes is known as digestion.

The term *apparatus digestorius* (digestive system) is applied collectively to the organs which are concerned in this process, in the reception of food into the body, and in the excretion of the undigested or unabsorbed residue.

The simple form of digestive system which is found in many of the lower animals consists of a hollow tube, passing through the interior of the body, from an anterior or mouth aperture, to a posterior or anal orifice. The wall and lining membrane of the tube are so constructed as to act mechanically and chemically upon the food in its interior.

In man, a tube of this kind forms the basis of the digestive system. It extends from the mouth through the neck, thorax, abdomen, and pelvis to the anal orifice. But the tube, originally simple, has become modified, in different directions in different parts, for the performance of the various stages of the complex processes of digestion, absorption, and excretion.

The principal modifications which it has come to present are the following :—

(1) The tube is very greatly elongated, so that its total length measures from seven to eight times the length of the trunk. This is effected by the tube being thrown into folds or coils, especially in that part known as the small intestine.

(2) Certain portions of the wall of the tube have become modified in structure for the performance of special digestive changes. Thus in the mouth there are found the teeth and tongue, for mastication or trituration of food and for deglutition, or swallowing. Further on in the course of the tube is found a dilated chamber, the stomach, in whose wall special glands, called gastric glands, are present, which produce the gastric juices; while in the succeeding portion, or small intestine, are found the villi—very numerous papillary projections of minute size, whose function is largely that of absorption.

(3) Certain special accumulations or masses of glandular tissue, producing secretions useful in digestion, are found situated altogether outside of the wall of the tube, but communicating with its interior by means of ducts, through which these secretions are conveyed.

The chief of such masses of glandular tissue are the salivary glands, which are placed in the head and neck, and communicate with the mouth; and the liver and pancreas, which lie in the abdomen, and are connected with the duodenum.

These glandular masses, though lying external to the wall of the tube, have been developed as outgrowths from it, and the ducts represent the stalks of connexion.

The digestive system, then, may be considered to present the following parts:—

- I. The alimentary canal, or digestive tube.
- II. Special organs, found in the wall of this canal.
- III. Accessory glands, placed external to the wall of the tube.

FIG. 873.—DIAGRAM OF THE GENERAL ARRANGEMENT OF THE DIGESTIVE SYSTEM.

The processus vermiformis is seen hanging down from the cæcum. The transverse colon is not represented, in order that the duodenum and pancreas, which lie behind it, may be seen.

The greater part of the digestive system is found in the abdomen, and hence, in this section, the abdominal cavity, together with its lining membrane the peritoneum, falls to be described.

I. Alimentary Canal.—The alimentary canal, taken as a whole, measures, when fully extended, about 30 feet (9 metres) in length, and consists (Fig. 873) of the

following parts in order:—mouth, pharynx, œsophagus, stomach, small and large intestines. The term **tubus digestorius** is applied to the whole of the canal below the lower end of the pharynx. The **mouth cavity** is the first division of the tube. It is separated from the nasal cavities above by the **palate**, and opens posteriorly into the **pharynx**. This latter is an expanded portion of the canal lying posterior to the mouth, nasal cavity and larynx, the mouth opening into it through the **isthmus of the fauces**, the nasal cavity through the **choanæ** (O.T. posterior nares); whilst lower down, immediately below the base of the tongue, the **aperture of the larynx** is found in its anterior wall. Opposite the lower border of the larynx, the pharynx is continued into the **œsophagus**, a long and comparatively straight portion of the digestive tube, passing through the neck and thorax to the abdomen, which it reaches by piercing the diaphragm. Immediately after entering the abdomen the tube expands into a pear-shaped dilated chamber, the **stomach**. This is followed by over 20 feet of **small intestine**, the junction of the two being marked by a constriction, the **pylorus**. The small intestine presents three more or less arbitrary divisions—namely, (a) the **duodenum**, a part about 10 inches in length, curved somewhat like a horse-shoe, and closely united to the posterior abdominal wall; (b) the **jejunum**, which includes the upper two-fifths, and (c) the **ileum**, the lower three-fifths of the small intestine beyond the duodenum. The jejunum and ileum are connected to the posterior abdominal wall by the **mesentery**, a fan-shaped fold of connective tissue covered by the **peritoneum**, or lining membrane of the abdominal cavity.

The terminal part of the ileum opens into the side of the **large intestine**, a few inches ($2\frac{1}{2}$) from the blind commencement of the latter. There is thus formed at the beginning of the great intestine a cul-de-sac, the **cæcum**, in connexion with which is found a small worm-shaped diverticulum, the **vermiform process**.

The orifice through which the ileum opens into the large intestine is guarded by the **valve of the colon** (O.T. ileo-cæcal valve), which prevents the return of its contents from the large into the small bowel. After the cæcum comes the **ascending colon**, which runs up in the right side of the abdomen. This is succeeded, in order, by the **transverse colon** crossing from right to left, the **descending colon** running down on the left side of the abdomen, and the **iliac colon**, lying in the left iliac fossa. Beyond this are the **pelvic colon**, which lies in part or entirely within the pelvis minor (O.T. true pelvis), the **rectum**, and the **anal canal**.

The **rectum** lies within the small pelvis, and the **anal canal**, the terminal part, is a short channel passing between the muscles which form the pelvic floor, to open on the surface at the anal orifice.

The term **colon sigmoideum** includes the portion named above as pelvic colon, and the term **colon descendens** the descending and iliac colon.

II. Special Organs found in the Wall of the Tube.—In the mouth are found the **teeth**, **gums**, **tongue**, and behind them, in the pharynx, are the **palatine tonsils**. The teeth, 32 in number in the adult, are portions of the mucous membrane of the mouth and of the subjacent tissue, calcified on the surface, and specially formed for mastication, that is, the division and trituration of the food which take place in the mouth before the bolus, as the resulting mass is termed, can be swallowed. They are rooted in the jaws and partly surrounded by the gums.

The tongue is a muscular organ, useful alike in mastication, deglutition, and speech. It is covered by epithelium, which in places is modified so as to form taste corpuscles, which are the end organs of the gustatory sense.

The roof of the mouth is formed by the palate, which separates the mouth from the nose. It consists of a bony part in front called the **hard palate**, and a movable sheet called the **soft palate** behind.

The palatine tonsils are two large masses of lymph tissue, found one on each side of the wall of the pharynx, just posterior to the mouth. They form the most prominent portions of an almost complete ring of lymph tissue placed around the circumference of the tube at this level.

III. Accessory Digestive Glands.—The largest of these is the liver (*hepar*), which occupies the upper and right portion of the abdominal cavity, immediately below the diaphragm, and its secretion—the bile—is conveyed into the duodenum by the **bile duct** (*ductus choledochus*). The **pancreas**, next in size, lies across the front of the vertebral column, with its right end or head resting in the concavity of the duodenum, into which its secretion flows through the **pancreatic duct**. The **salivary glands** consist mainly of three large paired glands, **parotid**, **submaxillary**, and **sublingual** (*glandula parotis*, *submaxillaris*, and *sublingualis*), and their ducts, which convey the saliva, open into the mouth. The saliva is a mechanical lubricant, which facilitates swallowing and the movements of the tongue in speaking and masticating, and also plays an important part in the chemical processes of digestion.

CAVUM ORIS.

1. Parts.—**Rima oris**, **vestibulum oris**, **cavum oris proprium**.
2. Boundaries.—1. **Labia oris**—their structure.
2. **Buccæ**—their structure.
3. **Palatum, palatum durum, palatum molle**—arrangement and structure.
4. **Isthmus faucium**.
3. Structures found in the Mouth.—**Gingivæ**, gums.
Dentes, teeth.
Lingua, tongue.
4. **Glandulæ oris**, buccal and salivary glands.

The **mouth** is the upper expanded portion which forms the first division of the alimentary canal. It lies between the maxillæ and mandible, bounded externally by the lips and the cheeks, and roofed in by the palate. It contains the teeth and greater part of the tongue; and the ducts of the salivary glands open into it. The cavity is divisible into two portions, the vestibule and the cavity proper of the mouth. These are separated from one another by the alveolar ridges, gums, and teeth of the maxillæ and mandible. The cavity of the mouth narrows at the back to a slight constriction, marked by a vertical fold on each side, called the **arcus glosso-palatinus** (**O.T. anterior pillar of the fauces**), and between them the cavity of the mouth is continuous with that of the pharynx.

FIG. 874.—OPEN MOUTH SHOWING PALATE AND PALATINE TONSILS.

It also shows the two palatine arches, and the pharyngo-nasal isthmus through which the naso-pharynx above communicates with the oral portion of the pharynx below.

conventional bow, to a circular or oval shape when the mouth is widely open, or the “pursed-up” condition produced by the contraction of the orbicularis oris muscle.

Vestibulum Oris.—The vestibule of the mouth lies immediately internal to the

Rima Oris.—The aperture of the mouth is bounded above and below by the corresponding lips, which, by their junction at the sides, form the labial commissures. In a state of rest, with the lips in apposition, the rima appears as a slightly curved line, corresponding in length to the interval between the first premolar teeth, and in level to a line drawn across just below the middle of the upper incisor crowns. The shape of the rima varies with every movement of the lips, from the resting linear form, curved like the

aperture of the mouth. It is that portion of the cavity which occupies the interval between the lips and cheeks externally, and the teeth and gums internally.

In the normal resting condition, when the mouth is closed and the lips and the teeth are in contact, its cavity is practically obliterated by the meeting of its walls, and it becomes merely a slit-like interval, with a narrow roof and floor formed by the reflection of the mucous membrane, from the deep surface of the lips and cheeks to the corresponding gum. This reflection is interrupted in the median plane by a small but prominent fold of the mucous membrane, the **frenulum**, which connects the back of each lip to the front of the gum. The upper frenulum is the better developed, and is readily brought into view by everting the lip. The frenulum of the lower lip is not always present.

On the outer wall of the vestibule, opposite the crown of the second upper molar, upon a variably developed eminence, is placed the small opening of the duct of the parotid gland, which conveys the saliva from the parotid gland to the mouth.

When the teeth are in contact the vestibule communicates with the cavity of the mouth only through the small and irregular spaces left between the opposing teeth, and posteriorly, on either side, by a wider but variable aperture between the last molars and the ramus of the mandible.

Advantage is sometimes taken of the presence of this aperture for the introduction into the cavity of the mouth of liquid food in certain cases—trismus, ankylosis, etc.—in which the jaws are rigidly closed.

On the outer wall of the vestibule, the anterior border of the masseter can be distinctly felt with the finger, when the muscle is thrown into a state of contraction. Still further back, the front of the coronoid process, bearing the lower part of the insertion of the temporal muscle, can also be made out. The speno-mandibular ligament, which corresponds to, and is felt along with, the anterior border of the internal pterygoid muscle, is distinguishable as a pliant ridge when the finger is carried from the front of the coronoid process behind the last molar tooth into the cavity of the mouth.

In addition to the duct of the parotid, the ducts of numerous small glands which are embedded in the lips and cheeks open into the vestibule.

Under normal conditions, as pointed out above, the lips and cheeks lie against the teeth and gums, obliterating the cavity of the vestibule, and helping, with the aid of the tongue, to keep the food between the grinding surfaces of the molar teeth during mastication. In facial palsy, however, owing to the paralysis of their muscles, and particularly of the buccinator muscle, the lips and cheeks fall away from the dental arches, and allow the food to pass out from between the teeth and to accumulate in the vestibule.

Cavum Oris Proprium.—The cavity proper of the mouth is the space situated within the dental arches, extending backwards to the glosso-palatine arches (O.T. anterior pillars of the fauces). Its boundaries consist of a roof, a floor, and a margin, formed by the teeth and gums. The roof is formed by the **hard palate** and the anterior portion of the **soft palate**, while the floor is formed by the anterior part of the tongue in the middle, and on each side by the reflection of the mucous membrane from the side of the tongue to the mandible.

On each side of the tongue, and in front of it, when it is at rest, there is only a slit or sulcus between the tongue and the gums, into which the ducts of the submaxillary and sublingual glands open.

FIG. 875.—DISSECTION OF SUBMAXILLARY REGION.

If, however, the tongue is raised, there is exposed a limited space, to which the term sublingual space is more usually applied (Fig. 876).

The term "floor of the mouth," or sublingual region, is frequently applied to the muscular and other structures, especially the mylo-hyoid muscles, which fill in the interval between the two halves of the body of the mandible. These structures, with the hyoid bone, form the basis upon which the tongue and the mucous membrane of the sublingual space are supported, and they extend from the symphysis menti in front to the body of the hyoid bone behind.

The sublingual region (Fig. 876) is covered by the mucous membrane between the deep surface of the gum and the inferior aspect of the tongue. When the tip of the tongue is raised the membrane forms in the median plane a prominent fold, the *frenulum linguæ*, stretching from the floor of the mouth to the inferior surface of the tongue. On each side of the frenulum, near its junction with the floor, there can be readily made out a prominent soft papilla, the *caruncula sublingualis*, on which the opening of the duct of the submaxillary gland (O.T. Wharton's duct) may be seen (Fig. 876). Running laterally and posteriorly, on each side, from this, and occupying the greater part of the floor of the mouth, there is a well-marked ridge, *plica sublingualis*, due to the projection of the underlying sublingual gland. Most of the ducts of this gland open near the crest of the ridge on each side. There is also another fold, called the *plica fimbriata*, medial to each of the others, on the inferior surface of the tongue (*q.v.*).

FIG. 876.—OPEN MOUTH WITH TONGUE RAISED, AND THE SUBLINGUAL AND ANTERIOR GLANDS EXPOSED.

The sublingual gland of the left side has been laid bare by removing the mucous membrane; to expose the anterior lingual gland of the right side a thin layer of muscle, in addition to the mucous membrane, has been removed. A branch of the lingual nerve is seen running on the medial aspect of the gland. The profunda vein is faintly indicated on this side also.

the cavum oris can be increased to a considerable size even when the teeth are in contact. Finally, by the simultaneous descent of the mandible and hyoid bone with the tongue, and the ascent of the soft palate, the cavity is increased to its greatest dimensions (Fig. 874).

Labia Oris.—The lips are the two movable folds, covered superficially by skin, and on their deep surface by mucous membrane, which surround the rima oris. The meeting of the lips at each side constitutes the *commissure*, and bounds the (*angulus oris*) angle of the mouth. Laterally they are prolonged into the cheeks, with which they are continuous. The junction of the lips and cheek is marked on the surface by the *sulcus naso-labialis*, which passes downwards and laterally from the margin of the nose towards the angle of the mouth, while the *sulcus mento-labialis* separates the lower lip from the chin. The upper lip presents on its superficial surface a well-marked vertical groove, the *philtrum*, bounded by two distinct ridges descending from the *columella nasi* (Fig. 876); inferiorly the groove

When the mouth is closed, and respiration is carried on through the nose, the cavum oris is reduced to a slit-like space, and practically obliterated by the tongue coming in contact with the palate above, and with the gums and teeth laterally and in front. When the mouth is slightly open and the teeth nearly in contact, the tongue becomes somewhat concave or grooved along the median plane, and leaves a channel-like space between it and the palate, while it remains in contact with the roof and gums laterally. By depressing the hyoid bone together with the root of the tongue,

widens out, and terminates opposite a slight projection—the *labial tubercle*—on the free edge of the upper lip. This tubercle is particularly well developed in children, and is chiefly responsible for the characteristic curve of the rima oris. The lower lip is usually longer and more mobile than the upper lip.

For the manner in which the various muscles enter into the formation of the lip, see section on the Muscles (pages 450 to 451).

The lips include within them the greater part of the orbicularis oris muscle, which surrounds the aperture of the mouth, and in each lip the following series of structures can be recognised from the external to the internal surface:—(1) The **skin**, which is closely beset with hairs, small and fine in the child and female, long and stout in the adult male. (2) A layer of fatty **superficial fascia** continuous with the fascia of the face generally. (3) The **orbicularis oris muscle**, continuous at its periphery with the various muscles converging towards the mouth. A number of its fibres, or those of the muscles joining it, pass through the superficial fascia and are attached to the skin, thus establishing a close connexion between the skin and the muscle. (4) The **submucous tissue**, which is occupied by an almost continuous layer of racemose glands—the **labial glands**. These open into the vestibule, and their secretion is said to be mucous. (5) The **mucous membrane** of the mouth, covered by stratified squamous epithelium. Between the orbicularis and mucous membrane, but nearer to the former, that is, in the deeper part of the submucosa, the labial artery is found a short distance from the free margin of the lip, running to meet its fellow of the opposite side.

The free margin of the lip is covered by a dry and otherwise modified mucous membrane. It begins where the integument changes colour at the outer edge of the lip, and ends posteriorly just behind the line along which the two lips meet when closed, where it passes into the ordinary moist mucous membrane of the vestibule. It presents numerous simple vascular papillæ, and its nerves terminate in special end organs, hence the acute sensitiveness of this part. In the child, at birth, the margin of the lip is divided by a very pronounced groove or fissure into an outer and an inner zone, differing considerably in their appearance.

When the tongue is pressed firmly against the back of the lips and moved about, the labial glands can be distinctly felt through the mucous membrane, giving the impression of a knobby or irregular surface. The glands, which are about the size of hemp-seeds and can be readily displayed by removing the mucous membrane, are more numerous in the lower than in the upper lip. Stoppage of their ducts, with the resulting distension of the glands, gives rise to “mucous cysts,” a well-known pathological condition.

Blood-vessels, Nerves, and Lymph-vessels.—The lips receive a free blood supply, the lower lip from the inferior labial, and the upper from the superior labial branches of the external maxillary artery.

The nerve supply of the lips is derived from the **trigeminal nerve**, that of the upper through the infra-orbital branch of the maxillary division, and that of the lower from the mental branch of the inferior alveolar branch of the mandibular division, while the **buccinator** branch of the mandibular division supplies the region of the angle. The lymph-vessels of the upper lip pass with the **external maxillary artery** to the submaxillary lymph-glands lying in the submaxillary triangle, while those from the lower lip pass in part to the same glands, and in part to the submental glands lying on the mylo-hyoid muscles, above the hyoid bone.

Buccæ.—The cheeks resemble the lips in structure, being formed of corresponding layers, but the place of the orbicularis oris muscle is taken by the buccinator muscle. They are covered externally by the skin and internally by the mucous membrane. Under the skin lies the fatty superficial fascia of the face, through which the **parotid duct** (O.T. **Stenson's duct**) runs inwards to pierce the buccinator. Here too are placed some of the muscles of facial expression. Near the end of the duct are found four or five mucous glands, as large as hemp-seeds. These are known as the **molar glands**; their ducts pierce the cheek and open into the vestibule. Beneath the superficial fascia lies the buccinator muscle, covered by the thin bucco-pharyngeal fascia. Deeper still is the submucosa, which, like that of the lips, contains numerous racemose **buccal glands**. And finally the mucous membrane is reached (Fig. 876).

An important constituent of the cheek of the infant is the **corpus adiposum buccæ** (O.T. **sucking pad**), an encapsuled mass of fat, distinct from the surrounding superficial fascia, which lies on the outer side of the buccinator, and passes backwards into the large recess between that muscle and the overlying anterior part of the masseter. This fatty mass, which is relatively more

developed in the child than in the adult, strengthens the cheek, and helps it to resist the effects of atmospheric pressure during the act of sucking. In the adult the remains of the pad can be distinctly made out under the anterior border of the masseter.

Some small superficial lymph-glands lie on the superficial surface of the buccinator, communicating with the vessels of the lips, while their efferent vessels pass onwards towards the parotid region.

Palatum.—The palate forms the roof of the mouth, and separates the mouth from the nasal cavities and nasal part of the pharynx.

It is not confined to the mouth, but extends backwards also into the cavity of the pharynx, forming the division between the oral and the nasal pharynx. It terminates behind in a free conical projection, the uvula. It consists of two distinct portions, an anterior, forming the anterior two-thirds, which has a bony foundation (palatine processes of the maxillæ and the horizontal parts of the palatine bones), and a posterior, forming the posterior third, with a fibrous basis; and they are termed the hard and the soft palate respectively. The palate is arched antero-posteriorly, and also transversely. The latter curvature is the more pronounced in the hard palate, but the shape and curvature of this portion depend upon the configuration of its bony foundation.

The hard palate is, on the whole, horizontal in direction, both transversely and antero-posteriorly. The soft palate is, on the other hand, during rest, as, for instance, in quiet nasal breathing, very oblique in direction, and it shuts off the mouth from the nasal and largely from the oral parts of the pharynx. When, however, the soft palate is raised by the action of its muscles, it more nearly continues backwards the plane of the hard palate, and it projects across the cavity of the pharynx, forming a nearly complete partition between the oral and the nasal parts of the pharynx. In this position it prevents food from passing upwards into the nasal part of the pharynx and nose.

Traversing the middle of the palate is seen a faint central ridge or *raphe* (Fig. 877), indicating its original development from two lateral halves. This raphe is continued posteriorly along the soft palate to the base of the uvula, and in front it ends in a slight elevation, the *papilla palatina* (O.T. incisive pad). From the anterior end of the raphe a series of transverse ridges of mucous membrane, about six in number, run laterally, just behind the incisor teeth; they are known as the *plicæ palatinæ*, and are composed of dense fibrous tissue. Sometimes a small pit, which will admit the point of a pin, is seen on each side immediately posterior to the central incisor teeth, and about 2 mm. from the median plane. These pits correspond to the inferior openings of the incisive canals, with which they are occasionally continuous.

Palatum Durum.—The hard palate consists of a horizontal plate formed by the palatine processes of the maxillæ and the horizontal parts of the palatine bones,

FIG. 877.—THE HARD PALATE AND UPPER PERMANENT TEETH, SEEN FROM BELOW.

covered on each surface, superior and inferior, by periosteum. The periosteum of the inferior surface is thick, and is in turn covered by a quantity of dense fibrous tissue firmly united both to the periosteum and to the mucous membrane. This dense tissue contains in its posterior half a large number of racemose palatine glands, and it also contains the larger nerves and blood-vessels of the palate. The mucous membrane covering the superior surface is largely ciliated in character, and forms the floor of the nasal cavity, while that on the inferior surface is a stratified squamous epithelium.

Palatum Molle.—The soft palate is attached anteriorly to the posterior margin of the hard palate. Its lower and posterior margin is free, and forms an arch, extending from one side of the pharynx to the other, but the arch is interrupted

in the centre by the conical projection of varying size called the uvula, which hangs down from its inferior margin. Laterally the soft palate is intimately connected on each side with two prominent folds, called the palatine arches. The exact relationship of the soft palate to these is as follows. The free posterior margin of the soft palate passes into the **pharyngo-palatine arch** (O.T. **posterior pillar of the fauces**), which passes downwards for some distance on the lateral wall of the pharynx.

The **glosso-palatine arch** (O.T. **anterior pillar of the fauces**), on the other hand, passes below into the side of the tongue. Traced upwards, it runs on to the inferior surface of the soft palate, and is continuous with the margin of the uvula.

The two palatine arches on each side are 7-8 mm. apart, and on the lateral wall between each pair is a fossa or depression which is occupied in part by the palatine tonsil. This region belongs properly to the pharynx, and will be described in detail when that part is dealt with, but at the present stage the relation of this fossa of the tonsil to the soft palate should be carefully noticed.

The superior surface of the soft palate forms a continuation backwards and downwards of the floor of the nasal cavity, and constitutes the floor of the nasal part of the pharynx. It is covered by a prolongation of the nasal mucous membrane, partly ciliated in character. The inferior surface is arched, and forms the backward prolongation of the roof of the mouth.

In the fœtus the whole of the epithelial covering of the soft palate is ciliated, but after birth the ciliated epithelium is largely replaced by stratified squamous epithelium, except at the margin of the palate.

Structure.—The framework of the soft palate is formed of a strong fibrous sheet, called the palatine aponeurosis. To it several muscles are attached. These structures, together with fibrous tissue, gland-vessels, and nerves, are covered by mucous membrane on each surface.

The palatine aponeurosis, which is confined to the anterior part of the soft palate, is in the form of a thin flat sheet, constituting a common tendon for the palatine muscles which are attached to (or blended with) its posterior margin. Its anterior margin is united to the posterior edge of the horizontal parts of the palatine bones. With the exception of the aponeurosis of the tensor veli palatini which passes into its lateral part, the muscles do not, as a rule, reach further forwards than to within 8 or 10 mm. of the posterior edge of the hard palate.

The muscles entering into the formation of the soft palate are the mm. pharyngo-palatini, uvulæ, levatores veli palatini, tensor veli palatini, and glosso-palatini. For the details of the attachments and arrangement of these muscles, see p. 466.

The anterior part of the soft palate for 8 or 10 mm. ($\frac{1}{2}$ in.) contains practically no muscular fibres; it is composed of the palatine aponeurosis, covered by an extremely thick layer of glands on the inferior surface and by mucous membrane on both surfaces. This anterior portion is much less movable than the rest of the soft palate, and forms a relatively horizontal continuation backwards of the hard palate, stretching across between the two medial pterygoid laminae. It is upon this portion chiefly that the tensor veli palatini muscles act. The posterior and larger part contains muscular fibres in abundance, slopes strongly downwards, and is freely movable, being the portion upon which the remaining palatine muscles act.

The **mucous membrane** of the inferior surface of the palate, which is covered by stratified squamous epithelium, is firmer and more closely adherent in front, near the rugæ, than behind, near the soft palate.

Mucous glands, the orifices of which can be seen as dots with the naked eye, are extremely abundant in the soft palate, and in the posterior half of the hard palate, except near the raphe. They are wanting in the anterior part of the palate, where the mucous membrane is particularly dense.

The **plicæ palatinæ** (which correspond to more strongly developed ridges in carnivora, etc.) are very well marked in the child at birth, although, perhaps, relatively less distinct in the fœtus of five or six months; in old age they become more or less obliterated and irregular. At birth, also, and in the fœtus, the incisive pad at the anterior end of the raphe is continued over the edge of the gum into the frenulum of the upper lip.

The **uvula**, already referred to, is a conical projection, very variable in length, which is continued downwards and backwards from the middle of the posterior border of the soft palate. It is composed chiefly of a mass of racemose glands and connective tissue covered by mucous membrane, and containing a slender prolongation of the uvular muscle in its upper part.

The **vessels** of the palate are :—

(1) Branches from the **descending palatine artery**, a branch of the internal maxillary artery. Of these, some small vessels, the **lesser palatine arteries**, emerge from the foramina palatina

minora, and are distributed to the tonsil and palate, and anastomose with branches of the ascending pharyngeal artery.

The largest branch, **greater palatine artery**, emerges through the foramen palatinum majus, and runs forwards over the lateral margin of the hard palate, about $\frac{1}{2}$ in. from the alveolar margin, as far as to the foramen incisivum, where it anastomoses with the naso-palatine artery.

(2) **Posterior nasal septal artery**, a small vessel which enters through the foramen incisivum.

(3) **Ascending palatine artery**, from the external maxillary, which anastomoses by a ramus tonsillaris with the descending palatine.

(4) Branches from the **ascending pharyngeal artery**, which enter the soft palate.

(5) Branches from the **rami dorsales linguae** of the lingual artery, which pass in the glosso-palatine fold to the palate tonsil and soft palate.

The **nerves** are all derived from branches from the sphenopalatine ganglion.

(1) **Nervi palatini**. The most important of these is the **nervus palatinus anterior**, which passes through the foramen palatinum majus, and divides in the roof of the mouth into branches which run in grooves on the hard palate, and extend forwards nearly to the incisor teeth.

The others are the **nn. palatini medius and posterior**, which emerge from the foramina palatina minora, and are distributed to the hard and soft palate.

(2) **N. nasopalatinus** (Scarpæ). This nerve sends branches to the palate through the foramen incisivum, which join with branches from the anterior palatine nerves.

For the motor nerves to the muscles of the soft palate, see p. 467.

The **lymph-vessels** of the palate pass beside the tonsil and the isthmus of the fauces to the upper deep cervical lymph-glands.

Isthmus Faucium.—The isthmus of the fauces is the aperture through which the mouth communicates with the oral part of the pharynx (Fig. 878). It is bounded at the sides by the glosso-palatine arches, above by the inferior surface of the soft palate, and below by the dorsum of the tongue; in width it corresponds pretty closely to the cavum oris.

FIG. 878.—OPEN MOUTH SHOWING PALATE AND PALATINE TONSILS.

It also shows the two palatine arches, and the pharyngo-nasal isthmus through which the nasal part of the pharynx above communicates with the oral portion of the pharynx below.

described in connexion with the tonsil (p. 1145).

Gingivæ.—The gums are composed of the red firm tissue which covers the alveolar borders of the maxillæ and mandible, and surrounds the necks of the teeth. In structure they consist of dense fibrous tissue, inseparably united to the periosteum, covered by mucous membrane. They are richly supplied with blood-vessels, but sparsely with nerves, and are covered by stratified squamous epithelium. Around the neck—or more correctly the base of the crown—of each tooth, the gum forms a free overlapping collar, and at this part particularly it is closely beset with small papillæ, visible to the naked eye.

In thickness it usually measures from 1 to 2 mm.

The **arcus glosso-palatini** (O.T. anterior pillars of the fauces) are two prominent folds of mucous membrane which bound the isthmus of the fauces laterally (Fig. 878). Each contains a glosso-palatine muscle in its interior. They are continuous above with the inferior surface of the soft palate, a little way (about 8 mm.) anterior to its free edge, and near the base of the uvula, and they pass downwards and slightly anteriorly to join the tongue a little behind the middle of its lateral border.

The **arcus pharyngo-palatini** (O.T. posterior palatine arches) are two vertical folds of mucous membrane which pass from the soft palate to the side wall of the pharynx. Each contains a muscle, the pharyngo-palatinus. The pharyngo-palatine arches are de-

DENTES.

Each tooth is a calcified papilla of the mucous membrane of the mouth, and consists like that membrane of two chief portions—namely, the *substantia eburnea* or *ivory* (O.T. *dentine*) derived from the connective tissue, and the *substantia adamantina* or *adamant* (O.T. *enamel*) from the epithelial layer of the mucous membrane. The *substantia eburnea* constitutes the chief mass of the tooth, whilst the *substantia adamantina* forms a cap for the portion which projects above the gum. There is also found in the teeth another special tissue—the *substantia ossea* (O.T. *cement*), a form of modified bone—encasing the roots, which are formed chiefly of *substantia eburnea*.

Both *ivory* and *adamant*, but particularly the latter, are the hardest and most resistant structures in the body, and are thus specially fitted for the functions which they have to perform.

Dentes Decidui and Dentes Permanentes (Deciduous and permanent teeth).—The mouth of the infant at birth contains no teeth, although a number, partly developed, lie embedded in the jaws beneath the gum. Some six months later, teeth begin to appear, and by the end of the second year a set, known as the **deciduous teeth** (O.T. **milk teeth**), twenty in number, has been “cut.” Then follows a pause of about four years, during which no visible change takes place in the mouth, although in reality an active preparation for further development is going on beneath the gum.

At the end of this period, namely, about the sixth year, the next stage in the production of the adult condition begins. It consists in the eruption of four new teeth—the first permanent molars—one on each side, above and below, behind those of the deciduous set. This is followed by the gradual falling out of the twenty teeth which have occupied the mouth since the second year (Fig. 879), and the substitution for them of twenty new teeth, which take up, one by one, the vacancies created by the dropping out of each of the deciduous set. Finally, the adult condition is attained by the eruption of eight additional teeth—the 2nd and 3rd molars—two on each side, above and below, behind those which have already appeared. All of these—the **permanent teeth**—have appeared by the end of the twelfth or thirteenth year, except the four *dentes serotini* (O.T. *wisdom teeth*), which are usually

FIG. 879.—TEETH OF A CHILD OVER SEVEN YEARS OLD (modified from Testut).

By removing the bony outer wall of the alveoli, the roots of the teeth which have been erupted, and the permanent teeth which are still embedded in the mandible and maxilla, have been exposed. The deciduous teeth are coloured blue, the permanent teeth yellow. It will be seen that the first permanent molars have appeared, the central and lateral deciduous incisors have been replaced by the corresponding permanent teeth in the maxilla, but the deciduous canine and molars have not yet been shed. In the mandible the central deciduous incisor has been replaced by the permanent central; the lateral has not yet been shed, but its permanent successor is making its way up to the surface on its lingual side. In addition, the canine and two molars of the deciduous set persist. The position of the crowns of the permanent teeth between the roots of the deciduous molars, and the deep situation occupied by the permanent canines, should be noted. Observe also the absorption of the root of the lower lateral incisor.

cut between the seventeenth and twenty-fifth year, but are often delayed until a very much later period, and occasionally never appear.

The set of teeth which, as indicated above, begin to appear in the infant about the sixth month, are known as the **deciduous teeth** (O.T. temporary, or milk teeth); whilst those which succeed them and form the adult equipment are the **permanent teeth**.

The **deciduous teeth** are twenty in number, and are named as follows in each jaw, beginning at the median plane:—**dentes incisivi**, or incisor teeth, central and lateral; **dens caninus**, or canine tooth; **dentes molares**, or molar teeth, first and second; or more briefly, two incisors, one canine, two molars. This is conveniently expressed by the “dental formula” for the deciduous teeth in man, which shows the number of each class of teeth above and below on one side of the mouth, viz.:—

$$i. \frac{2}{2}, c. \frac{1}{1}, m. \frac{2}{2} = 20.$$

The **permanent teeth**, thirty-two in number, are named **dentes incisivi**, or incisor teeth, a central and a lateral; **dentes canini**, or canine teeth; **dentes præmolares**, premolar (O.T. bicuspid) teeth; **dentes molares**, molar teeth; and are arranged as follows in each jaw, beginning at the median plane:—central incisor, lateral incisor, canine, 1st premolar, 2nd premolar, 1st molar, 2nd molar, and 3rd molar or **dens serotinus** (O.T. wisdom tooth). The dental formula for the permanent set in man is thus:—

$$i. \frac{2}{2}, c. \frac{1}{1}, pm. \frac{2}{2}, m. \frac{3}{3} = 32.$$

General Form and Structure.—A tooth consists (Fig. 880) of (1) the **corona dentis** or **crown**, the portion projecting above the gum. It varies in shape in the different teeth, and in all, except the incisors and canines, bears on its masticating surface a number of tubercles, the **tubercula coronæ** (O.T. **cusps**), varying in number from two to five in the different teeth; (2) the **collum dentis** or **neck**, the faintly constricted part surrounded collar-wise by the gum, which connects the crown with (3) the **radix dentis** or **root**, the portion of the

FIG. 880.—VERTICAL SECTION OF CANINE TOOTH, to illustrate its various parts, and its structure.

tooth which is embedded in the alveolus of the jaw. In the majority of teeth, namely, in all except the molars, the root, as a rule, is single, or nearly so, and consists of a long, tapering, conical, or flattened piece, perfectly adapted to the alveolus in which it lies. In the molar teeth (and in some of the others occasionally) the root is divided into two or three tapering or flattened roots or fangs. At the apex of each root there can be made out, even with the naked eye, a minute opening, the **foramen apicis**, through which the vessels and nerves enter the tooth.

On making a section of a tooth (Fig. 880), it will be seen that the interior of the body is occupied by a cavity of some size, called the **cavum dentis** or **tooth cavity**, which is filled in the natural state by the soft and sensitive tissue known as the **pulpa dentis** or **tooth pulp**. The tooth cavity gradually narrows, and is prolonged into each root of the tooth as a slender tapering passage, the **canalis radialis** (root-canal), which opens at the apical foramen already referred to. Through these root-canals, which also contain some pulp, the vessels and nerves, which enter at the apex, pass to the interior of the tooth.

Short diverticula of the pulp cavity are prolonged into the bases of the tubercles

in the molar and premolar teeth, and in the incisors also there are similar slight prolongations of the cavity towards the angles of the crown.

The roots of the teeth are embedded in the **alveoli** or sockets of the jaws, to which they are accurately adapted, and firmly united (Fig. 880) by a highly vascular layer of connective tissue—the **periosteum alveolare**. This is attached to the wall of the alveolus on the one hand and to the root of the tooth on the other, whilst above it is continuous with the connective tissues of the gum.

So accurately are the root and the alveolus adapted to each other over their whole extent, and so firmly does the periosteum bind them together, that, under normal conditions, the tooth is quite firmly fixed in the bone, and no movement of the root within the alveolus can take place; the vessels and nerves entering at the apex are thus secured against pressure or strain.

When, however, the alveolar periosteum is inflamed it becomes swollen and exquisitely sensitive; the tooth, as a result of the swelling, is pushed partly out of its socket, its crown projects above those of its neighbours, and strikes against the opposing tooth when the mouth is closed, giving rise to much pain and discomfort.

The **neck**, although the term is useful, can scarcely be recognised as a distinct constriction in the permanent teeth; it corresponds to the line along which the gum and alveolar periosteum meet, or along which the gum is united to the tooth; but, as already pointed out, the gum does not stop at the neck, but forms a free fold which surrounds the base of the crown collar-wise for a short distance. The outline of the margin of the gum opposite the labial and lingual surfaces of the crown is usually concave, but opposite the contact surfaces of the tooth it is convex, and reaches much nearer to the edge of the crown than on the other surfaces.

In the incisors and canines the **tooth cavity**, which is about $\frac{1}{8}$ to $\frac{1}{4}$ the diameter of the tooth, passes very gradually into the root-canal (Fig. 880), so that it is difficult to say where one ends and the other begins. The reverse is the case in the molars, whilst the premolars are somewhat variable in this respect.

Tartar is a hard calcareous deposit from the saliva (salivary calculus), often found on the teeth near their necks. It is composed of lime salts, and its deposit is largely determined by the presence of organisms (leptothrix, etc.) in the mouth.

DENTES PERMANENTES.

The **permanent teeth** (Figs. 881 and 882) are thirty-two in number, sixteen above and sixteen below, or eight in each half of either jaw; and, although they can be grouped under four heads—incisors, canines, premolars, and molars—the individual teeth differ so much in their characters that each tooth requires a separate description.

Descriptive Terms.—Before describing the permanent teeth, it is requisite that certain terms which are employed to denote the surfaces of the teeth should be defined. This is a matter of some importance, seeing that the terms medial and lateral, anterior and posterior, cannot, owing to the curvature of the dental arches, be properly applied to all the teeth in the same sense. The terms given below have been adopted seeing that they are free from the danger of misconception.

The part of a tooth which comes in contact with the teeth of the opposite jaw is known as the **facies masticatoria** (grinding or masticating surface) (Fig. 883). The surface in contact with or looking towards its predecessor in the row is known as the **facies medialis** in incisors and canines, **facies anterior** in premolars and molars; the opposite surface, namely, that which looks towards its successor in the row, is known as the **facies lateralis** in incisors and canines, **facies posterior** in molars and premolars. The surface which looks towards the tongue is the **facies lingualis** (lingual surface), and that looking in the opposite direction, *i.e.* towards the lips and cheek, the **facies labialis** (labial surface). The portion of a tooth which touches its neighbour in the same row is known as the **facies contacta** (contact surface).

Dentes Incisivi (Figs. 881 and 882).—The incisor teeth, four in number in each jaw, are used specially for cutting the food, hence their name. The **crown** of each is chisel-shaped, and presents a labial surface which is convex in all directions, a concave lingual surface, and a chisel-like edge, which, when first cut, is surmounted by three small tubercles separated by two grooves. These tubercles, however, are soon worn down, and the edge becomes straight or nearly so. Owing to the fact that the upper incisors overlap those in the mandible, the

cutting edge is worn away, or becomes bevelled, on the lingual aspect in the former, but on the labial aspect or summit in the latter. The upper, and particularly the central upper incisors, are of large size, and slope somewhat forwards; whilst the lower incisors, all of nearly equal size, are much smaller—being

FIG. 881.—THE PERMANENT TEETH OF THE RIGHT SIDE, LABIAL ASPECT.

The upper row shows the upper teeth, the lower row the lower teeth. The wide vertical “labial ridge” is distinct on the upper canine and premolar teeth.

the smallest of all the teeth—and are placed vertically. The roots of the incisors are single, though a groove is occasionally seen on each side, suggesting a division.

The central upper incisors are very much larger than the upper lateral incisors (Fig. 881), but in the lower jaw the opposite is the case, the lateral incisors being slightly the larger. In all incisors

FIG. 882.—THE PERMANENT TEETH OF THE RIGHT SIDE, LINGUAL ASPECT.

The upper row shows the upper teeth, the lower row the lower teeth. The cingulum is distinct on the upper incisors and both canines, the lingual tubercle on the upper lateral incisor and the upper canine.

the lateral angle of the crown is more rounded than the medial. The concave lingual surface of the crown in the upper incisors is usually limited towards the gum by a Λ -shaped ridge (Fig. 882), known as the **cingulum**. The two limbs of the Λ are continued up along the sides of the lingual surface, whilst the apex is turned towards the gum; and here, particularly in the lateral incisor, there is often developed a small lingual tubercle (Fig. 882). The cingulum is rarely found on the lower incisors.

The roots of the upper incisors and canines are conical and rounded (the lateral incisors and canines not so distinctly as the central incisors) (Fig. 881), whilst those of the mandible are flattened from side to side (medio-laterally).

Dentes Canini.—In the four canine teeth, which succeed the incisors in each row (Figs. 881 and 886), the crown is large and conical, corresponding closely in general form to a very large central incisor with its angles cut away, so that the crown assumes a pointed or conical shape. The labial surface is convex, the lingual usually somewhat concave. The root is single and long, particularly in the upper canine, the root of which is longer than that of any other tooth, and produces the canine eminence on the anterior surface of the maxilla. The upper canines are larger than the corresponding lower teeth, behind which they bite; and they are sometimes known as the “eye teeth.”

The upper canine presents on its lingual surface a well-marked cingulum, and often a distinct lingual tubercle; in addition, there is usually a median ridge running from the point of the crown to the apex of the cingulum, which is separated from the lateral part of the cingulum on each side by a slight depression. These points are neither so well marked, nor so constant, in the lower as in the upper canine.

Of the two margins sloping away from the apex of the crown, the lateral is the longer in both teeth. After it has been a little worn the lower canine is less distinctly pointed than the upper; its root is also more flattened. On the labial surface of the crown, of both canines and premolars, a wide low vertical ridge (labial ridge) can generally be made out (Fig. 882); it is most distinct on the canine and first upper premolar.

Dentes Præmolares

(Figs. 881 and 882). — The premolar teeth, eight in number, two in each jaw above and below, are placed posterior to the canines, and anterior to the molars, as the name indicates. The crown, which, unlike that of the incisors and canines, is flattened antero-posteriorly, is characterised by the presence of two tubercles (O.T. cusps) (Fig. 883). One of the tubercles, the larger, is placed on the labial, the other on the lingual side. The labial and lingual surfaces are both convex. The root is single, but it is, as a rule, flattened antero-posteriorly and grooved, showing in this a tendency to division, which often actually takes place in the first upper premolar. The upper premolars are easily distinguished by the fact that their two tubercles are large and are separated from one another by a distinct antero-posterior fissure (Fig. 883); whilst in the lower premolars, on the other hand, the separation between the two tubercles is not effected by a continuous fissure as in the upper teeth, but by two dimple-like depressions separated by a ridge which joins the two tubercles (Fig. 884). In the upper premolars, therefore, the two tubercles are separated by a fissure, in the lower they are united by a ridge.

The first upper premolar is often slightly larger than the second; the reverse is the case in the mandible. The labial surface of the crown is usually somewhat larger than the lingual surface in all premolars. As a general rule in the lower premolars the labial surface of the crown is sloped medially near the masticating surface. The first can usually be distinguished from the second by the fact that, while the lingual tubercle and surface are smaller than the labial in the first premolar, they are nearly of the same size in the second. In addition, the root of the first upper premolar is bifid or nearly so, and its labial ridge is fairly distinct, but is indistinct in the second. In the first lower premolar the lingual tubercle and surface are very small, in fact the tubercle is quite rudimentary. It should, however, be added that it is often extremely difficult to identify the various premolars.

The first upper premolar is often slightly larger than the second; the reverse is the case in the mandible. The labial surface of the crown is usually somewhat larger than the lingual surface in all premolars. As a general rule in the lower premolars the labial surface of the crown is sloped medially near the masticating surface. The first can usually be distinguished from the second by the fact that, while the lingual tubercle and surface are smaller than the labial in the first premolar, they are nearly of the same size in the second. In addition, the root of the first upper premolar is bifid or nearly so, and its labial ridge is fairly distinct, but is indistinct in the second. In the first lower premolar the lingual tubercle and surface are very small, in fact the tubercle is quite rudimentary. It should, however, be added that it is often extremely difficult to identify the various premolars.

Dentes Molares.—The molar teeth are twelve in number—three on each side

FIG. 883.—THE HARD PALATE AND UPPER PERMANENT TEETH, VIEWED FROM BELOW.

above and below—and are distinguished as first, second, and third molars. The last in each jaw is also known as the *dens serotinus*. All the molars are characterised by the large size of the crown and the possession of three or more trihedral tubercles on the masticating surface (Figs. 883 and 884). They are the largest of all the teeth, but they diminish in size, as a rule, from the first to the third. In shape the crown is more or less quadrangular, with convex labial and lingual surfaces. The roots are either two or three in number, but frequently in the last molars they are united to a varying degree.

The molars of the maxilla and mandible differ so considerably in their further details that they must be considered separately. They may be most readily distinguished from one another by the fact that normally the **upper molars** possess three roots (Figs. 881 and 882), whilst the **lower molars** have two at most. The number of tubercles, though not so reliable a guide as the form of the root, is also generally sufficient to distinguish them. In the upper molars there are either three or four tubercles, whilst in the lower the number is most commonly five (see, however, below).

In the **upper molars**, the **crown**, viewed from the masticating surface (Fig. 883), is rhomboidal in shape (*i.e.* quadrangular with the angles not right angles). The labial and the lingual surfaces are convex. The number of **tubercles** is either four or three. On the *first* there are invariably four—two on the labial and two on the lingual side—the anterior lingual of these being connected with the posterior labial by an oblique ridge (Fig. 883), which is also found on the *second* and *third* molars when these bear four distinct cusps. The *second* upper molar has either four or three tubercles in about an equal proportion of European skulls, whilst in the *third* the number is much more frequently three than four. The **roots** in the upper molars are three in number (except, occasionally, when the three roots of the *third* are confluent), two being labial, and the *third* lingual (Figs. 881, 882, and 885).

In the **lower molars**, the **crown**, viewed from above (Fig. 884), is somewhat cubical. The labial and lingual surfaces are convex, as in the upper molars. The *first*, as a rule, bears five tubercles, two being on the labial side, two on the lingual, and the fifth behind and lateral, that is, between the two posterior tubercles and somewhat to the labial side. The *second* has usually only four tubercles; a fifth, however, is sometimes present. The *third* has either four or five, the former number more frequently than the latter.

The **roots** of the lower molars are two in number, each wide, grooved, and flattened antero-posteriorly. One root is anterior, the other posterior, and both are usually recurved in their lower portions (Fig. 885). As in the corresponding teeth of the maxilla, the roots of the lower last molars are often more or less united into a single mass.

The chief characters of the upper and lower molars may be summarised thus:—

The first molar is usually larger than the second, and the second than the third. The upper molars are directed downwards and laterally; whilst the lower molars, which the former partly overlap, slope upwards and medially, with the result that the labial tubercles of the lower molars lie in the groove separating the lingual from the labial tubercles of the upper teeth (Fig. 886, p. 1120). As a result of this overlapping, the labial edge of the crown is sharp and the lingual edge rounded in the upper molars; whilst the lingual edge is sharp and the labial edge rounded in the lower set.

The fissures which separate the cusps on the grinding surfaces of the molar teeth are generally continued as faint grooves on the labial and lingual surfaces.

Upper Molars.—The crowns, as already stated, are rhomboidal in shape, and when viewing their masticating surfaces, as in Fig. 883, if the planes of separation between them be prolonged, they would strike the median plane near the posterior part of the hard palate; in other words, their anterior and posterior surfaces are not in transverse but in oblique planes, sloping strongly postero-medially, and converging in that direction. A knowledge of this is useful in determining the side to which an upper molar belongs, as is the fact that the anterior labial root is broader than the posterior (Fig. 882).

As regards the *number of tubercles* (Fig. 883):—The first upper molar has four tubercles in practically all skulls (99 per cent); occasionally, indeed, another, but very rudimentary, tubercle is present on the lingual side of the antero-lingual tubercle. The second molar has either three or four in an almost equal proportion of Europeans, but more frequently four, taking the teeth of all nations together. (According to Topinard, four are present in 66 per cent of all races,

and in 58 per cent of European, Semitic, and Egyptian skulls; according to Zuckerkandl, in 73.5 per cent of the lower races and 45.6 per cent of Europeans.) The third upper molar has three tubercles much more frequently than four amongst Europeans (four only in 36 per cent, although it has four more frequently in certain lower races). It should be remarked that, while there are practically always four tubercles in the first molar, still there is a tendency to the disappearance of the postero-lingual one, which tendency grows more pronounced as we pass backwards to the second and third molars. The other tubercles are practically constant.

The three roots of the upper molars (Figs. 881, 882, and 885) are, a large palatine, subcylindrical in shape, and two labial roots, smaller and flattened from before backwards. The palatine root, which is placed opposite the posterior labial root, is often united to one of the others. The lower part of the maxillary sinus generally extends down between the palatine and the two labial roots (Fig. 879, p. 1113), but the latter project on its floor more frequently than the palatine root. In the last molars the three roots are frequently more or less united into a single conical process (Fig. 881).

Lower Molars.—The crowns are more massive than those of the upper molars, and are elongated antero-posteriorly (Fig. 884). A crucial groove separates the four chief tubercles from

FIG. 884.—THE LOWER PERMANENT TEETH, VIEWED FROM ABOVE.

one another; this bifurcates behind to enclose the fifth, which lies slightly to the labial side of the middle of the tooth. The number of tubercles present in the lower molars is as follows:—The first has usually five (62 per cent of all races, 61 per cent of Europeans); the second has four, as a rule (five in only 24 per cent of all skulls); the lower dens serotinus has four a little more frequently than five (five in 46 per cent of all skulls), but like the upper last molar tooth it is extremely variable.

The roots of the lower molars (Fig. 881), two in number, are flattened from before backwards, and very wide. The anterior of these has two root-canals; the posterior but one (Fig. 885). The dens serotinus has commonly two roots like its fellows; occasionally the two are united. In determining the side to which a lower molar belongs, it should be remembered that the deep part of the root is generally curved backwards, and also that the blunter margin of the crown (see above) and the fifth tubercle, if present, are on the labial side.

Arrangement of the Teeth in the Jaws.—The teeth are arranged in each jaw in a curved row—the *arcus dentalis*—of approximately a semi-oval form (Figs. 884 and 885). The curve formed by the upper teeth, *arcus dentalis superior*, however, is wider than that formed by the lower set, *arcus dentalis inferior*, so that when the two are brought in contact the upper incisors and canines overlap their fellows in front, and the labial tubercles of the upper premolars and molars overlap the corresponding ones of the lower teeth (Fig. 886, p. 1120). It will also be seen that, as a rule, the teeth in one jaw are not placed exactly opposite their fellows, but rather opposite the interval between two teeth, in the other jaw

(Fig. 886). This arrangement is brought about largely by the great width of

FIG. 885.—HORIZONTAL SECTIONS THROUGH BOTH THE MAXILLA AND MANDIBLE to show the roots of the teeth. The sections were carried through the bones a short distance from the edge of their alveolar borders. The upper figure shows the upper teeth, the lower figure the lower teeth. Note the flattened roots of the lower incisors, the two root-canals in the anterior root of each lower molar, and the confluence of the three roots of the upper last molars.

gums, the *order* of eruption is practically constant in different individuals, and is as follows:—Before any of the deciduous teeth are lost the first permanent molars appear behind the 2nd deciduous molars. Next the central deciduous incisors fall out, and their places are taken by the permanent teeth of the same name; then follow the remaining teeth in the following order: Lateral incisors, 1st premolars, 2nd premolars, canines, 2nd molars, and 3rd molars. It will be observed that the eruption of the canine is delayed until the two premolars, which succeed it in the row, are cut, so that it breaks the otherwise regular order of eruption. The 1st molar is sometimes popularly known, owing to the date of its eruption, as the “six-year-old tooth,” and the 2nd molar as “the twelve-year-old tooth.”

The dates at which the eruption usually takes place may be simply stated as follows for the lower teeth; those of the upper jaw appear a little later:—

the upper central incisors as compared with their fellows of the mandible, which throws the upper canines and the succeeding teeth into a position behind that of the same-named teeth of the lower set. But as the lower molars are larger in their antero-posterior diameter than those of the upper row—and this remark applies particularly to the third molars—the two dental arches terminate behind at approximately the same point.

The upper dental arch is said to form an *elliptical*, the lower a *parabolic curve* (Figs. 884 and 885). The line formed by the masticating surfaces of the upper teeth, as seen on profile view (Fig. 886), is usually somewhat convex, owing largely to the failure of the third molar to descend into line with the others. Similarly the line of the lower teeth is as a rule concave.

In both jaws the crowns of the front teeth are higher (longer) than those of the molars.

Period of Eruption of the Permanent Teeth.—Although there is considerable variety in the *dates* at which the various permanent teeth appear above the

FIG. 886.—To show the relation of the upper to the lower teeth when the mouth is closed. The manner in which a tooth of one row usually strikes against two teeth of the opposite row, and the resulting interlocking of the teeth, are to be noted.

1st molars appear soon after the 6th year.

Central incisors appear soon after the 7th year.

1st premolar " " 9th "

2nd " " " 10th "

Canine " " " 11th "

2nd molar " " 12th "

3rd " " " from the 17th " to 21st year, or even later.

Variations in the Number of the Teeth.—The presence of an additional tooth is by no means uncommon. It may appear in connexion with the incisor, premolar, or the molar groups. A distinction is drawn between "supernumerary" or imperfect additions to the dentition and "supplemental" teeth which correspond in size with those with which they are associated. When a supplemental incisor appears it has an interesting bearing upon the solution of the much-debated point as to which incisor has disappeared from the primate dentition. A fourth molar is occasionally present.

DENTES DECIDUI.

The deciduous teeth (O.T. temporary or milk) are twenty in number, ten above and ten below, or five in each half of each jaw—namely, two incisors, one canine, and two molars. They may be distinguished from the permanent teeth by their smaller size, their well-marked and constricted necks, and, in the case of the molars, by the wide divergence of their roots (Fig. 887). Otherwise they correspond so closely to the same-named teeth of the permanent set, that they require no separate description, except in the case of the molars. The first upper molar has but three tubercles on its crown—two lateral and one medial; the first lower molar has four—two lateral and two medial, and the crowns of both are flattened from side to side. The second molars of the maxilla have four, those of the mandible five tubercles each. In every case the second are much larger than the first molars. The tubercles are sharper and are separated by deeper fissures or fossæ than those of the permanent teeth, whilst the roots of the deciduous molars, except for their greater divergence, agree with those of the permanent set.

FIG. 887.—THE DECIDUOUS TEETH OF THE LEFT SIDE.

The masticating surfaces of the two upper molars are shown above. In the second row the upper teeth are viewed from the outer or labial side. In the third row the lower teeth are shown in a similar manner; and below are the masticating surfaces of the two lower molars. In the specimen from which the first upper molar was drawn the two labial tubercles were not distinctly separated, as is often the case.

The marked constriction at the neck of the deciduous teeth (Fig. 887) is due to a great thickening of the cap of adamant on the crown, and its abrupt termination as the neck is reached. The adamant, too, is much whiter as a rule than in the permanent teeth. It should be added that the labial surface of the canines and molars departs very markedly from the vertical; it slopes strongly inwards towards the mouth cavity as it approaches the masticatory surface of the crown, which latter is, as a result, much reduced in width.

The divergence of the roots in the deciduous molars allows the crowns of the permanent premolars to fit in between them before the former molars are shed.

STRUCTURE OF THE TEETH.

As mentioned above, the teeth are composed of three special tissues, *substantia adamantina* or *adamant* (O.T. *enamel*), *substantia eburnea* or *ivory* (O.T. *dentine*), and *substantia ossea* (O.T. *crusta petrosa* or *cement*), in addition to the pulp which occupies the tooth cavity. The chief mass of the tooth is formed of *substantia eburnea*, which surrounds the tooth cavity and extends from crown to root; outside this is a covering of *substantia adamantina* on the crown, and a layer of *substantia ossea* on the root.

The *substantia adamantina* is the dense, white, glistening layer which forms a cap, thickest over the tubercles, for the portion of each tooth projecting above the gum (Fig. 888). At the neck it ceases gradually, being here slightly overlapped by the *substantia ossea*.

FIG. 888.—VERTICAL SECTION OF CANINE TOOTH to illustrate its various parts, and its structure.

It is composed chiefly of phosphate and carbonate of lime (phosphate of calcium 89.82 per cent, carbonate of calcium 4.37 per cent, magnesium phosphate 1.34 per cent, a trace of calcium fluoride, other salts .88 per cent), and has generally been considered to contain about 3.6 per cent of organic substance; but this Tomes has recently shown to be inaccurate: "That which has heretofore been set down as organic matter is simply water combined with the lime salts. The *substantia adamantina* is to be regarded as an inorganic substance composed of lime salts, which have been deposited in particular patterns and formed under the influence of organic tissues, which have themselves disappeared during its formation."

The adamantine substance consists of calcified microscopic prisms, *prismata adamantina*, radiating from the surface of the ivory, on which their inner ends lie, to the surface of the crown, on which they terminate by free ends. These prisms are hexagonal in shape, solid, and of considerable length, for most of them reach from the ivory to the surface of the crown without interruption. The prisms, which are calcified themselves, are held together by the smallest possible amount of calcified matrix (Tomes). In old teeth the cap of adamantine substance is often worn away over the tubercles, the ivory is then exposed, and is easily recognised by its yellowish colour, which contrasts strongly with the whiteness of the adamant.

Whilst adjacent adamantine prisms are in general parallel to one another, they do not usually take a straight, but rather a wavy course, and in alternate layers they are often inclined in opposite directions, thus giving rise to certain radial striations seen by reflected light (Schreger's lines). Certain other pigmented lines, more or less parallel to the surface, are also seen in the adamant (brown striae of Retzius). They are due to true pigmentation (Williams), and mark the lines of deposit of the adamant during its development. The adamantine prisms are more or less tubular in certain animals—viz., in all marsupials except the wombat, in the hyrax, certain insectivora, and certain rodents.

Cuticula dentis (O.T. *Nasmyth's membrane*) is an extremely thin ($\frac{1}{200000}$ of an inch) cuticular layer which covers the adamant of recently-cut teeth, and is very indestructible, resisting almost all reagents. Two chief views are held as to its origin. One that it is the last formed layer of adamant, which has not yet been calcified, and therefore the final product of the adamant cells. The other that it is produced by the outer layer of cells of the adamant organ. This latter seems to be the more probable view.

Substantia eburnea or *ivory* (O.T. *dentine*) is the hard and highly elastic substance, yellowish white in colour, which forms the greater part of the mass of every tooth (Fig. 888). Like the adamant it is highly calcified, but it differs from it in containing

a very considerable amount of organic matter and water incorporated with its salts, which are chiefly phosphate and carbonate of lime.

Fresh human ivory contains 10 per cent of water, 28 per cent of organic and 62 per cent of inorganic material. The organic matter is composed chiefly of collagen, and to a less extent of elastin. The organic matter consists of (1) calcium phosphate (with a trace of fluoride), (2) calcium carbonate, and (3) magnesium phosphate, the percentages present in dried dentine being 66·72, 3·36, 1·08 respectively.

Ivory consists of a highly calcified organic matrix, which is itself practically structureless, although everywhere traversed by tubes—the *canaliculi dentales*, or *dentinal canaliculi*—which give to this tissue a finely striated appearance, the striæ usually running in wavy lines. The canaliculi begin by open mouths on the wall of the pulp cavity, whence they run an undulating, and at the same time a somewhat spiral course, towards the periphery of the ivory. They give off fine anastomosing branches, and occasionally divide into two. Somewhat reduced in size, they usually end in the outer part of the ivory.

The *canaliculi dentales* are generally described as being lined by special sheaths (dentinal sheaths of Neumann) which are composed of a most resistant material, and possibly are calcified. It should be mentioned that the presence of these sheaths as separate structures is doubted by some authorities, who hold that the part described as the sheath is only a modified portion of the ivory which forms the tubules.

The *canaliculi dentales* are occupied by processes, prolonged from the outermost cells of the pulp—the odontoblasts. These processes are called after their discoverer, *Tomes' fibrils* (dentinal fibrils), and they are probably sensory in function.

The concentric lines of *Schreger*, frequently seen in the ivory, are due to bends in successive canaliculi along regular lines running parallel to the periphery of the ivory. Other lines (the incremental lines of *Salter*), due to imperfect calcification, are found arching across the substance of the ivory, chiefly in the crown. There must also be mentioned the *interglobular spaces*, intervals left in the ivory, as a result of imperfect calcification, bounded by the fully calcified surrounding tissue, the contour of which is in the form of a number of small projecting globules. These interglobular spaces are very numerous in the outer or "granular layer" of the ivory, particularly beneath the osseous substance.

The *substantia ossea* (O.T. *cement*) is a layer of modified bone which encases the whole of the tooth except its crown. It begins as a very thin stratum, slightly overlapping the adamant at the neck. From this it is continued, increasing in amount, towards the apex, which is formed entirely of this substance. It is relatively less in amount in the child, and increases during life. In places the ivory seems to pass imperceptibly into the *substantia ossea* (the "granular layer" marking the junction of the two, and some of the *canaliculi dentales* are continuous with the lacunæ of the *substantia ossea*. Like true bone, it is laminated, it possesses lacunæ, canaliculi, and, when in large masses, it may even contain a few Haversian canals.

The *pulpa dentis* occupies the tooth cavity and the root-canals of the teeth. It is composed of a number of branched connective tissue cells, the anastomosing processes of which form a fine network, containing in its meshes a jelly-like material, in addition to numerous vessels and nerves, but no lymph-vessels. The most superficial of these cells are arranged in the young tooth as a continuous layer of columnar, epithelium-like cells, lying on the surface of the tooth pulp against the ivory; they are known as *odontoblasts*, for they are the active agents in the formation of the ivory. From the outer ends of these odontoblasts processes are continued into the *canaliculi dentales*, where they have been already referred to as *Tomes' fibrils*. The vessels of the tooth pulp are numerous, and form a capillary plexus immediately within the odontoblasts. The nerves form rich plexuses throughout the pulp, but their exact mode of ending is unknown.

The *periosteum alveolare* is a layer of connective tissue free from elastic fibres, but well supplied both with blood-vessels and nerves, which fixes the root of the tooth in the alveolus, being firmly united by perforating fibres of *Sharpey*, to the *substantia ossea* on the one hand, and to the bone of the alveolus on the other. It establishes a communication between the bone of the jaw and the *substantia ossea*, and it is continuous with the tissue of the gum. Its blood comes chiefly from the arteries, which subsequently enter the apical foramina for the supply of the tooth pulp, but in part also from the vessels of the surrounding bone and of the gum (hence the relief obtained in dental periostitis by lancing the gum).

LINGUA.

The **tongue** is a large mobile mass, which occupies the floor of the mouth and forms the anterior wall of the oral part of the pharynx (Fig. 889). It is composed chiefly of muscular tissue, and is covered by mucous membrane.

Whilst the sense of taste resides chiefly in its modified epithelium, the tongue is also an important organ of speech, and, in addition, it assists in the mastication

FIG. 889.—SAGITTAL SECTION THROUGH MOUTH, TONGUE, LARYNX, PHARYNX, AND NASAL CAVITY.

The section was slightly oblique, and the posterior edge of the nasal septum has been preserved. The specimen is viewed slightly from below, hence the apparently low position of the inferior concha.

tion and deglutition of the food—functions which it is well fitted to perform, owing to its muscular structure and great mobility. In length it measures about three and a half inches (9 cms.), when at rest, but both its length and width are constantly varying with every change in the condition of the organ, an increase in length being always accompanied by a diminution in width, and *vice versa*.

In describing the tongue we distinguish the following parts: the *corpus linguæ* (body), made up chiefly of striped muscle, and forming the mass of the organ; the *dorsum linguæ* (Fig. 890), which looks towards the palate and pharynx, and is free

in its whole extent; the base, the posterior wide end which is attached to the hyoid bone; the *apex linguæ*, the pointed and free anterior extremity; the *margo lateralis*, which is free in its anterior half or more, *i.e.* in front of the attachment of the anterior palatine arch (Fig. 890). Finally, the unattached portion on the inferior aspect, seen when the apex is turned strongly upwards (Fig. 892), constitutes the *facies inferior*, or inferior surface; whilst the thick posterior portion, fixed by muscles and mucous membrane to the hyoid bone and mandible, is known as the *radix linguæ* or root.

The *dorsum* of the tongue, when the organ is at rest, is strongly arched antero-posteriorly in its whole length (Fig. 889), the greatest convexity corresponding to the attachment of the glosso-palatine arch. When removed from the body

FIG. 890.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE PALATINE TONSILS. The stylopharyngeus muscle, which is shown immediately to the medial side of the external carotid artery, and the prevertebral muscles, are not indicated by reference lines.

the tongue, unless previously hardened *in situ*, loses its natural shape, and appears as a flat, elongated oval structure, which gives a very erroneous idea of its true form and connexions.

Both in structure and in function, as well as in embryological history, the *dorsum linguæ* is divisible into two areas—an anterior or *oral part*, which lies nearly horizontally on the floor of the mouth, and constitutes about two-thirds of the length of the whole tongue (Fig. 890); and a posterior or *pharyngeal part*, the remaining third of the organ, which is placed nearly vertically, and forms the anterior wall of the oral pharynx (Fig. 889). The separation between these two parts, which differ in appearance as well as in direction, is indicated by a distinct V-shaped groove, called the *sulcus terminalis* (Fig. 890), the apex of which is

directed backwards, and corresponds to a depression on the surface of the tongue, the *foramen cæcum*, whilst its diverging limbs pass laterally and forwards towards the attachments of the glosso-palatine arch. The *foramen cæcum* is the remains of a tubular downgrowth formed early in embryonic life, in the floor of the primitive pharynx, from which the isthmus of the thyreoid gland is developed (see p. 44).

The anterior portion presents a velvety surface and is covered with innumerable papillæ; the taste-buds are situated in it, and it is horizontal in position. It is developed from the tissues of the floor of the pharynx behind the first visceral arch. The posterior portion, on the other hand, has a smooth glistening surface, contains numerous serous glands and small lymph follicles, and is more vertical in position. It is developed from the tissue covering the ventral ends of the second and third visceral arches (see p. 45).

The anterior or oral portion of the *dorsum linguæ* (Fig. 890) is convex, both from before backwards and from side to side in the resting condition of the organ (Fig. 893). It usually presents a slight median depression, *sulcus medianus*, in the form of an irregular crease, which ends posteriorly near the *foramen cæcum*. The mucous membrane of this portion of the *dorsum* is thickly covered with the prominent and numerous *papillæ linguales* which give this portion of the tongue its characteristic appearance.

On the pharyngeal part of the tongue there are also small papillary projections of the corium, but the epithelium fills up all the intervals between the papillæ, and, as it were, levels off the surface, so that none are visible to the eye as projections above the general level. Over the anterior part of the tongue, on the contrary, the projections of the corium are large and prominent, and the intervals between them, while they are covered, yet are not filled up, by the epithelium, so that the projections stand out distinctly and independently, and in places attain a height of nearly 2 mm. above the general surface.

The posterior or pharyngeal portion of the *dorsum linguæ* (Fig. 889), nearly vertical in direction, forms the greater portion of the anterior wall of the oral part of the pharynx (Fig. 890). Its surface is free from evident papillæ, but is thickly studded with rounded projections, each presenting, as a rule, a little pit, visible to the naked eye, at its centre; the great majority of these *folliculi linguales* (lingual follicles, Fig. 889), are similar to the lymph follicles found in the palatine tonsils; some few are said to be mucous glands; all are covered by a smooth mucous membrane, and they combine to give to this region a characteristic nodular appearance. To this collection of follicles the name *tonsilla lingualis* is applied.

The *mucous membrane* of this portion of the tongue is separated from the muscular substance by a submucous layer in which the lymph follicles and the mucous glands lie embedded (Fig. 893). At the sides it is continuous with the *tunica mucosa* covering the palatine tonsils and the side wall of the pharynx; whilst posteriorly it is reflected on to the front of the epiglottis, forming in the middle line a prominent fold, the *plica glosso-epiglottica mediana* (Fig. 889), at each side of which is a wide depression, the *vallecula*.

On each side is a *pharyngo-epiglottic fold*, which passes from the side of the epiglottis, upwards along the wall of the pharynx, upon which it is soon lost.

Papillæ of the Tongue (Fig. 891).—These are formed by variously shaped projections of the corium of the mucous membrane, covered by thick caps of epithelium. They are of three main varieties: 1, Conical and filiform (*papillæ conicæ, p. filiformes*); 2, Fungiform and lenticular (*papillæ fungiformes et p. lenticulares*); and 3, Vallate and foliate (*papillæ vallatæ et p. foliatæ*).

The conical and filiform papillæ (Fig. 891) are the smallest and most numerous, forming as they do a dense crop of minute projections all over the anterior two-thirds of the *dorsum*, and also upon the superior part of the margin and tip, of the tongue. Posteriorly they are arranged in divergent rows running laterally and forwards from the raphe, parallel to the limbs of the *sulcus terminalis*. More anteriorly, the rows become nearly transverse, and near the tip irregular. Each

papilla is composed of a conical projection of the corium, beset with microscopic papillæ like those of the skin, and covered by a thick long cap of stratified squamous epithelium.

In many of them the cap of epithelium is broken up into several long slender hair-like processes, giving rise to the variety known as *filiform papillæ*. The cap of epithelium is being constantly shed and renewed, and an excessive or diminished rate of shedding or renewal, coupled with the presence of various fungi, gives rise to the several varieties of "tongue" found in different diseases.

The conical papillæ are longer and larger than the filiform, and have a wider base. They are situated on the dorsum among the filiform papillæ, and resemble them in their structure.

The conical and filiform papillæ are probably of a prehensile or tactile nature, and are highly developed, and horny, in carnivora.

The fungiform and lenticular papillæ (Fig. 890) are larger and redder, but less numerous than the first variety, and they are found chiefly near the tip and margins of the tongue, comparatively few being present over the dorsum generally.

Each is in shape like a "puff-ball" fungus, consisting of an enlarged rounded head, attached by a somewhat narrower base. As in the case of the conical papillæ, the corium is studded over with microscopic papillæ, which are buried in the covering of squamous epithelium and do not appear on the surface. Most of the fungiform papillæ, if not all, appear to be furnished with taste-buds, and they are probably intimately connected with the sense of taste. The lenticular papillæ are placed on the margin of the tongue. They are flatter than the fungiform papillæ, and do not contain taste-buds.

The vallate papillæ (O.T. circumvallate) (Fig. 891), much the largest of all the papillæ of the tongue, are confined to the region immediately in front of the sulcus terminalis and foramen cæcum. Usually about nine to fourteen in number, they are arranged in the form of the letter V, with the apex posteriorly, just in front of and parallel to the sulcus terminalis. One or two of the papillæ are usually placed at the apex of the V, immediately anterior to the foramen cæcum. In appearance a vallate papilla resembles very closely the impression left by pressing the barrel of a small pen on soft wax (Fig. 891). Each is composed of a cylindrical

central part (1 to 2.5 mm. wide), slightly tapering towards its base, and flattened on its crown, which projects a little above the general surface of the tongue. This is surrounded by a deep, narrow, circular trench or *fossa*, the outer wall of which is known as the *vallum*. The *vallum* appears in the form of an encircling collar very slightly raised above the adjacent surface (Fig. 891).

As in the case of the other forms, the vallate papillæ are made up of a central mass of corium, beset with numerous microscopic papillæ on the crowns, but not on the sides, and covered over, as are the surfaces of the fossa and vallum, by stratified squamous epithelium. Into the fossæ open the ducts of some small serous glands (Fig. 891 A).

On the sides of the vallate papillæ, as well as upon the opposed surface of the vallum, are found, in considerable numbers, the structures known as *taste-buds*, the special end-organs of the nerves of taste.

Just anterior to the glosso-palatine arch, on the margin, are usually seen about five or six distinct vertical folds, forming the *folia linguæ*, which are beset with taste-buds. They correspond to the papillæ foliatæ on the side of the tongue in certain animals (rabbit, hare, etc.), in which they form an important part of the organ of taste.

The *apex* and the *margin* of the tongue in front of the attachment of the glosso-palatine arch are free, and lie in contact with the teeth when the tongue is at rest.

On the superior half or more of the margin and apex, papillæ are present as on the dorsum; but on the inferior part they are absent, and the surface is covered by smooth mucous membrane.

The *inferior surface* of the tongue, which is exposed by turning the apex of the organ upwards, is limited in extent (Fig. 892), and is free from visible papillæ, the surface being covered by a smooth mucous membrane. Running along its middle, except near the tip, is a depression, from

FIG. 892.—OPEN MOUTH WITH TONGUE RAISED, AND THE SUBLINGUAL AND ANTERIOR LINGUAL GLANDS EXPOSED.

The sublingual gland of the left side has been laid bare by removing the mucous membrane; to expose the anterior gland of the right side a thin layer of muscle, in addition to the mucous membrane, has been removed. A branch of the lingual nerve is seen running on the medial aspect of the gland. The *vena profunda linguæ* is faintly indicated on this side also.

which a fold of mucous membrane, the *frenulum linguæ*, passes down to the floor of the mouth, and on towards the posterior aspect of the mandible. At each side of the frenulum, and a short distance from it, the large *profunda linguæ* vein is distinctly seen through the mucous membrane. Further out still are situated two indistinct, fringed folds of mucous membrane, the *plicæ fimbriatæ*, which converge somewhat as they are followed forward towards the tip, near which they are lost.

From the inferior surface of the tongue the mucous membrane passes across the floor of the mouth to the medial surface of the gum, with the mucous covering of which it becomes continuous.

The *plicæ fimbriatæ* correspond pretty closely to the course of the deep lingual arteries as they

run towards the tip; the arteries, however, are deeply placed in the substance of the tongue, at a distance of 3 to 6 mm. from the inferior surface. The plicæ, which are more distinct at birth and in the fœtus, are said to correspond to the under tongue found in the lemurs.

The **root of the tongue** is the portion of the inferior aspect which is connected by muscles and mucous membrane to the mandible and hyoid bone. It is of very considerable extent, and is, with the base, the most fixed part of the organ. It is also the situation at which the vessels, nerves, and the extrinsic muscles enter.

Structure of the Tongue.—The tongue is chiefly composed of striped muscular tissue, with a considerable admixture of fine fat. A median septum of connective tissue occupies the central part of the organ. In addition, there are vessels, nerves, glands, and lymph tissue, the whole being covered over by mucous membrane, except at the root (Fig. 893).

The muscular tissue is derived partly from the terminations of the extrinsic muscles—namely, the hyoglossus, styloglossus, genioglossus, glossopalatinus, and chondroglossus; and also largely from the intrinsic muscles—namely, the longitudinalis superior, longitudinales inferiores, the transversus linguæ, and the verticalis linguæ. These are so arranged that they form a **cortical portion**, made up chiefly of longitudinal fibres—derived above from the longitudinalis superior and the hyoglossus, at the sides from

FIG. 893.—A, TRANSVERSE, AND B, LONGITUDINAL VERTICAL SECTION THROUGH THE TONGUE (Krause); C, A LYMPH FOLLICLE FROM POSTERIOR PART OF THE TONGUE. (Macalister, slightly modified.)

the styloglossus, and below from the longitudinales inferiores. This cortex surrounds a central or **medullary portion**, divided into two lateral halves by the **septum**, and formed in great part by the transverse and vertical fibres, and also by the fibres of the genioglossi ascending to the dorsum. The muscular fibres derived from these various sources end by being inserted into the deep surface of the mucous membrane.

The detailed description of the extrinsic and intrinsic muscles will be found on page 462.

The **septum** is a median fibrous partition found in the medullary portion only, and easily exposed by separating the two genioglossi on the inferior surface of the tongue. Anteriorly it usually extends to the apex; whilst posteriorly it grows gradually narrower, and expanding transversely at the same time, it passes into a broad sheet (the hyoglossal membrane) which is united to the upper border of the hyoid bone, and gives attachment to the posterior fibres of the genioglossus. From the sides of the septum the fibres of the transverse muscle of the tongue arise.

The **mucous membrane** on the anterior two-thirds of the dorsum, and on the free margins, is firm and closely adherent to the underlying muscular substance, the fibres of which are inserted into it. On the posterior third of the dorsum, and on the inferior surface, it is neither so firm nor so closely united to the muscular substance, from which it is separated in both of these situations by a layer of submucous tissue.

The mucous membrane of the tongue, like that of the rest of the mouth, is covered by stratified squamous epithelium.

Glandulæ Linguales.—Numerous small racemose glands are found scattered beneath the mucous membrane of the posterior third of the tongue; and a small collection of similar glands is present at the margin, opposite the vallate papillæ. Small serous glands are also found embedded in the dorsum near the vallate papillæ, into the fossæ of which their ducts open (Fig. 891).

The chief collections of glandular tissue in the tongue, however, are found embedded in the muscle of the under surface, a little way posterior to the apex, on each side of the middle line (Fig. 892). They are known as the *glandulæ linguales anteriores* of Blandin or Nuhn.

These glands are displayed after removing, from the under surface of the tongue, the mucous membrane and a layer of muscle fibres about 2 mm. thick which is composed of fibres of the styloglossus and the longitudinalis inferior muscles a little distance behind the apex. The anterior lingual glands are oval in shape, often partly broken up by muscular fibres, and they measure from $\frac{1}{2}$ to $\frac{3}{4}$ in. (12 to 19 mm.) in length. They are mixed serous and mucous glands, and they open by three or four very small ducts on the inferior surface of the tongue.

FIG. 894.—LYMPH VESSELS OF THE TONGUE (after Poirier and Cuneo, modified).

Vessels.—The chief *artery* is the *lingual*. This vessel passes forwards on each side medial to the hyoglossus muscle, and then is continued on to the apex—between the genioglossus on the medial side and the longitudinalis inferior laterally—under the name of the *a. profunda linguæ*. Anteriorly it is covered by the fibres of the longitudinalis inferior, and lies $\frac{1}{8}$ to $\frac{1}{4}$ in. from the surface. Near the apex the arteries of opposite sides are connected by a branch which pierces the septum; but otherwise, with the exception of capillary anastomosis, they do not communicate. The *rami dorsales linguæ* of the lingual artery are distributed to the pharyngeal part of the tongue, whilst some twigs of the *ramus tonsillaris* of the external maxillary artery are also distributed in the same region.

The *veins* are: The *v. profunda linguæ*, the chief vein, which lies beneath the mucous membrane at the side of the frenulum, and runs backwards over the hyoglossus with the hypoglossal nerve; two *venæ comites*, which accompany the lingual artery; and two *dorsalis linguæ* veins from the back of the tongue. These either unite and form a common trunk, or open separately into the internal jugular vein.

The *lymph-vessels* of the tongue take their origin in an extensive lymph network in the submucous coat, and a smaller network connected with the first, in the muscular substance of the tongue. The network at the apex, including the tip, margins, and front of the dorsum, is drained by some two to four vessels on each side, which pass downwards by the margin of the genioglossus muscle and pass outwards to the inferior deep cervical lymph glands. These vessels may be connected with the submental lymph glands also.

From the margins and dorsum of the tongue, behind the former area, and extending back to the vallate papillæ, lymph-vessels pass to the submaxillary lymph glands, and also, on the hyo-

glossus muscle, to the upper deep cervical lymph glands, especially to some glands near the bifurcation of the common carotid artery. From the posterior part of the tongue the lymph-vessels pass laterally on each side below the palatine tonsil, and thence follow the course of the tonsillar lymph-vessels to the upper deep cervical lymph glands. Some central vessels, from the median portion of the tongue, pass downwards to the submaxillary glands, and also to the upper deep cervical glands, on the lateral side of the internal jugular vein.

Nerves.—The nerves which supply the tongue are: (1) The **hypoglossal nerve**, the motor nerve of the tongue, which enters the genioglossus and passes up in its substance to the intrinsic muscles, in which it ends. (2) The **lingual nerve**, a branch of the mandibular nerve, which is accompanied by the **chorda tympani** branch of the facial nerve. The lingual, after crossing the hyoglossus, breaks up and enters the longitudinalis inferior and genioglossus muscles, and thus makes its way upwards to the mucous membrane of the anterior two-thirds of the tongue—the lingual itself conferring common sensation on this part, the chorda tympani probably carrying to it taste fibres. (3) The **glosso-pharyngeal nerve** passes forwards beneath the upper part of the hyoglossus muscle, and sends its terminal branches to the mucous membrane of the posterior third of the tongue, supplying the papillæ vallatæ, and the part of the tongue behind these, with both gustatory and common sensory fibres. (4) The **internal laryngeal nerve** also distributes a few fibres to the posterior part of the base of the tongue, near the epiglottis.

GLANDULÆ.

Numerous organs, differing widely in structure, function, and development, are commonly included under the term **glands**. It may indicate any of the following structures:—

(1) Glands producing a visible fluid or semi-fluid secretion, which is discharged from the cells of the gland, either directly or by a duct, on to a free surface, where it is useful chemically or mechanically, or by which it is drained away. Glands of this type connected with the alimentary canal are, serous and mucous glands, salivary glands, gastric and intestinal glands, the liver and pancreas.

(2) The so-called **ductless glands**, which possess no ducts, but secrete some substances, which are directly and gradually transmitted from the cells of the gland to the blood or lymph stream, and are of use in the general metabolism of the body. Such structures are the thyroid gland, the suprarenals, the parathyroids, and the hypophysis cerebri.

(3) **Cytogenic** or cell-producing glands, not always epithelial, and usually with no distinct duct, consist of aggregations of special cells, enclosed in a more or less definite framework of connective tissue, freely supplied with blood- and lymph-vessels. Glands of this type are concerned in the production, from the cells in the glands, of special cells, which are liberated from the gland tissue, and pass away from it. Such glands are lymph glands, the bone marrow, and the reproductive glands—testes and ovaries.

In structure they present wide differences.

Glands may also be classified according to their development, and on this basis the following groups are recognised:—

(1) **Glandulæ epitheliales**, developed from epithelial cells. These may (*a*) possess a duct, in which case they are termed **glandulæ evehentes**; or (*b*) they may be constituted as ductless glands, and they are then termed **glandulæ clausæ**. To this last group belong the thyroid gland, the hypophysis, and the suprarenal glands.

(2) **Glandulæ vasculares**, developed in connection with vessels, and not containing epithelial cells. This group includes all the lymph glands, the lymph nodules found in the intestine, the tonsils, the thymus, and the spleen.

In the following paragraphs only the true glands of the alimentary system—namely, the glands of epithelial origin, characterised by the possession of ducts—are considered.

Such glands may be defined as epithelial organs used for the secretion or excretion of some particular substance or substances from the body. They usually consist of a number of cells, and there may be different kinds of cells in a gland.

The simplest form of this type of gland is a portion of an epithelial surface, continuous with adjacent portions of the surface, but involution from the surface to which it originally belonged.

The simplest form in which this involution occurs is as a single pocket, of uniform size throughout, forming a simple tubular gland. Of this kind are the intestinal glands in the wall of the small intestine.

In other cases there may be a bag-like enlargement of the end of the gland, forming a sort of pocket, called an *alveolus* (alveolus, small stomach or bag), and this type of gland is known as the simple alveolar gland. It does not exist in the alimentary canal.

Sometimes the lower part or fundus of the gland does all the secretion, and the upper part forms a tube or duct that carries the secretion to the surface.

When the outgrowth forming the gland remains undivided, the gland is known as a **simple gland**. It may, on the other hand, break up into two or more branches, and it then is known as a **compound gland**, and this compound gland may be tubular, alveolar, or of a mixed tubular and alveolar form.

When the fundus of the gland at the extremities of the ducts becomes a highly differentiated saccular region, consisting of several enlargements (alveoli)

at the end of a duct, it is called an **acinus** (*ἄκινος*, a grape, or grape-stone), from the fancied resemblance it presents to a cluster of grapes at the end of a stalk. A gland formed of several such structures collected together is often called a **compound acinous** or **racemose gland** (*racemus*, a cluster).

FIG. 895.—SECTION OF A SEROUS GLAND ON THE LEFT, A MUCOUS GLAND ON THE RIGHT SIDE (Böhm and v. Davidoff.)

In the serous gland the granular secreting cells and the centrally-placed nuclei should be noted. The relatively clear cells, with the dark crescents of Gianuzzi, are distinctive in the mucous gland.

Most of the glands of the body are examples of this variety—e.g. the salivary glands, the small glands of the mouth, tongue, pharynx, oesophagus, etc.

A compound acinous (racemose) gland is composed of a main duct which branches and re-

branches more or less freely according to the size of the gland. The terminal divisions of the ducts end finally in specialised secreting parts, the acini or alveoli, quite distinguishable from the ducts or conducting parts. In typical acinous glands the acini or alveoli are distinctly saccular; in other glands, such as the pancreas, this is not the case, the acini being long and narrow. Accordingly, the term *alveolo- or acino-tubular* has been introduced and applied to glands of this latter type, which is usually made to include the pancreas, and Brunner's duodenal glands.¹

It should be added that the term acino-tubular is by some authors used exclusively instead of acinous for all racemose glands.

The foregoing may be summarised in tabular form thus :—

I. **Simple glands**.—Duct undivided.

- (a) **Simple tubular** (undilated at end)—e.g. intestinal glands and certain gastric glands.
- (b) **Simple alveolar** (dilated at end)—not met with in alimentary canal.

II. **Compound glands**.—Duct divided.

- (a) **Compound tubular**, branched elongated tubes, no acini—e.g. most gastric glands.
- (b) **Compound acinous or alveolar** (racemose glands), branched duct with saccular acini on terminal branches—e.g. salivary glands; the mucous glands of the mouth, tongue, palate, pharynx, and oesophagus.

¹ Some authorities consider the duodenal glands of Brunner to belong to the class of compound tubular glands (Heidenhain, Watney, Jonnesco, etc.).

- (c) **Acino-tubular**, branched duct, with elongated narrow acini on terminal branches—*e.g.* pancreas, Brunner's glands.

General Structure of Glands.—Whilst the small glands, such as those of the mouth and pharynx, are placed in the mucosa or submucosa close to the point at which their ducts open on the surface, the large glands forming distinct masses, often lie at a considerable distance from the points at which their ducts open, and are generally surrounded by special capsules.

Each of these large glands of the acinous type, such as the parotid or submaxillary, presents the following general arrangement. The gland is made up, as can be seen with the unaided eye, of a number of masses, often as large as peas, which are surrounded and held together by connective tissue. These are known as lobes, and to each a branch of the duct passes. The lobes are in turn made up of a number of smaller masses—lobules—each having a special branch of the lobar duct. These again are composed of smaller lobules, and so on to a varying degree. Finally, the smallest are made up of a terminal branch of the duct, with a cluster of acini or alveoli developed upon it.

The **acini or alveoli**, the special secreting portions of the gland, are composed of a basement membrane, often fenestrated or basket-like, formed of flattened cells, on the outer side of which the blood- and lymph-vessels lie. The inner surface of this membrane is lined by the secreting epithelial cells, usually polygonal in shape, which almost completely fill the alveolus. A small lumen, however, is left, into which the secretion of the cells is shed; thence it passes into the duct of the lobule, and thus to the main duct.

The blood- and lymph-vessels, on entering the gland, break up and run, branching as they go, in the connective tissue which conveys them to all parts of the gland.

GLANDULÆ SALIVALES.

Salivary Glands.—This term is generally understood to include only the three large masses of glandular tissue found on each side of the face and upper part of the neck—namely, the parotid, submaxillary, and sublingual glands. But, as previously pointed out, numerous other small glands of a similar nature are found in the lips, cheeks, palate, tongue, etc. These have already been sufficiently described, and require no further mention.

Glandula Parotis.—The **parotid gland** is the largest of the salivary glands, and lies on the side of the face, below and in front of the ear, and is prolonged inwards deeply from the surface.

It forms a lobulated mass, of a yellowish or light reddish-brown colour, with a large triangular superficial surface. From this mass a process of the gland passes medially posterior to the upper part of the ramus of the mandible below the base of the skull almost to the side wall of the pharynx. It is known as the **processus retromandibularis**.

The superficial surface extends upwards nearly to the zygoma, and downwards as far as to the angle of the mandible. It is prolonged anteriorly on the superficial surface of the masseter muscle in the form of a process, often triangular in shape, called the **facial process**, while at the back it comes into contact with the cartilaginous external acoustic meatus, the front of the sterno-mastoid muscle, and the mastoid process.

Processus Retromandibularis.—This portion of the gland occupies a deep fossa, called the parotid fossa, of considerable size, which has two nearly vertical sides, an anterior and posterior. These sides converge towards one another and meet deeply, and so form the apex of the fossa. This fact is well brought out by a horizontal section through the head about the middle of the gland (Fig. 896).

From this it will be seen that the posterior wall of the fossa is formed, medial to the sterno-mastoid muscle, by the posterior belly of the digastric and the stylohyoid muscles, with the occipital artery, and more deeply still, by the root of the styloid process and the carotid sheath and its contents, and especially by the internal jugular vein separating the gland from the vertebral column.

The anterior wall of the fossa is formed by the ramus of the mandible and the masseter and internal pterygoid muscles.

Fascia Parotideomasseterica.—The parotid recess is covered over on the one hand,

and lined on the other, by fascia. The covering layer is specially known as the **fascia parotidomasseterica** (O.T. **parotid fascia**) and both it and the lining layer are derived from the deep cervical fascia, which divides to enclose the gland. The parotideo-masseteric fascia is connected, on the surface, above to the zygoma; posteriorly, to the acoustic meatus and anterior border of the sterno-mastoid; below, it is continuous with the deep cervical fascia, and anteriorly it passes over the masseter, and blends with the fascia bucco-pharyngea. The fascia forms a lining for the recess, and is united above to the periosteum over the acoustic meatus and posterior part of the glenoid fossa; medially it is

FIG. 896.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE PALATINE TONSILS.

The stylopharyngeus, which is shown immediately to the medial side of the external carotid artery, and the prevertebral muscles, are not indicated by reference lines.

connected to the styloid process; whilst below it joins the deep cervical fascia. Taken together, the two layers form a definite capsule which completely encloses the gland. In connexion with the lower and anterior part of this capsule is developed a special flat band, the **stylo-mandibular ligament**, which passes downwards and laterally from the styloid process to the angle of the mandible. It separates the anterior part of the parotid gland from the posterior border of the internal pterygoid muscle; perhaps occasionally, also, from the upper and posterior part of the submaxillary gland.

Shape and Relations of the Parotid Gland.—The main mass of the parotid gland is three-sided (Fig. 896), the three surfaces being superficial, anterior, and posterior.

Superficial Surface.—This surface is somewhat triangular in form, and irregular in outline. Its long posterior border lies in front of the external acoustic meatus, and the sterno-mastoid muscle. Its superior border lies below the zygomatic arch, and the inferior border passes irregularly upwards and anteriorly to

join it. The apex, directed anteriorly, is formed by the facial process of the gland, and lies on the masseter muscle, and the duct of the gland issues from it, or just below it.

This superficial surface is frequently prolonged beyond the limits of the parotid fossa, and passes downwards over the digastric muscle. It may descend beyond the angle of the mandible, and come into immediate relation with the posterior part of the submaxillary gland, from which it is separated merely by a thin layer of the deep cervical fascia.

Deep Portion of the Gland.—This portion of the gland presents an anterior surface looking forwards, deeply concave, and a posterior surface, irregular in outline, directed backwards and medially.

These surfaces meet medially at the medial border, which may lie so deeply as to be in contact with the side wall of the pharynx. The lower part of the styloid

FIG. 897.—THE SALIVARY GLANDS AND THEIR DUCTS.

process in many cases lies in contact with the inferior part of this border, and in such cases the process, together with the styloglossus and stylopharyngeus muscles, separates the medial border from the pharynx. The superior and inferior borders, at the union of the anterior and posterior surfaces, are irregular in outline, and indefinite.

The relations of these two surfaces are as follows:—

The anterior surface is wrapped round the ramus of the mandible, and extends on to the muscles which cover this portion of the bone laterally and medially, that is, on to the masseter and internal pterygoid muscles respectively.

The posterior surface, in contact with the posterior wall of the fossa, is moulded upon the structures which form that wall. It is in contact, from the surface medially, with the sterno-mastoid muscle, the mastoid process, the external acoustic meatus, the posterior belly of the digastric muscle, the internal jugular vein, and the root of the styloid process and the styloid muscles. It is often deeply grooved by the posterior belly of the digastric.

The posterior surface is occasionally prolonged medially beyond the lower portion of the styloid process, towards the pharynx. In such cases, the lower part of the styloid process lies in a groove on the posterior surface of the gland, and is not in contact with its medial border as described above.

The gland frequently gives off processes which pass into the intervals between the structures bounding the fossa. Occasionally from its superior end a small

process termed the glenoid lobe is found, passing into the posterior or tympanic part of the glenoid cavity.

Another runs into the interval between the sterno-mastoid and digastric muscles; and a pharyngeal process is occasionally found running medially anterior to the styloid process towards the side of the pharynx.

A pterygoid extension, between the two pterygoid muscles, cannot properly be said to exist.

Embedded in the superficial surface there are usually found several small rounded lymph glands, which can be recognised from the gland tissue by the difference in their colour.

FIG. 893.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE PALATINE TONSILS.

The prevertebral muscles and the stylopharyngeus (which is shown just at the medial side of the external carotid artery) are not indicated by reference lines.

The facial process of the gland—often of considerable size—is a flat and somewhat triangular portion which runs forwards from the upper part of the front of the gland, and overlaps the masseter muscle to a varying extent; from its most anterior part the parotid duct emerges, and a separated portion of this process, often found lying immediately above the duct, is known as the *glandula parotis accessoria* (O.T. *socia parotidis*).

Ductus Parotideus (Stenonis).—The parotid duct (O.T. *Stenson's*) leaves the anterior border of the gland at its most prominent part (Fig. 897). It first runs forwards across the masseter, below the accessory parotid gland, and accompanied by branches of the facial nerve, and the transverse facial artery, which is commonly some distance above, though its relation is variable. Having crossed the masseter, it turns abruptly round the anterior border of this muscle and runs

inwards through the fat of the cheek, practically at right angles to the first part of its course, to reach the buccinator, which it pierces. Then passing for some distance (5 to 10 mm.) between the buccinator and the mucous membrane, it opens into the vestibule of the mouth by a very small orifice, on a variably developed papilla, opposite the crown of the second upper molar tooth.

The course of the duct, which is fairly constant, can be marked on the side of the face by drawing a line from the inferior edge of the acoustic meatus to a point midway between the ala of the nose and the red of the lip; the middle third of this line corresponds fairly accurately, on the surface, to the course pursued by the duct.

The duct measures from $1\frac{1}{2}$ to $2\frac{1}{2}$ inches (38 to 62 mm.) in length, and $\frac{1}{8}$ inch (3 to 4 mm.) in diameter. The calibre of the duct is very much greater than that of its orifice, which only admits a fine bristle, and for this reason the duct may, to some extent, be looked upon as a reservoir for the saliva, as well as a duct for its conveyance. In the child it pierces the "sucking pad" on its way to the mouth.

A number of vessels and nerves are found in intimate relation to the parotid gland.

These are: (1) The external carotid artery and its two terminal branches. This artery lies at first in a groove in the inferior and deep aspect of the gland. It then enters the gland substance and lies deeply in it, as far up as to the neck of the mandible, when it divides into its two terminal branches. The superficial temporal artery passes onwards and emerges from the superior superficial part of the gland, and the internal maxillary artery turns inwards and emerges from the deep part of the anterior surface.

The transverse facial artery is given off in the substance of the gland, and emerges from it between the zygomatic arch and the duct.

The posterior facial vein descends in the substance of the gland superficially, and divides in it into the two terminal branches which emerge from the inferior part of the gland.

The facial nerve enters the posterior surface of the gland, slightly below its middle, and runs forwards and laterally, dividing into its main branches within the gland, and lying superficially to the external carotid artery and posterior facial vein. Communicating branches from the auriculo-temporal and great auricular nerves to the facial also traverse the gland substance.

Vessels and Nerves.—The arteries which supply the gland arise from the external carotid artery, and from the branches of this artery in relation to the gland.

The veins join the posterior facial vein and its tributaries. The lymph vessels pass to both the superficial and the deep cervical glands; there are also a few small parotid lymph glands, which lie on the surface of the superior and inferior part of the parotid beneath the capsule. Some are said to be embedded in the substance of the parotid itself.

The nerves are derived (a) from the auriculo-temporal, great auricular, and facial, and (b) from the plexus caroticus externus. The fibres of the sympathetic are mainly vaso-constrictor.

The secretory fibres to the gland, arising in the brain-stem, pass out through the glossopharyngeal nerve, and pass from it through the lesser superficial petrosal nerve to the otic ganglion, and from that ganglion to the gland in the auriculo-temporal nerve.

Glandulæ Submaxillares.—The submaxillary glands are next in size to the parotid, and resemble them in their lobulation and colour. Each is placed partly in the submaxillary triangle and partly under cover of the mandible (Fig. 897).

In each gland two portions may be recognised, a somewhat superficial larger part, the body, lying in the submaxillary triangle, and a smaller deep part, the deep process, which springs from the middle of the deep surface of the body.

The superficial part, like the parotid, presents a superficial convex surface, which projects below the mandible, in the submaxillary triangle, but it frequently extends beyond the limits of that space, and overlaps the digastric muscle.

This surface looks downwards and laterally, and is covered by the deep cervical fascia and the platysma and crossed superficially by the anterior facial vein.

Deeply to this surface the *body of the gland* is wedged upwards, between the medial surface of the mandible and the mylo-hyoid and hyoglossus muscles. It thus presents two surfaces, a lateral, which is in contact with the submaxillary fossa of the mandible, and a medial, related to the mylo-hyoid, hyoglossus, the posterior belly of digastric, and stylo-hyoid muscles.

The deep process passes still further medially, around the posterior free margin of the mylo-hyoid muscle, and comes to lie between the mylo-hyoid and hyoglossus muscles.

Embedded in the substance of the gland are found a few submaxillary lymph glands, which are of importance from the connexion they have with the lymph vessels of the lip and of a portion of the tongue.

major (O.T. duct of Bartholin), is very rare, and must be considered as an exceptional condition in man, although normal in the ox, sheep, and goat. The same may also be said of ducts from the sublingual, which are described as opening into the submaxillary duct.

Vessels and Nerves.—The arteries are derived from the sublingual artery, a branch of the lingual, and from the submental, a branch of the external maxillary. The nerves come from the lingual, chorda tympani, and the external maxillary plexus, through a branch of the submaxillary ganglion which joins the lingual, and is conveyed by it to the gland. The secretory fibres run in the chorda tympani nerve, and thence through the submaxillary ganglion to the gland.

The *glandula lingualis anterior* (Blandini, Nuhni) has been described with the tongue.

Structure of the Salivary Glands (Fig. 900).—Each of the principal salivary glands consists of a number of lobules, loosely united together by connective tissue. From each of them one or more ducts emerge. Each duct when traced onwards divides into branches, which terminate in a group of saccular or tubular alveoli.

The epithelium lining the ducts is columnar in character, but becomes flattened at the junction with the alveoli.

The epithelium lining the alveoli shows different characters in different glands. In the parotid, and the small salivary glands of the vallate papillæ in which the secretion is watery or albuminous, the cells are uniform in character, and of small size. When the gland is at rest, the cells are filled with small granules, which when the secretion is poured out are transformed into the gland ferment (ptyalin). After secretion, only the deeper parts of the cells show the presence of granules. The nuclei are rounded, and lie near the centre of the cells. In the sublingual, labial, buccal, and other glands of the mouth and palate the secretion is of a mucous character and the cells are larger, and the nuclei are placed deeply. The cells appear clear and swollen unless special methods of preparation are employed. In such cases, *e.g.* when examined in serum, the cells are seen to contain large and distinct granules of mucigen which in secretion are transformed into mucus.

In the submaxillary gland and the anterior lingual gland both varieties of cells are present. In these cases, the larger, clear mucous cells line the cavity of the alveolus, and the smaller granular serous cells are arranged upon the basement membrane, deeply to the former cells, in crescentic masses, termed the crescents or demilunes of Gianuzzi. They communicate with the cavity of the alveolus by small channels between adjacent mucous cells.

After secretion, the mucous cells become smaller, and stain more deeply than when loaded with mucigen before secretion.

PHARYNX.

The **pharynx** is the expanded upper portion of the alimentary canal which lies posterior to and communicates with the mouth, the larynx, and the nasal cavities, and is continuous inferiorly with the superior end of the œsophagus or gullet (Fig. 901).

It extends from the base of the skull above to the level of the sixth cervical vertebra (Fig. 903), and the lower border of the cricoid cartilage below.

Its total length varies from 5 to 5½ inches (12·5 to 14·0 cm.).

The inferior portion alone, that is, the parts lying opposite and inferior to the opening of the mouth, is functionally a part of the alimentary canal, for the portion above the level of the soft palate is used for respiration only. It is, however, convenient to study the structure and relations of the whole of the pharynx at once.

Structurally the pharynx is a fibro-muscular bag, of conical form, wide above and narrow below. The wall of the superior part of the pharynx, in the region of the base of the skull, is firmly attached to the surrounding bony structures, especially around the orifice of the choanæ, and hence in this superior portion of the pharynx there is a permanent cavity containing air.

The lower portion gradually assumes a more tubular form, and the anterior and posterior walls approach one another, so that below the level of the opening of the larynx they are in contact with one another, and the cavity, except during the passage of food, is reduced to a slit.

Dimensions of the Pharynx.—From the fornix pharyngis, the highest part of the roof, to the superior surface of the soft palate at its junction with the hard palate, measures about 1¼ inches, or 3 cms. The vertical extent of the oral part of the pharynx is about 2¼ inches, or 6 cms., and that of the laryngeal part is about 2¾ inches, or 7 cms.

The inferior end of the pharynx is usually about 5½ to 6½ inches from the margins of the incisor tooth, in a line passing through the cavities of the mouth and of the oral and laryngeal parts of the pharynx.

The other diameters are as follows: the antero-posterior diameter (depth) of the superior

segment (nasal portion), from the posterior margin of the septum of the nose at its inferior part horizontally backwards, measures 15 to 18 mm., and that of the middle segment, from the glosso-palatine arches to the posterior wall, about 10 mm. Below this level, the anterior and posterior walls gradually approach one another, until, below the laryngeal orifice, they are in contact with one another.

The transverse width of the pharynx also varies considerably. Immediately below the base of the skull the cavity is wide, as there is on each side a deep lateral recess, and it measures 35 mm., or rather more than $1\frac{1}{4}$ inches.

Opposite the middle of the soft palate the cavity narrows, and measures transversely 25 mm., or 1 inch.

It again widens out below this level, and expands to a width of 45 mm., opposite the inferior margin of the laryngeal opening, where on each side there is a wide recess, called the piriform recess.

FIG. 901.—INTERIOR OF PHARYNX AND STRUCTURES IN RELATION TO ITS LATERAL WALLS, VIEWED FROM BEHIND.

Cavum Pharyngis.—The cavity of the pharynx is partially intersected by the soft palate, which is attached anteriorly to the hard palate, and laterally to the lateral walls of the pharynx. This sheet, sloping obliquely backwards and downwards, cuts into the cavity of the pharynx (Fig. 901), and, falling short of the posterior wall, incompletely divides it into two, namely, an upper part, *pars nasalis* (O.T. *naso-pharynx*), and a lower part or pharynx proper. This lower portion is further subdivided into the *pars oralis* (O.T. *oral pharynx*) lying behind the mouth and tongue, and the *pars laryngea* (O.T. *laryngeal pharynx*) behind the larynx.

The aperture left between the soft palate and the posterior wall of the pharynx, through which the nasal part of the pharynx communicates with the inferior divisions of the cavity, is called the *isthmus pharyngonasalis*.

The pharynx presents *seven openings* by which it communicates with

neighbouring cavities (Fig. 901). These are the two *choanæ* (O.T. posterior nares) on the anterior wall of the *pars nasalis*, and the two *tubæ auditivæ* (O.T. Eustachian tubes) on its lateral walls; the isthmus of the fauces leading into the mouth from the oral part; the orifice of the larynx on the anterior wall of the laryngeal part of the cavity; and finally, the opening of the œsophagus at its inferior end.

Pars Nasalis (O.T. **Naso-Pharynx**) (Figs. 901 and 902).—Although morphologically and developmentally this is a portion of the true pharynx, it is functionally an annexe to the respiratory portion of the nasal cavities, and both anatomically and

FIG. 902.—THE NASAL PART OF THE PHARYNX FROM THE FRONT.

A frontal section was made through the upper part of the head; this passed immediately in front of the posterior edge of the nasal septum, and extended into the mouth below. Through the choanæ, the nasal part of the pharynx is seen. The prominence of the posterior margin of the ostium pharyngeum of the auditory tube, and the lymph nodules constituting the pharyngeal tonsil, should be noted. The palatine arches and tonsils, and an unusually wide pharyngo-nasal isthmus, are also seen.

functionally it is distinctly marked off from the digestive tube. It differs from the rest of the pharynx in that its cavity remains, under all conditions, a distinct open chamber incapable of obliteration, owing to the fact that all its walls, with the single exception of the floor, are practically immovable.

The cavity of the *pars nasalis* is irregular in shape, and is enclosed by *six walls*—namely, anterior, posterior, two lateral, a floor and a roof or vault.

These walls all merge into one another, and the lines of separation between them are arbitrary. Through the *anterior wall*, which slopes upwards and backwards, open the *choanæ* (O.T. posterior nares), separated from each other by the nasal septum. The margins of the choanæ form the line of separation between the *pars nasalis* and the cavity of the nose. This separation is occasionally marked by a furrow or fold on the lateral wall, called the *naso-pharyngeal furrow*.

The *posterior wall* is nearly vertical, and may be considered to extend upwards as far as to the level of the body of the sphenoid bone, where it becomes continuous with the rounded vault forming the roof.

The *roof* lies under the body of the sphenoid, and on each side it extends downwards to the superior margin of the orifice of the auditory tube. It slopes from in front downwards and backwards to meet the posterior wall at the junction of the basilar part of the occipital and sphenoid bones immediately anterior to the pharyngeal bursa—a small median recess in the pharyngeal wall, found constantly in the child and occasionally in the adult.

The *lateral walls* are occupied by the pharyngeal opening of the auditory tube, and posterior to them, by a vertical slit-like depression leading into a recess, the recessus pharyngeus (Rosenmülleri).

The *floor* is formed by the upper surface of the soft palate.

Between the floor and the posterior wall is the aperture, the *isthmus pharyngonasalis*, through which the pars nasalis communicates with the cavity of the pharynx proper.

When the soft palate is raised, this communication becomes closed, by contact of the soft palate with the posterior wall, and the floor of the pars nasalis is complete.

A number of important structures are found in the walls of the pars nasalis.

In the posterior part of the roof, and superior part of the posterior wall, there is a considerable accumulation of lymph tissue, known as the **pharyngeal tonsil**. It is most distinct in the child, and becomes indistinct, or entirely disappears, in adult life. It extends from the body of the sphenoid down as far as to the margin of the occipital bone, and, laterally, as far as to the superior part of the lateral wall. The mucous membrane which covers it is thickened and thrown into transverse folds.

In connexion with the inferior part of the pharyngeal tonsil, there is found, constantly in the child and occasionally in the adult, a small median recess which runs upwards and backwards in the wall of the pharynx for some distance, and is known as the **bursa pharyngea** (Fig. 903). The origin and morphological significance of this pouch are not yet solved.

Enlargement of the lymph tissue here occurs frequently in children, and the swollen lymph nodules are known as adenoids. The enlargement may become so great as to fill up a great part of the cavity of the nasal part of the pharynx.

Ostium Pharyngeum Tubæ Auditivæ.—On each lateral wall is placed the pharyngeal orifice of the auditory tube (O.T. **Eustachian tube**), an opening of a somewhat triangular form, with a characteristic infundibular or funnel-like appearance (Fig. 903). It is bounded superiorly and posteriorly by a prominent rounded ridge, the **torus tubarius** (O.T. **Eustachian cushion**). This ridge is due to the projection of the cartilage, which surrounds the auditory tube superiorly and posteriorly, but is absent inferiorly and anteriorly. The prominence of the posterior margin (**labium posterius**) as contrasted with the anterior margin (**labium anterius**) of the orifice, and the direction of the tube itself, which runs posteriorly and laterally (from the pharynx to the tympanum), greatly facilitate the introduction of a Eustachian catheter.

The exact position of the orifice is of importance. It is situated on the lateral wall of the pars nasalis, a short distance (about $\frac{1}{3}$ to $\frac{1}{2}$ inch) behind the posterior end of the inferior concha, and immediately above the level of the hard palate (Figs. 902 and 903).

A slight ridge of the mucous membrane descends from the inferior end of the torus tubarius on the lateral wall of the pharynx, and gradually becomes lost. This is known as the **plica salpingopharyngea**. Another less-developed ridge, the **plica salpingopalatina**, passes from the anterior border of the ostium pharyngeum downwards and forwards to join the palate. In front of the latter lies the indistinct groove, the **naso-pharyngeal groove**, which indicates the separation of the nasal cavity from the nasal part of the pharynx.

The levator veli palatini in descending runs parallel to the tuba auditiva, and along its lower border. As it enters the palate, it produces, particularly when in a state of contraction, an elevation just below the pharyngeal orifice of the tube, known as the **torus levatorius** (Figs. 902 and 903), which in its upper portion abuts against the lower part of the orifice, and forms its base when that opening assumes its usual triangular shape.

Occasionally the ostium pharyngeum is of an oval or slit-like form, with sloping edges, but the triangular shape described above is much more commonly found.

Immediately posterior to each ostium pharyngeum is seen the **recessus pharyngeus** (O.T. lateral recess of the pharynx or fossa of Rosenmüller), a nearly vertical depression of considerable depth (Figs. 903 and 905), which runs outwards in the form of a flattened pouch or diverticulum.

FIG. 903.—SAGITTAL SECTION THROUGH MOUTH, TONGUE, LARYNX, PHARYNX, AND NASAL CAVITY.

The section is slightly oblique, and the posterior edge of the nasal septum has been preserved. The specimen is viewed slightly from below, hence, in part, the low position of the inferior concha.

The pharyngeal recesses project outwards over the superior margin of the superior constrictor, below the petrous portion of the temporal bone, and correspond in position to the sinus of Morgagni on each side (cf. description of pharyngeal wall, p. 1143). The recess has been considered to be the remains of the inner or pharyngeal portion of the second visceral cleft, the lower part of which is represented in the supra-tonsillar fossa, but more probably it is not connected with any of the visceral clefts, but makes its appearance after they have disappeared.

Pars Oral.—The oral part of the pharynx lies behind the mouth, between the soft palate above and the superior aperture of the larynx below. On its *anterior aspect* is the isthmus of the fauces, leading into the mouth. Below this the vertical pharyngeal portion of the tongue forms the anterior wall. Its *lateral wall*

(Fig. 903) presents a triangular area, *sinus tonsillaris*, bounded anteriorly by the glosso-palatine arch, posteriorly by the pharyngo-palatine arch, and below by the sides of the tongue in its pharyngeal portion. This area is occupied in the greater part of its extent by the tonsil. Above the tonsil there is a depression, the *fossa supratonsillaris* (Fig. 903), which is of considerable clinical interest.

The *arcus pharyngopalatinus* (O.T. posterior pillar of the fauces) is a prominent fold of mucous membrane, containing in its interior the pharyngopalatinus muscle. It springs from the posterior edge of the soft palate, and, passing downwards and slightly backwards, ends inferiorly on the lateral wall of the pharynx (Fig. 903). The two pharyngo-palatine arches form the lateral boundaries of the pharyngo-nasal isthmus, and the orifice can be modified in size by the contraction of the pharyngo-palatine muscles.

The *arcus glossopalatinus* is described on p. 1111.

The *isthmus pharyngonasalis* is the very oblique and somewhat triangular orifice through which the oral part communicates with the nasal part of the pharynx (Fig. 904). It differs considerably in size and shape in different individuals, being in some so small that the nasal part can be explored from the mouth only with very great difficulty; whilst in others it is of much larger dimensions (Fig. 905) and affords ample space for the rhinoscopic examination of the nasal part of the pharynx and the posterior part of the nasal cavities.

In general it may be described as triangular in shape, the sides corresponding to the pharyngo-palatine arches, and the base, which is behind, being formed by the posterior wall of the pharynx. The apex of the triangle is directed towards the soft palate, and is encroached upon, and overlapped from below by the uvula, which assists in the closure of the orifice (Fig. 902).

By the contraction of the pharyngo-palatine muscles, which are enclosed within the pharyngo-palatine arches, the sides of the isthmus can be approximated, like two curtains, and its size correspondingly diminished. When, at the same time, the uvula and soft palate are elevated, and the whole pharynx in this region is narrowed by the contraction of the superior constrictor, the aperture can be completely closed, and the oral separated from the nasal part of the pharynx, as in the acts of swallowing and vomiting.

Tonsillæ Palatinæ.—The palatine tonsils are two large, oval masses of lymph tissue which are embedded in the lateral walls of the oral part of the pharynx, between the glosso-palatine and pharyngo-palatine arches (Fig. 904). As already pointed out, there is in this region a triangular interval (the *sinus tonsillaris*). The greater part of this interval is occupied by the tonsil. In its superior part, however, above the tonsil, there is usually found a variably developed depression already referred to as the *fossa supratonsillaris*.

The tonsillar sinus is bounded anteriorly by the glosso-palatine arch, passing from the inferior surface of the soft palate to the side of the tongue. Posteriorly it is bounded by the more vertical pharyngo-palatine arch, passing from the margin of the uvula to the lateral wall of the pharynx. The inferior boundary is formed by the margin of the tongue, while the narrow apex above passes up to the side of the soft palate. The tonsil occupies the inferior part of this sinus.

FIG. 904.—OPEN MOUTH SHOWING PALATE AND PALATINE TONSILS.

It also shows the two palatine arches, and the pharyngo-nasal isthmus through which the nasal part above communicates with the oral part of the pharynx below.

From the posterior surface of the glosso-palatine arch a thin triangular fold of mucous membrane, called the *plica triangularis*, passes backwards. Its base corresponds to the glosso-palatine arch, its superior border is free, and passes downwards and backwards, frequently overlapping the tonsil. Its lower border is attached to the side of the tongue. It covers, medially, the inferior part of the tonsillar fossa.

The palatine tonsil presents very different forms in different individuals.

It may project from the fossa into the cavity of the pharynx, or it may be flat and limited to the tonsillar fossa. In some cases the *plica triangularis* is fused with the free surface of the tonsil, and the lymph tissue may in some cases be developed on the median surface of that plica.

FIG. 905.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE PALATINE TONSILS.

The stylopharyngeus, which is shown immediately to the medial side of the external carotid artery, and the prevertebral muscles, are not indicated by reference lines.

The palatine tonsils are oval in shape, with the long axes directed vertically, and each presents a medial and a lateral surface, and a superior and inferior pole, and an anterior and posterior margin.

The medial surface is prominent and free, studded with small pit-like depressions, the fossulae or crypts of the tonsil.

The lateral, or attached surface, is enclosed in a distinct fibrous capsule, connected with the pharyngo-basilar fascia, and this capsule separates the tonsil from the superior constrictor muscle of the pharynx.

The superior pole is rounded and blunt, and presents numerous fossulae. The inferior pole projects downwards towards the tongue. The anterior margin looks towards the glosso-palatine arch, and is often overlapped by the *plica triangularis*, the posterior margin is directed towards the pharyngo-palatine arch.

Relations of the Tonsil.—The lateral relations of the tonsil consist of the fibrous capsule and the superior constrictor muscle. Lateral to the pharyngeal wall lies the internal pterygoid muscle, and behind it a region filled with connective tissue, containing blood-vessels and nerves.

The nearest and most important vessel is the external maxillary artery, which, especially if tortuous, has a very close relation to the pharyngeal wall at this level.

The ascending palatine and tonsillar branches of the artery are also in close relation.

The internal carotid artery and internal jugular vein lie considerably further back ($\frac{3}{4}$ to 1 inch) and to the lateral side, and the external carotid artery is still more lateral.

The ascending pharyngeal artery is well behind the tonsil.

The size of the palatine tonsils is extremely variable, but as a rule, in early life, they measure something under 1 inch (20 to 22 mm.) from above downwards, about $\frac{3}{4}$ inch (18 to 20 mm.) antero-posteriorly, and $\frac{1}{2}$ inch (12 to 15 mm.) medio-laterally.

The arteries of the palatine tonsil are derived from the ascending palatine and tonsillar branches of the external maxillary artery, the ascending pharyngeal branch of the external carotid, and the dorsalis linguæ of the lingual. The veins pass to the tonsillar plexus, on the lateral side of the tonsil, which is an offshoot of the pharyngeal venous plexus.

Nerves.—The palatine tonsil receives a special branch from the glossopharyngeal; this unites with branches from the pharyngeal plexus to form a small **plexus tonsillaris** which supplies the organ.

The lymph vessels are extremely numerous. They begin in a plexus which surrounds each follicle, whence vessels pass to the lateral surface of the tonsil. Thence they pass through the wall of the pharynx, and pass to the deep cervical glands in the neighbourhood of the greater cornu of the hyoid bone, behind and inferior to the angle of the mandible.

Structure of the Palatine Tonsils.—Each palatine tonsil is composed of masses of small rounded lymph cells with a delicate connective tissue reticulum. These resemble in structure the folliculi linguales, *q.v.*

Upon its medial surface it is covered with epithelium, continuous with the epithelium covering the adjacent parts of the wall of the pharynx. This surface is very irregular, and on section crypts, termed fossulae tonsillares, are seen to be formed by deep infoldings of the epithelial wall. On its lateral surface, the lymph tissue is invested by a connective tissue capsule.

Pars Laryngea.—The laryngeal part of the pharyngeal cavity lies posterior to the larynx (Fig. 903). It is wide above, where it is continuous with the oral portion, and maintains a considerable width until within about an inch of its termination, where, posterior to the cricoid cartilage it narrows rapidly and passes down to join the œsophagus. Except during the passage of food, the anterior and posterior walls of this latter part are in contact, and its cavity is reduced to a mere transverse slit (Fig. 906).

The *anterior wall* of the laryngeal portion of the pharynx is formed in its whole extent by the posterior surface of the larynx, of which the following parts are seen from the pharyngeal cavity (Fig. 901):—The epiglottis above; below this the superior aperture of the larynx, bounded at the sides by the ary-epiglottic folds; lateral to these folds is seen on each side a deep recess, the **recessus piriformis** (Fig. 905). Lower down still, the posterior surfaces of the arytenoid and cricoid cartilages, covered by muscles and mucous membrane, are visible.

Its *posterior* and *lateral walls* are directly continuous with the corresponding walls of the oral portion, and present no features which require special notice.

The **recessus piriformis** (O.T. **sinus pyriformis**) is a deep depression, seen on each side between the ary-epiglottic fold and the lamina of the thyroid cartilage. When viewed from above, as in laryngoscopic examinations, it appears of a piriform shape, the wider end being directed upwards and forwards. When viewed from behind, the recess is boat-shaped and elongated in the vertical direction. Its lateral wall is formed by the thyroid cartilage and thyreo-hyoid membrane, covered with mucous membrane; its medial wall by the ary-epiglottic fold, and slightly, below, by the superior part of the cricoid cartilage.

Relations of the Pharynx.—In considering the relations of the pharynx, it is at once evident that these are very different in the superior and inferior portions.

1. Throughout its whole extent it lies anterior to the cervical region of the vertebral column, and is separated from the bodies of the vertebrae and the intervertebral fibro-cartilages by the loose areolar tissue of the prevertebral or retro-pharyngeal space, posterior to which lie the anterior longitudinal ligament of the vertebral column, the longus capitis and longus colli muscles.

2. In the neck, laterally, it is in contact with the superior part of the thyroid gland, the carotid sheath, and especially the common and external carotid arteries, and, more posteriorly, the internal carotids.

The branches arising from the inferior part of the external carotid are also in close relation to the pharyngeal wall, viz., the superior thyroid and lingual arteries in the lower part, while the external maxillary artery, as it passes under the digastric and stylo-hyoid muscles, comes into contact with the superior constrictor, and the ascending pharyngeal artery runs upwards by the side of the pharyngeal wall.

3. The relations of the cranial portion are more complex, but are of great importance. Reference to Fig. 906 will help to elucidate them. At the upper

FIG. 906.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE PALATINE TONSILS.

The stylopharyngeus, which is shown immediately to the medial side of the external carotid artery, and the prevertebral muscles, are not indicated by reference lines.

part, the wall of the pharynx is related to the internal pterygoid muscles, separated from them by the levator and tensor veli palatini muscles. As each internal pterygoid passes posteriorly and downwards to its insertion, it diverges away from the pharynx, and a triangular space is left between its medial surface and the wall of the pharynx. The styloid process, and the muscles which arise from it, project downwards into this space, and lying beside them are numerous vessels and some nerves. Thus, the styloglossus and stylopharyngeus come into contact with the lateral wall, and with the latter the glosso-pharyngeal nerve. The ascending palatine and tonsillar branches of the external maxillary artery ascend in close relation to the pharyngeal wall.

The internal carotid artery lies rather further back, with the vagus, accessory, and hypoglossal nerves.

The external carotid lies more superficially, and is here separated by a considerable interval from the pharyngeal wall.

Lastly, a process of the parotid gland may insert itself on the medial aspect of the internal pterygoid, and come into contact with the pharynx.

The pharyngeal plexus of nerves lies in contact with the lateral wall.

Structure of the Pharyngeal Wall.—The wall of the pharynx is strong and mobile; it is firmly fixed above to the base of the skull, but below that level it is not attached firmly to any surrounding structures, except to the hyoid bone and the skeleton of the larynx, and hence the inferior end can easily be displaced from side to side in the neck.

The wall is composed of a strong fibrous membrane, called the **fascia pharyngo-basilaris** (O.T. **pharyngeal aponeurosis**), lined internally by mucous membrane, and covered incompletely on its outer surface by a series of three overlapping muscles, the constrictor muscles of the pharynx.

These muscles are themselves covered externally by a thin layer of fibrous tissue or fascia, which passes anteriorly, at its superior part, on to the surface of the buccinator muscle, and is called the **fascia buccopharyngea**.

Externally to this fascia the wall of the pharynx is in contact with loose cellular tissue by which it is connected to and separated from adjacent structures.

With the wall of the pharynx are associated several accessory muscles, viz., the muscles of the soft palate and the stylopharyngeus and pharyngo-palatine muscles, which blend with the wall but are also attached to the larynx (see p. 466).

The fibrous aponeurosis which forms the principal constituent of the pharyngeal wall is firmly attached (round the margins of the openings into the pharynx) to other structures as follows:—

Above, it blends with the periosteum covering the basilar portion of the occipital bone in front of the pharyngeal tubercle, and body of the sphenoid bone, and on each side it extends out to the angular spine of the sphenoid and the apex of the petrous part of the temporal bone.

Laterally it is attached to the structures which lie on each side of the orifices of the nose, mouth, and larynx. As it descends it gradually becomes thinner, and is eventually lost.

The fascia pharyngo-basilaris is particularly strong in the superior part, where there is an area on each side which is not covered by the superior constrictor muscle. This area forms the sinus of Morgagni, and here the tuba auditiva and tensor and levator veli palatini muscles pass through the wall.

Mucous Membrane of the Pharynx.—The superficial layer of the mucous membrane of the pharynx consists, in the lower part, of a stratified squamous epithelium, while in the upper or nasal portion it is in part composed of ciliated epithelium. In the superior part of the pharynx and in the lateral wall, there are found large masses of lymph tissue, constituting the pharyngeal tonsil in the roof, and the palatine tonsil on each side. The same tissue is found in considerable amount in the pharyngeal recess and on the pharyngeal portion of the dorsum of the tongue.

There are also numerous racemose glands, of the mucous type, in the walls of the pars nasalis, and in the soft palate, and in the ary-epiglottic folds.

Pharyngeal Muscles.—For the details of the attachment and relations of these muscles, see pp. 464-467.

Externally to the pharyngeal muscles lies the fascia buccopharyngea.

The fascia pharyngobasilaris, which is thick above and thin below, and the fascia buccopharyngea, which is thin above and stouter below, are practically blended into one layer above, near the base of the skull, where the muscular coat is absent. Lower down they are separated by the constrictors, and become two distinct sheets. They are strengthened in the median plane posteriorly by a fibrous band descending from the pharyngeal tubercle.

Vessels and Nerves of the Pharynx.—The arteries of the pharynx are derived from—1, the ascending pharyngeal; 2, the ascending palatine branch of the external maxillary; 3, the descending palatine from the internal maxillary, with a few twigs from the dorsalis lingue, tonsillar (of external maxillary), the artery of the pharyngeal canal, and the pterygo-palatine branch of the internal maxillary. The veins go to the pharyngeal venous plexus, which is found between the constrictors and the fascia pharyngobasilaris. The plexus communicates with the pterygoid plexus above and with the internal jugular or common facial vein below.

The lymph vessels of the pharynx pass chiefly to the superior set of deep cervical glands.

2. In the neck, laterally, it is in contact with the superior part of the thyroid gland, the carotid sheath, and especially the common and external carotid arteries, and, more posteriorly, the internal carotids.

The branches arising from the inferior part of the external carotid are also in close relation to the pharyngeal wall, viz., the superior thyroid and lingual arteries in the lower part, while the external maxillary artery, as it passes under the digastric and stylo-hyoid muscles, comes into contact with the superior constrictor, and the ascending pharyngeal artery runs upwards by the side of the pharyngeal wall.

3. The relations of the cranial portion are more complex, but are of great importance. Reference to Fig. 906 will help to elucidate them. At the upper

FIG. 906.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE PALATINE TONSILS.

The stylopharyngeus, which is shown immediately to the medial side of the external carotid artery, and the prevertebral muscles, are not indicated by reference lines.

part, the wall of the pharynx is related to the internal pterygoid muscles, separated from them by the levator and tensor veli palatini muscles. As each internal pterygoid passes posteriorly and downwards to its insertion, it diverges away from the pharynx, and a triangular space is left between its medial surface and the wall of the pharynx. The styloid process, and the muscles which arise from it, project downwards into this space, and lying beside them are numerous vessels and some nerves. Thus, the styloglossus and stylopharyngeus come into contact with the lateral wall, and with the latter the glosso-pharyngeal nerve. The ascending palatine and tonsillar branches of the external maxillary artery ascend in close relation to the pharyngeal wall.

The internal carotid artery lies rather further back, with the vagus, accessory, and hypoglossal nerves.

The external carotid lies more superficially, and is here separated by a considerable interval from the pharyngeal wall.

Lastly, a process of the parotid gland may insert itself on the medial aspect of the internal pterygoid, and come into contact with the pharynx.

The pharyngeal plexus of nerves lies in contact with the lateral wall.

Structure of the Pharyngeal Wall.—The wall of the pharynx is strong and mobile; it is firmly fixed above to the base of the skull, but below that level it is not attached firmly to any surrounding structures, except to the hyoid bone and the skeleton of the larynx, and hence the inferior end can easily be displaced from side to side in the neck.

The wall is composed of a strong fibrous membrane, called the **fascia pharyngo-basilaris** (O.T. **pharyngeal aponeurosis**), lined internally by mucous membrane, and covered incompletely on its outer surface by a series of three overlapping muscles, the constrictor muscles of the pharynx.

These muscles are themselves covered externally by a thin layer of fibrous tissue or fascia, which passes anteriorly, at its superior part, on to the surface of the buccinator muscle, and is called the **fascia buccopharyngea**.

Externally to this fascia the wall of the pharynx is in contact with loose cellular tissue by which it is connected to and separated from adjacent structures.

With the wall of the pharynx are associated several accessory muscles, viz., the muscles of the soft palate and the stylopharyngeus and pharyngo-palatine muscles, which blend with the wall but are also attached to the larynx (see p. 466).

The fibrous aponeurosis which forms the principal constituent of the pharyngeal wall is firmly attached (round the margins of the openings into the pharynx) to other structures as follows:—

Above, it blends with the periosteum covering the basilar portion of the occipital bone in front of the pharyngeal tubercle, and body of the sphenoid bone, and on each side it extends out to the angular spine of the sphenoid and the apex of the petrous part of the temporal bone.

Laterally it is attached to the structures which lie on each side of the orifices of the nose, mouth, and larynx. As it descends it gradually becomes thinner, and is eventually lost.

The fascia pharyngo-basilaris is particularly strong in the superior part, where there is an area on each side which is not covered by the superior constrictor muscle. This area forms the sinus of Morgagni, and here the tuba auditiva and tensor and levator veli palatini muscles pass through the wall.

Mucous Membrane of the Pharynx.—The superficial layer of the mucous membrane of the pharynx consists, in the lower part, of a stratified squamous epithelium, while in the upper or nasal portion it is in part composed of ciliated epithelium. In the superior part of the pharynx and in the lateral wall, there are found large masses of lymph tissue, constituting the pharyngeal tonsil in the roof, and the palatine tonsil on each side. The same tissue is found in considerable amount in the pharyngeal recess and on the pharyngeal portion of the dorsum of the tongue.

There are also numerous racemose glands, of the mucous type, in the walls of the pars nasalis, and in the soft palate, and in the ary-epiglottic folds.

Pharyngeal Muscles.—For the details of the attachment and relations of these muscles, see pp. 464-467.

Externally to the pharyngeal muscles lies the fascia buccopharyngea.

The fascia pharyngobasilaris, which is thick above and thin below, and the fascia buccopharyngea, which is thin above and stouter below, are practically blended into one layer above, near the base of the skull, where the muscular coat is absent. Lower down they are separated by the constrictors, and become two distinct sheets. They are strengthened in the median plane posteriorly by a fibrous band descending from the pharyngeal tubercle.

Vessels and Nerves of the Pharynx.—The arteries of the pharynx are derived from—1, the ascending pharyngeal; 2, the ascending palatine branch of the external maxillary; 3, the descending palatine from the internal maxillary, with a few twigs from the dorsalis linguae, tonsillar (of external maxillary), the artery of the pharyngeal canal, and the pterygo-palatine branch of the internal maxillary. The veins go to the pharyngeal venous plexus, which is found between the constrictors and the fascia pharyngobasilaris. The plexus communicates with the pterygoid plexus above and with the internal jugular or common facial vein below.

The lymph vessels of the pharynx pass chiefly to the superior set of deep cervical glands.

Those from the superior part of the posterior wall join a few post-pharyngeal glands which are found on each side between the pharynx and the rectus capitis anterior muscle. These latter glands, which are large in the child, small in the adult, but apparently always present (Fig. 906), are of considerable clinical interest, as they often form the starting-point of post-pharyngeal abscess. For fuller details see section on Lymph Glands.

The nerves of the pharynx, both motor and sensory, are derived chiefly from the pharyngeal plexus, which is formed by branches of the vagus, glosso-pharyngeal, and sympathetic. The soft palate and the neighbourhood of the palatine tonsil are supplied by the palatine branches of the sphenopalatine ganglion. The tonsil receives a branch from the glosso-pharyngeal direct. The vault of the pharynx, and the region around the orifice of the tuba auditiva, as well as the orifice itself, are supplied by the sphenopalatine ganglion. Finally, the internal laryngeal nerve supplies the mucous membrane of the back of the larynx, where it forms the anterior wall of the laryngeal portion of the pharynx.

ŒSOPHAGUS.

The **œsophagus** or **gullet** is the portion of the digestive canal which intervenes between the pharynx above and the stomach below. With the exception of the pylorus, it is the narrowest, and at the same time one of the most muscular parts of the whole alimentary tube.

It extends from the termination of the pharynx, at the inferior border of the cricoid cartilage and opposite the sixth cervical vertebra, to the cardiac orifice of the stomach, opposite the eleventh thoracic vertebra. Between these two points it traverses the inferior part of the neck, the whole length of the thorax, and, having pierced the diaphragm, it enters the abdomen, and immediately afterwards joins the stomach. In this course it does not adhere to the median plane of the body, but twice leaves it, and curves to the left. The first of these curvatures corresponds to the inferior part of the neck and the superior part of the thorax, where the œsophagus projects beyond the left margin of the trachea to the extent of $\frac{1}{6}$ or $\frac{1}{4}$ inch (4 to 6 mm.). It returns to the median plane at the level of the fourth thoracic vertebra posterior to the aortic arch. Lower down, posterior to the pericardium, it again passes to the left, and at the same time anteriorly, in order to reach the œsophageal opening in the diaphragm (which is placed anterior to and to the left of the aortic opening), and it maintains this direction until the stomach is reached. It leaves the median plane at the seventh thoracic vertebra, crosses anterior to the aorta at the level of the eighth thoracic vertebra, and traverses the diaphragm at the level of the tenth.

FIG. 907.—DIAGRAM TO SHOW THE COURSE OF THE ŒSOPHAGUS.

the form of the vertebral column upon which it, in great part, lies.

In *length* it usually measures about ten inches (25 cm.).

Its *breadth*, where the tube is widest, varies between half an inch (13 mm.) in the empty contracted condition and an inch or more (25 to 30 mm.) in the fully distended state.

When seen in sections of the frozen body (Fig. 908), the œsophagus usually appears either as a flattened tube with a transverse slit-like cavity, or as an oval or rounded canal with a more or less stellate lumen. The former condition is more common in the neck, owing to the pressure of the trachea, and the latter in the thorax.

When exposed in the ordinary post-mortem examination soon after death, it has rather the appearance of a solid muscular rod or band than of a hollow tube.

The œsophagus presents three distinct *constrictions*, one situated at its beginning, another at the point where it is crossed by the left bronchus, and the third where it passes through the diaphragm. The two upper constrictions are of the same size, and will admit without injury an instrument with a maximum diameter of $\frac{4}{5}$ inch (20 mm.). At each of these points the tube is flattened from before backwards.

The œsophagus varies in length in different individuals, from 8 to 14 inches (20 to 35 cm.). The distance from the upper incisors to the beginning of the œsophagus averages about 6 inches (15 cm.).

During life the cervical portion is said, under ordinary circumstances, to be closed and flattened from before backwards by outside pressure, whilst the thoracic portion may be open owing to the negative pressure in the thorax. The passage into the stomach is also said to be open (Mickulicz), but this is doubtful.

The size at the two constrictions, when the tube is fully distended, is 23 mm. transversely, and 17 mm. antero-posteriorly. The other parts vary in diameter between 26 and 30 mm. (Jonnescio).

In its first curvature to the left the divergence is greatest opposite the third thoracic vertebra. The second inclination to this side begins about the seventh thoracic vertebra, and continues to the end of the œsophagus, being considerably increased as the diaphragm is approached.

Relations of the Œsophagus.—The relations (Fig. 908) differ so widely in the neck and thorax that they must be described separately for each of these regions.

In the Neck.—Anteriorly lies the trachea—to the posterior membranous wall of which the œsophagus is loosely connected by areolar tissue—and in the groove at each side, between the trachea and œsophagus, the recurrent nerve ascends to the larynx (Fig. 908, A). Posteriorly lie the vertebral column and the longus colli muscles, from which the œsophagus is separated by the prevertebral layer of the cervical fascia. Laterally are placed the carotid sheaths with their contained vessels, and the lateral lobes of the thyroid gland and the inferior thyroid arteries. Owing

Fig. A is at level of the superior part 1st thoracic vertebra, and shows the chief relations of the œsophagus in the neck and also its divergence to the left.

Fig. B, at the 3rd thoracic vertebra, shows the thoracic duct lying on left side of the œsophagus.

In Fig. C, at the level of the 5th thoracic vertebra, the left bronchus is seen in relation to the anterior surface of the œsophagus.

Fig. D is at the level of the 8th thoracic vertebra, and shows the pericardium lying on the anterior surface of the œsophagus.

Fig. E, at the 9th thoracic vertebra, shows the œsophagus inclining to the left just before piercing the diaphragm.

FIG. 908.—TRACINGS FROM FROZEN SECTIONS TO SHOW THE RELATIONS OF THE ŒSOPHAGUS at the levels of the 1st, 3rd, 5th, 8th, and 9th thoracic vertebra, respectively.

A, Aorta; C, Common carotid artery; D, Diaphragm; L.B., Left bronchus; L.C., Left subclavian artery; L.R., Left recurrent nerve; L.V., Left vagus; O.E., Œsophagus; P, Pleura; Pc, Pericardium; R.B., Right bronchus; R.R., Right recurrent nerve; R.V., Right vagus; T, Trachea; T.D., Thoracic duct; V.A., Vena azygos.

to the deviation of the tube to the left in the inferior part of the neck, its relation to the carotid sheath and thyroid gland is much more intimate on the left than on the right side.

In the Thorax.—The œsophagus passes successively through the superior and posterior mediastina, in the former lying close to the vertebral column, but in the latter advancing somewhat into the thoracic cavity and coming into contact with the back of the pericardium. The trachea still lies anteriorly as far as its bifurcation at the level of the fifth thoracic vertebra. Immediately below this the œsophagus is crossed by the left bronchus (Fig. 908, C), and in the rest of its thoracic course it lies in the closest relation to the back of the pericardium. Posteriorly, in the upper part of the thorax, it rests on the longus colli muscle and the vertebral column; but below the bifurcation of the trachea, as already explained, it advances into the cavity of the posterior mediastinum, and is soon separated from the vertebral column by the vena azygos, the thoracic duct, the upper six aortic intercostal arteries of the right side, and in its lower part by the thoracic aorta as well.

On its *left side*, in the upper part of the thorax, lie the left pleura and the left subclavian artery, with the thoracic duct in a plane posterior to the artery; in the middle region, the aorta, and lower down the left pleura again, for a little way, before the œsophagus pierces the diaphragm. On the *right side* the tube comes into relation with the arch of the vena azygos, whilst the right pleura clothes it both below and above that level.

The two vagus nerves, after forming the anterior and posterior pulmonary plexuses descend to the œsophagus, where they form, by uniting with one another and with the branches of the sympathetic, the anterior and posterior **œsophageal plexuses**. Lower down the left nerve winds round to the anterior, whilst the right turns to the posterior surface of the œsophagus, and in this relation they pass with the tube through the diaphragm to reach the stomach.

The **diaphragmatic portion**, about half an inch in length (1 to 1·5 cm.), corresponds to the portion of the tube which lies in the œsophageal orifice (or canal) of the diaphragm. The plane of this orifice is very oblique or almost vertical, and its abdominal opening looks forwards and to the left, and but little downwards. Above and in front, where it is bounded either by the posterior edge of the central tendon or by a few decussating fibres of the muscular portion of the diaphragm, which meet behind the tendon, the œsophageal orifice has practically no length, and consequently the œsophagus here passes into the abdominal cavity immediately after leaving the thorax. At the sides and behind, on the other hand, the decussating bands from the two crura, which embrace the orifice, are so arranged that they turn a flat surface (not an edge) towards the opening, and thus, posteriorly and laterally, the orifice or canal is of some length; and on these aspects there is a portion of the tube in contact with the diaphragm for a distance of 1 to 1½ cm. But this contact takes place not around a horizontal line, but in a very oblique plane corresponding to that of the orifice.

The œsophagus, in passing through the orifice, is connected to its boundaries by a considerable amount of strong connective tissue, but it is extremely difficult, or impossible, to demonstrate any direct naked-eye connexion between the œsophageal muscular fibres and those of the diaphragm.

The anterior or right boundary of the œsophageal orifice, formed of fibres derived from both crura of the diaphragm, is strongly developed and prominent, and usually lies in the œsophageal groove, on the back of the left lobe of the liver, which groove is rarely due to the pressure of the œsophagus alone.

The **pars abdominalis** of the œsophagus is very short, for immediately after piercing the diaphragm the tube expands into the stomach. However, when the empty stomach is drawn forcibly downwards, a portion of the front and left side of the tube, about half an inch in length (1 to 1·5 cm.), is seen, to which the above term is applied. This part is covered with peritoneum, derived from the great sac in front and on the left, whilst its right and posterior surfaces are uncovered. It is generally described as lying against the œsophageal groove and the left triangular ligament of the liver in front, but it never actually comes in contact with the latter of these structures, which is attached to the upper surface of the left lobe of the liver by one edge, and to the diaphragm, over an inch in front of the œsophagus, by the other. As regards the former, the œsophageal groove of the liver is generally occupied by the prominent right margin of the œsophageal orifice of the diaphragm and occasionally by the œsophagus as well. Possibly this margin is so strongly developed and so prominent in order that it may bear the pressure of the liver off the gullet, which otherwise might be interfered with in its dilatation during the passage of food.

When the stomach is fully distended the abdominal part of the œsophagus almost disappears, being absorbed into the stomach in its distension.

The portion of the œsophagus which adjoins the stomach is sometimes described as consisting of two parts, namely, the ampulla phrenica and the antrum cardiacum. The former is a

fusiform expansion of the tube, of variable length and girth, which lies within the thorax immediately above the point where the gullet is grasped between the two muscular margins of the œsophageal opening and the diaphragm. It lies in the lowest part of the posterior mediastinum where this is bounded anteriorly by the back of the diaphragm.

The antrum cardiacum is another name for the abdominal portion of the œsophagus. It is funnel-shaped, and expands towards the stomach.

Relation of the Aorta to the Œsophagus.—The arch of the aorta, passing back to reach the vertebral column, crosses to the left side of the œsophagus; consequently the descending thoracic aorta lies at first to its left; lower down, however, as the aorta passes on to the anterior aspect of the vertebral column, and the gullet inclines forwards and to the left, the aorta comes to lie posteriorly, and then, as the diaphragm is approached, it lies not only posteriorly, but also somewhat to the right of the œsophagus (Figs. 907 and 908).

Relation of the Thoracic Duct to the Œsophagus.—The thoracic duct, lying to the right of the aorta below, is not directly related to the œsophagus (Fig. 908, E); but higher up (Fig. 908, D and E) it lies posterior to it. About the level of the aortic arch the duct passes to the left, and above this (Fig. 908, B and A) will be found on the left side of the œsophagus, and on a plane somewhat posterior to it.

Relation of the Pleural Sacs to the Œsophagus.—Above the level of the arches of the aorta and of the vena azygos, between which the œsophagus descends, the pleuræ, though not lying in immediate contact with the œsophagus, are separated from it only by a little connective tissue, and on the left side also, behind the subclavian artery, by the thoracic duct (Fig. 908, B). Here, in thin bodies, the left pleura is very close to the œsophagus, and the thoracic duct, lying on its left side, may occasionally be seen through the pleural membrane. Below the arch of the azygos vein the right pleura clothes the right side of the œsophagus—and very often even a considerable portion of its posterior surface too, thus forming a deep recess behind it—almost as low down as the opening in the diaphragm. On the left side, below the level of the aortic arch, the left pleura comes in contact with the gullet, only for a short distance, just above the diaphragm (Fig. 908, E).

Variations.—The chief anomalies found in the œsophagus are: (1) Annular or tubular constrictions; (2) diverticula, of which the most interesting—known as “pressure pouches”—are usually situated on the posterior wall close to its junction with the pharynx, and these sometimes require surgical interference; (3) doubling in part of its course; and (4) communications between the trachea and œsophagus.

Structure of the Œsophagus (Fig. 911).—The œsophageal wall is composed of three proper coats—(1) *tunica muscularis*, (2) *tela submucosa*, and (3) *tunica mucosa*. In addition, it is surrounded by an outer covering of areolar tissue (4) *tunica adventitia*, by which it is loosely connected to the various structures related to it in its course. This loose covering permits of its free movement and of its increase in size, or of its diminution, during the act of swallowing.

The *tunica muscularis* is composed of two layers—an outer of longitudinal, and an inner of circular fibres. The *longitudinal layer* is highly developed, and, unlike the condition usually found in the digestive tube, it is as stout as, or in places stouter than, the circular layer. Its fibres form along the greater length of the tube an even covering outside the circular layer, and below they are continued into the longitudinal fibres of the stomach. Above, near the superior end of the œsophagus, the longitudinal fibres of each side, separating at the back, pass round towards the anterior aspect and form two longitudinal bands (Fig. 909), which run up on the front of the tube, and are attached by a tendinous band to the superior part of the posterior surface of the cricoid cartilage (Fig. 909).

The *circular muscular fibres*, though not forming such a thick layer as the longitudinal fibres, are nevertheless well developed. Below, they are continued into both the circular and oblique fibres of the stomach. Above, they pass into the inferior fibres of the inferior constrictor of the pharynx.

The muscular fibres are entirely of the striated variety at the superior end of the œsophagus. Soon unstriated fibres begin to appear, increasing in number as we descend. In the inferior half or two-thirds, only unstriated muscle is found.

The longitudinal fibres for about the superior fifth of the tube are entirely striped; in the second fifth striped and unstriated are mixed; whilst in the inferior three-fifths unstriated fibres alone are present. The circular fibres are entirely striated for the first inch; after this unstriated fibres appear; and in the inferior two-thirds, only unstriated muscle fibres are found.

The longitudinal fibres are often joined by slips of unstriated muscle, or elastic fibres, which spring from various sources, including the left pleura (*m. pleuro-œsophageus*) (constant, Cunningham), the bronchi (*m. broncho-œsophageus*), back of trachea, pericardium, aorta, etc. These slips assist in fixing the œsophagus to the surrounding structures in its passage through the thorax, and have been aptly compared to the tendrils of a climbing plant (Treitz).

The *tela submucosa*, composed of areolar tissue, is of very considerable thickness, in

order to allow of the expansion of the tube during swallowing. It connects the mucous

FIG. 909. — DISSECTION to show the arrangement of the muscular fibres on the posterior aspect of the oesophagus and pharynx. Traced upwards, the longitudinal muscular fibres of the oesophagus are seen to separate posteriorly; passing round to the sides, they form two longitudinal bands which meet anteriorly and are united to the cricoid cartilage, as shown in the next figure.

FIG. 910. — THE INFERIOR PART OF THE PHARYNX AND THE SUPERIOR PART OF THE OESOPHAGUS have been slit up from behind, and the mucous membrane removed to show the muscular fibres. The two longitudinal bands are seen passing round to the front to be attached by a common tendon to the superior border of the cricoid cartilage. See explanation of last figure.

membrane loosely to the muscular coat, and admits of the former being thrown into folds

FIG. 911. — TRANSVERSE SECTION OF WALL OF HUMAN OESOPHAGUS.

when empty. In this coat are contained the numerous racemose mucous glands (glandulae oesophageae) which open into the cavity of the oesophagus (Fig. 911).

The **tunica mucosa** is of a grayish-pink colour, much paler than that of the pharynx, and of a firm and resistant texture. It is covered with a thick stratified, squamous epithelium, on the surface of which the openings of numerous glands are found. Below, its junction with the gastric mucous membrane is indicated by a distinct, irregularly dentated or crenated line, which runs transversely round the tube. In carefully pre-

served specimens the smooth mucous membrane of the oesophagus above this line contrasts strongly with the mammillated gastric mucous membrane below.

Owing to the inelasticity of this coat, and the fact that it is but loosely connected to

the muscular coat by the submucosa, it is thrown into a series of longitudinal folds when the œsophagus is empty and contracted; hence the stellate lumen often seen in sections of the gullet.

Glands.—Numerous racemose mucous glands, the *glandulæ œsophageæ*, large enough to be distinctly seen with the naked eye, are found in the submucosa. They are pretty evenly distributed over the whole tube, and do not appear to be more numerous towards either end. In addition to these, other glands, resembling closely those of the cardiac end of the stomach, are found in the mucous membrane of certain portions of the œsophagus. They are entirely confined to the mucosa, and do not extend beyond the lamina muscularis mucosæ. These glands are specially numerous at both the upper and lower ends of the tube.

Vessels and Nerves.—Its arteries consist of numerous small branches derived, in the neck, from the inferior thyroid, in the thorax, from the bronchial arteries and thoracic aorta, and in the abdomen, from the left gastric artery, and also from the left inferior phrenic.

The veins form a plexus on the exterior of the œsophagus, from which branches pass, in the lower part of the tube, to the coronary vein of the stomach, and, higher up, to the azygos, and thyroid veins. There is thus established on the lower part of the œsophagus a free communication between the portal and systemic veins.

The lymph vessels pass to the inferior set of deep cervical glands in the neck, and to the posterior mediastinal glands, many of which, of large size, are seen around the tube, in the thorax.

The nerves are derived from the recurrent, and from the cervical sympathetic in the neck, from the vagus and sympathetic nerves in the thorax.

THE ABDOMINAL CAVITY.

As the remaining parts of the digestive system lie within the abdomen it will be necessary to describe that cavity, and to refer briefly to its lining membrane—the peritoneum—before passing on to the consideration of the viscera which are contained within it.

The **abdomen** is that portion of the trunk which lies below the diaphragm. It consists of a wall, composed in part of bones, muscles, tendons, fascia, etc., enclosing a large cavity, in which lie the greater part of the digestive, urinary, and generative systems of organs, as well as blood-vessels, nerves, and other structures. The greater part of the wall, and the surfaces of the viscera, are clothed by a continuous smooth membrane, the peritoneum. The cavity is completely filled by these organs. They lie in contact with one another, and when the organs are *in situ* the so-called cavity is merely a potential space between the peritoneal surfaces of adjacent viscera. When air is admitted, as, for instance, by opening the abdominal wall in any place, the viscera fall away from one another and a space is formed, in place of the capillary interval which exists under normal conditions between them.

In the following description, the term **abdomen** or **abdominal cavity** is used to indicate the region enclosed by the muscular and bony walls, and the term **peritoneal cavity** the potential space inside the peritoneal membrane between the viscera.

Shape.—In general shape the cavity is of a somewhat oval form, with the long axis directed vertically. The superior end is wider than the inferior. It is strongly flattened from before backwards, and is encroached upon in the median plane posteriorly by the projection forwards of the vertebral column.

On transverse section, it will be noticed that the front of the vertebral column lies at no great distance from the back of the anterior abdominal wall (usually $2\frac{1}{2}$ to 3 inches), while on each side of the vertebral column there is a deep recess, occupied by the kidneys and portions of the intestine.

The abdominal cavity is divisible into the abdominal cavity proper and the pelvis minor. Vertical section of the trunk shows that the **pelvis minor** (O.T. true pelvis) lies below and behind the abdominal cavity, and forms a funnel-shaped termination for it, whose long axis is directed downwards and backwards.

As the walls of these two regions are markedly different, the boundaries will be considered separately.

Boundaries of the Abdomen Proper.—The cavity is limited *above* by the concave vault of the diaphragm, which is dome-shaped and presents a right and a left cupola

separated by an intervening depression. Into the right cupola fits the greater part of the liver; in the left lie a part of the stomach and spleen. On the superior surface of each cupola is placed the base of the corresponding lung, whilst between them, on the depression, rests the inferior surface of the heart.

During expiration, the right cupola ascends almost to the level of the right nipple; it is highest at a point about one inch medial to the nipple line, and here it reaches the superior border of the fifth rib, or even the middle of the fourth intercostal space. On the left side it is one-half to one inch (12-25 mm.) lower, and in the median plane it crosses the inferior extremity of the body of the sternum about the level of the sixth rib cartilage.

FIG. 912.—THE COURSE OF THE LARGE INTESTINE. The jejunum and ileum have been removed.

Below, the cavity is continued into the cavity of the pelvis minor.

The *anterior wall* is formed by the aponeuroses of the three flat abdominal muscles, obliquus externus, obliquus internus, and transversus abdominis, together with the two recti, which latter constitute powerful braces for the wall, on each side of the median plane.

Anteriorly, below the junction of abdomen and pelvis, lies the pubic symphysis. The body of the pubis looks upwards as well as posteriorly, and appears to form a support or floor for the viscera contained within the anterior part of the abdominal cavity.

The *lateral walls* are formed by the muscular portions of the obliqui and transversi muscles, and below by the iliac bones and the iliacus muscles.

Finally, the cavity is limited *posteriorly* by the lumbar portion of the vertebral column with the crus of the diaphragm and psoas major muscle on each side, and the quadratus lumborum still more laterally. The iliac bones also enter into the formation of the inferior portion of the posterior wall.

The superior portion of the cavity lies under cover of the ribs, which afford considerable protection to this part of the abdomen, particularly laterally and

posteriorly, in which latter position the cavity is further protected by the vertebral column. Anteriorly, on the other hand, the ribs are wanting below the sternum, and here the abdominal wall is formed only of aponeuroses and muscles. But even at the sides and back there is a considerable zone, usually one to two inches wide, between the lower ribs above and the crest of the ilium below, which has no bony support except that afforded by the vertebral column.

Whilst the circumference of the diaphragm is attached to the inferior part of the thoracic framework anteriorly and laterally, and to the lumbar vertebræ posteriorly, the central portion of the dome, on the other hand, namely, the central tendon, is placed high up, under cover of the ribs, and in a more or less horizontal plane. As a result, the peripheral muscular part slopes upwards and medially from the circumference of the thoracic framework to the central tendon, and lies for a considerable distance in contact with the deep surface of the ribs; thus the diaphragm comes to form, not only the roof of the cavity, but it also enters into the formation of the lateral, posterior, and, to a less extent, of the anterior walls; and *almost as much of the cavity of the abdomen as of the thorax lies under shelter of the ribs.*

Owing to the fact that the boundaries of the abdomen are formed chiefly of muscles, it follows that its walls are capable of contraction to a very considerable extent, and the size of the cavity can consequently be altered in all directions. Its chief changes in form are due to the descent or elevation of the diaphragm, the contraction or relaxation of the anterior and lateral walls, and the raising or lowering of the pelvic floor.

The superior aperture of the pelvis (Figs. 234 and 235, p. 236), which separates the two natural divisions of the cavity, is formed behind by the base of the sacrum, at the sides by the linea terminalis of each hip bone, and in front by the pubic crests and the symphysis pubis. In the erect position it usually makes an angle of about 55 to 60 degrees with the horizontal. The two portions of the abdominal cavity which the superior aperture separates meet at an angle, the abdomen proper running almost vertically upwards from it, whilst the pelvic cavity slopes backwards and slightly inferiorly.

The pelvic cavity is bounded in front and at the sides by the portions of the hip bones below the level of the linea terminalis. These bony walls are partly clothed, in front and laterally, by the obturator internus muscles, and internal to these by the parietal portion of the pelvic fascia, as low down as the arcus tendineus. The posterior wall is formed by the front of the sacrum, covered on each side by the piriformis muscle. This wall (as represented by the piriformes muscles) meets the lateral wall at the anterior border of the greater sciatic foramen; through this foramen the piriformis passes out, thus closing up what would otherwise be a large aperture in the parietes of the cavity. The floor is composed of the two pairs of muscles which form the pelvic diaphragm, namely, the levatores ani and coccygei—covered by the visceral layer of the endopelvic fascia. These muscles pass on each side, from the lateral wall of the pelvis, downwards and medially towards the median plane, and present a concave superior surface towards the pelvic cavity.

Within the muscles forming its walls, the abdomen is lined by an envelope of fascia, which separates the muscles from the extraperitoneal connective tissue and peritoneum. This aponeurotic layer is distinguished in different localities as:—(1) the *fascia transversalis* on the anterior and lateral walls, lining the deep surface of the transversalis muscle and continuous above with the fascia clothing the inferior surface of the diaphragm; (2) the *fascia iliaca* on the posterior wall, covering the psoas and iliacus muscles; (3) the *fascia diaphragmatica*, covering the inferior surface of the diaphragm; and (4) the *fascia endopelvina*, lining the pelvis.

Apertures.—Certain apertures are found in the walls of the abdomen, some of which lead to a weakening of the parietes. These are: the three openings in the diaphragm for the passage of the inferior vena cava, the œsophagus, and the aorta respectively; the apertures in the pelvic floor, through which the rectum, the urethra, and the vagina in the female, reach the surface; the inguinal canal, through which the spermatic funiculus (or round ligament) passes, in leaving the abdominal cavity; and lastly, the femoral canal, a small passage which runs down from the abdomen along the medial side of the femoral vessels. The two latter

particularly constitute on each side weak points in the abdominal wall, through which a piece of intestine occasionally makes its way, giving rise to inguinal or femoral hernia respectively. Similar protrusions may also occur at other points in the abdominal wall, and also through apertures in the pelvic wall.

Tela Subserosa (O.T. **Extraperitoneal or Subperitoneal Connective Tissue**).—Between the fascia which covers the deep surfaces of the abdominal muscles, and the peritoneum which lines the cavity, there is found a considerable quantity of connective tissue, generally more or less loaded with fat, which is known as the tela subserosa. This is part of an extensive fascial system which lines the whole of the body cavity, outside its various serous sacs, and is continued on the several vessels, nerves, and other structures which pass from the trunk into the limbs and neck.

In the abdomen it is divisible into a parietal and a visceral portion, both composed of loose connective tissue. The former lines the cavity, whilst the latter passes forwards between the layers of the mesenteries and other peritoneal folds to the viscera. These two portions of the extraperitoneal tissue are perfectly continuous with one another, and contain in their whole extent a vascular plexus, through which a communication is established between the vessels of the abdominal wall, on the one hand, and those of the contained viscera on the other.

The *parietal portion* is thin and comparatively free from fat over the roof and anterior wall of the abdomen, and here the peritoneum is more firmly attached than where the tissue is fatty and large in amount. In the pelvis, on the other hand, the tissue is loose and fatty, and, as such, it is continued up for some inches on the anterior abdominal wall above the pubes, to permit of the ascent of the bladder during its distension, in the interval between the peritoneum and the anterior abdominal wall. Here also the urachus and the obliterated umbilical arteries will be found passing up in its substance. On the posterior wall the tissue is large in amount and fatty, particularly where it surrounds the great vessels and the kidneys.

From this parietal portion the *visceral expansions* are derived, in the form of prolongations around the various branches of the aorta. These expansions are connected with the areolar coats of the blood-vessels and are conducted by them into the mesenteries and other folds of the peritoneum, and thus reach the viscera.

The chief uses of this tissue are: (1) to unite the peritoneum to the fascial and muscular layers of the abdominal wall; (2) to connect the viscera to these walls and to one another in such a loose manner that their distension or relaxation may not be interfered with. This would not be the case if the connecting medium were firm or rigid; (3) in addition, it is a storehouse of fat, forms sheaths for the vessels and nerves, and establishes, through its vascular plexus, communication between the parietal vessels and those distributed to the abdominal viscera.

Subdivision of the Abdomen Proper.—Owing to the large size of the cavity, and in order to localise more correctly the position of the various organs contained within it, the abdomen proper is artificially subdivided by two horizontal and two sagittal planes (Fig. 913).

Of the two *horizontal planes*, one divides the trunk at the level of the lower border of the tenth costal cartilage; this is known as the *subcostal plane*, and the line where it intersects the abdominal wall is the *subcostal line*. The second horizontal plane is at the level of the highest point of each iliac crest which is visible from the front; this point corresponds to the tubercle seen on the lateral lip of the crest, about two inches posterior to the superior anterior spine, and can be easily located; the line and plane are consequently known as the *intertubercular line and plane* respectively.

The *sagittal planes* are drawn, one on each side, perpendicularly upwards from a point on the *inguinal ligament* midway between the superior anterior spine and the symphysis pubis. These planes and the corresponding lines are known as the *lateral planes and lines* respectively.

By the two horizontal planes the abdomen is divided into *three zones*, a superior or *costal*, a middle or *umbilical*, and an inferior or *hypogastric zone*. By the two

perpendicular planes each of these is subdivided into three parts, a central and two lateral. Thus, in the upper zone, we get a **hypochondriac region** or **hypochondrium** on each side, and an **epigastric region** or **epigastrium** in the centre. Similarly, the umbilical zone is divided into **right** and **left lumbar regions**, with an **umbilical region** between. And the hypogastric zone has a **hypogastric region** or **hypogastrium** in the centre, with **right** and **left iliac regions** at the sides.

In addition, the portion of the abdominal wall above the body of the pubis is known as the *suprapubic region*, and that immediately above the inguinal ligaments as the *inguinal region*.

The three central divisions, namely, the epigastric, umbilical, and hypogastric

FIG. 913.—PLANES OF SUBDIVISION OF THE ABDOMINAL CAVITY, AND OUTLINE TRACING OF THE LIVER, STOMACH, AND INTESTINE IN RELATION TO THE ANTERIOR ABDOMINAL WALL.

The oblique position of the stomach and the high position of the transverse colon are largely due to the fact that the subject was in the horizontal position.

regions, can conveniently be further subdivided by the median sagittal plane, passing through the middle of the body, into right and left halves.

The superior horizontal, or subcostal, plane passes posteriorly, through the superior part of the third lumbar vertebra, or the fibro-cartilage between the second and third lumbar vertebræ. The intertubercular plane cuts through the middle or superior part of the fifth lumbar vertebra.

The inferior margin of the tenth costal cartilage frequently corresponds to the most dependent part of the thoracic framework. Often, however, the eleventh costal cartilage descends $\frac{1}{4}$ to $\frac{1}{2}$ inch lower. Nevertheless, the tenth cartilage is selected in drawing the subcostal plane, for two chief reasons, namely, it is visible from the front as a rule, and it is comparatively fixed, whilst the eleventh, being a floating rib, is much more movable, is variable in length, and more difficult to locate.

Another plane which is of some practical value is the *transpyloric plane* (Addison). This is a horizontal plane which is taken to intersect the trunk at the level of the first lumbar vertebra. That level is ascertained during life by taking the mid-point of a line drawn on the surface of the trunk from the superior border

of the sternum to the crest of the pubis. The same level is obtained usually, but not so accurately, by taking the mid-point of a line drawn from the xiphi-sternal articulation to the umbilicus.

Contents of the Abdomen.—The following structures are found within the abdominal and pelvic cavity:—

1. The greater part of the *alimentary canal*, viz., stomach, small intestine, and large intestine.
2. *Digestive glands*: the liver and pancreas.
3. *Ductless glands*: the spleen and the two supra-renal glands.
4. *Urinary apparatus*: the kidneys, ureters, bladder, and part of urethra.
5. The internal *generative organs* according to the sex.
6. *Blood and lymph vessels*, and *lymph glands*.
7. The abdominal portion of the cerebro-spinal and sympathetic *nervous systems*.
8. Certain *fœtal remains*.
9. The *peritoneum*—the serous membrane which lines the cavity, and is reflected over most of its contained viscera.

PERITONÆUM.

The arrangement of the peritoneum is so complicated, and its relations to the abdominal contents so intricate and detailed, that it will be expedient to postpone its complete description until the various organs, with their special peritoneal relations, have been separately considered. Nevertheless, it will be necessary to give here a general account of the disposition of the membrane, and to refer to some of the folds which it forms in passing from organ to organ, or from these to the abdominal wall.

The **peritoneum** is the serous membrane which lines the abdominal cavity and invests most of the abdominal viscera, to a greater or less degree. Like the pleuræ, pericardium, and other serous sacs, its walls are composed of a thin layer of fibrous tissue, containing numerous elastic fibres, covered over on the side turned towards the cavity of the sac by a layer of flattened endothelial cells forming the *tunica serosa*. Like them, too, the peritoneum in the male is a completely closed bag, but in the female this is not the case, for the ostium abdominale of each uterine tube opens into the sac, whilst the ostium uterinum of that tube communicates with the interior of the uterus, and thus, indirectly, with the exterior of the body. Normally the mem-

FIG. 914.—DIAGRAMMATIC MEDIAN SECTION OF FEMALE BODY, to show the peritoneum on vertical tracing. The great sac of the peritoneum is black and is represented as being much larger than in nature; the bursa omentalis is very darkly shaded: the peritoneum on section is shown as a white line; and a white arrow is passed through the foramen epiploicum from the great sac into the bursa omentalis.

brane secretes only sufficient moisture to lubricate its surface, otherwise the sac is perfectly empty, and its opposing walls lie in contact, thus practically obliterating its cavity.

The use of these lubricated and highly polished serous linings, found in the

abdomen and certain other cavities, is to facilitate the movements of the contained viscera during any changes in size or form which they or their containing cavity may undergo. As a result of this arrangement, notwithstanding the tonic pressure of the abdominal wall on its contents, the stomach and intestines are free to move with the greatest ease and the least degree of friction, when any change takes place either in the organs themselves or in their surroundings.

The peritoneum is a thin glistening membrane, which may aptly be compared to a coat of varnish applied to the inner aspect of the abdominal walls, and to the surface of the contained viscera, except where these are directly applied to the walls or to one another. It forms throughout its entire extent a continuous and distinct sheet, but it is united so intimately to the viscera, and follows the irregularities of their walls so closely, that it appears at first sight to be a superficial layer of these walls, rather than a separate membrane. Outside the peritoneum lies the tela subserosa—already described—by which the peritoneum is connected more or less intimately to the fascial lining of the abdominal walls and to the abdominal viscera.

The portion of peritoneum which lines the walls of the cavity is known as the **peritoneum parietale** and that which clothes the viscera as the **peritoneum viscerale**.

If we trace the peritoneum, beginning in front, we find that it lines the deep surface of the anterior abdominal wall, and is continued upwards to the inferior surface of the diaphragm (Fig. 914), the greater portion of which it covers. From the posterior part of the diaphragm it is reflected or carried forwards on to the superior surface of the liver. From the liver it can be traced over the stomach, intestines, and other abdominal viscera to the pelvis. In like manner, when traced laterally from the anterior wall, the membrane will be found to line the sides of the cavity, and passing backwards to clothe the posterior abdominal wall, and the

FIG. 915.—DIAGRAMMATIC TRANSVERSE SECTIONS OF ABDOMEN, to show the peritoneum in transverse tracing. A, at level of foramen epiploicum; B, lower down. In A note, one of the short gastric arteries passing to the stomach between the layers of the gastro-lienal ligament, and also the foramen epiploicum leading into the bursa omentalis which lies behind the stomach.

viscera lying upon it (Fig. 914). It should be pointed out that all the abdominal viscera are either directly fixed by connective tissue to the posterior abdominal wall, or connected by blood-vessels with it. In the former case the peritoneum is reflected directly from the wall on to the viscera; in the latter it runs along the blood-vessels to reach the viscera, which it clothes, and then returns to the wall on the opposite sides of the vessels, which it thus encloses in a fold.

Whilst the greater part of the general peritoneal cavity lies anterior to the various abdominal viscera, covering them over and dipping down between them, it should be mentioned that there is a special diverticulum derived from it, situated mainly behind the stomach, and covering its posterior surface; this is known as the *bursa omentalis* (O.T. *small sac*), and it will be described in detail later on. The aperture through which one sac communicates with the other is termed the *foramen epiploicum* (Winslow) (O.T. *foramen of Winslow*).

In passing from organ to organ, or from these to the abdominal wall, the peritoneum forms numerous folds, the principal ones being as follows:—

(1) **Omentum Majus.**—The *greater omentum* hangs down like an apron from the transverse colon, in front of the coils of the jejunum and ileum. It consists embryologically of four layers of peritoneum, two anterior and two posterior, which are usually, in the adult, adherent to one another. The four layers form a thin, translucent, and often perforated membrane. The two anterior layers were originally connected with the stomach above, and passed down in front of the transverse colon, but as development proceeds they become adherent to the anterior surface of the transverse colon. The fold which extends from the stomach to the colon is termed the gastro-colic ligament. If the two anterior layers be separated from the two posterior and from the front of the transverse colon, a cavity is formed, continuous with the *bursa omentalis*, and the anterior layers of the great omentum are directly continuous with the layers of the gastro-colic ligament. This condition is that usually described in English text-books as the normal adult condition and is represented in Fig. 914, where the gastro-colic ligament is separated from the transverse colon, and passes in front of the transverse colon directly into the anterior layers of the omentum majus, and the great omentum thus descends from the stomach above.

(2) **Omentum Minus.**—The *lesser omentum* is a fold passing from the inferior surface of the liver to adjacent organs. It consists of two, or occasionally three, portions:—

(a) The *ligamentum hepatogastricum*, a wide peritoneal fold, extending from the left end of the porta hepatis, the fossa of the ductus venosus, and partly also from the concave surface of the left lobe of the liver and the caudate process, to the lesser curvature of the stomach, where it is continued into the peritoneal coats of the anterior and posterior surfaces of that organ.

(b) The *ligamentum hepatoduodenale* passes from the porta hepatis to the pars superior of the duodenum. On the left this fold is continuous with the hepatogastric ligament, on the right it ends in a rounded margin. Traced downwards, the layers of peritoneum which form it clothe the commencement of the duodenum on two sides, and are continued into the transverse mesocolon, and into the duodeno-renal ligament.

(c) The *ligamentum hepatocolicum* is an occasional fold passing from the region of the gall-bladder to the transverse colon and right colic flexure.

(3) **Ligamentum Gastrospleniale.**—The *gastro-splenic ligament* (O.T. *gastro-splenic omentum*) is a double layer of peritoneum extending between the fundus of the stomach and the hilus of the spleen, and continuous below with the gastro-colic ligament.

(4) The *ligamentum gastrocolicum* extends from the greater curvature of the stomach to the transverse colon. It consists of two layers of peritoneum, continuous above with the layers on the anterior and posterior surfaces of the stomach, and below with the anterior layers of the great omentum.

In English text-books this is not usually recognised as a separate ligament, but is considered to be a portion of the great omentum, and to pass downwards in front of the transverse colon. It will be found, however, that the arrangement in the adult is usually that described above.

Mesenteries are folds of peritoneum which unite portions of the intestine to the posterior abdominal wall, and convey to them their vessels and nerves. There are several mesenteries, *e.g.* the *mesenterium* (*mesentery proper*), which connects the jejunum and ileum to the posterior abdominal wall, the *mesocolon transversum* (*transverse mesocolon*), the *mesocolon pelvinum* (*pelvic mesocolon*), and occasionally others.

Other folds, specially named, but described elsewhere, are the ligaments of the liver, the so-called "false ligaments" of the bladder, the lieno-renal ligament, and the broad ligament of the uterus.

VENTRICULUS.

The **stomach** is the large dilatation found on the digestive tube immediately after it enters the abdomen (Figs. 916 and 920). It constitutes a receptacle in which the food accumulates after its passage through the œsophagus, and in it take place some of the earlier processes of digestion, resulting in the conversion of the food into a viscid soup-like mixture, known as chyme. The chyme as it is formed is allowed to escape intermittently through the pylorus, into the small intestine, where the digestive processes are continued.

The form and the position of the stomach present great variations, not only among different individuals, but also in the same individual at different times. The degree to which it is filled, the size and position of adjacent organs, the condition of the abdominal walls, and even the assumption of the erect or the recumbent attitude can influence its shape and relations.

Of recent years, examination of the stomach by X-rays has afforded information, otherwise unattainable, of the shape and position of the stomach in life, and of the changes which it undergoes. The results obtained by this method have modified considerably current conceptions regarding the stomach in the living. A necessary preliminary to the proper comprehension of these appearances is a careful study of the stomach as it presents itself to anatomical examination.

General Shape and Position.—In shape, the stomach may be described as an irregularly piriform or conical organ, with a wide end directed upwards and backwards, lying deeply in the hollow of the diaphragm, mainly in the left hypochondriac region, and a narrow tapering extremity which passes downwards and forwards, and is bent over to the right side, in the epigastric region.

The long axis of the organ forms a spiral curve, directed downwards, anteriorly and to the right, and finally backwards.

The superior end, or fundus, is almost always dome-shaped, and is distended with gas, and its wall is thinner and more flaccid than that of the lower portion, which is thicker and somewhat cylindrical in shape.

The walls of the stomach are composed of an inner thick layer of mucous membrane (*tunica mucosa*), supported by submucous tissue (*tela submucosa*), a muscular coat, consisting of three layers, more or less complete, of muscle fibres (*tunica muscularis*), running in different directions, covered externally by a serous, peritoneal investment (*tunica serosa*). The special characters of each of these walls will be described later.

The stomach presents the following parts for examination :—

Two surfaces, an anterior (**paries anterior**) directed at the same time forwards and to the left, and a posterior (**paries posterior**) which looks posteriorly and also to the right. These surfaces meet above and to the right at the lesser curvature, **curvatura minor**, and below at the greater curvature, **curvatura major**. At the superior end of the lesser curvature the œsophagus enters the stomach, at the œsophageal opening, while at the inferior the stomach passes into the duodenum at the pylorus. The dome-shaped portion to the left of the œsophagus is the **fundus**, while the remainder of the stomach is divisible into the body, **corpus ventriculi**, and the pyloric portion, **pars pylorica**.

The œsophageal opening is termed the **cardia**, and the portion of the stomach adjacent to it the **pars cardiaca**, while the inferior orifice is termed the **pylorus**, and the portion of the stomach adjacent to it is the **pars pylorica**, a dilated portion of

FIG. 916.—THREE VIEWS OF A STOMACH FIXED BY FORMALIN INJECTION *IN SITU*.

A. From the front.

B. From the back.

C. From above.

The orientation of the stomach was determined by inserting long pins into it in the sagittal, frontal, and transverse planes. These views show the comparatively horizontal position of the stomach associated with the horizontal posture of the trunk. They also show the partial division into chambers produced by temporary constrictions of the stomach wall fixed by the action of formalin.

which forms the **antrum pyloricum**.

Cardia.—The opening is situated at the superior end of the lesser curvature, on the right side of the fundus, and more on the anterior than the posterior surface of the stomach.

Around this opening the muscular walls of the **æso-phagus** and the mucous membrane become continuous with corresponding coats of the stomach wall. The longitudinal muscular coat passes onwards into a longitudinal set of fibres, and the circular **æso-phageal** fibres pass into the circular muscular coat. The whitish-coloured stratified squamous epithelium of the **æso-phagus** is continuous with the pinkish-coloured columnar epithelial wall of the stomach, and the junction is marked by a sharp irregular line running round the margin of the opening.

The orifice itself is oval or angular rather than round, being compressed from side to side.

To the right of the orifice, the right margin of the **æso-phagus**

merges with a slight curve into the lesser curvature of the stomach, while on the left side there is a deep notch, the *incisura cardiaca*, between the inferior end of the œsophagus and the fundus, in which lies a strong projecting ridge of the right crus of the diaphragm.

This notch on the outer surface produces a fold in the interior of the stomach, which may assist in closing the œsophageal opening, and this, with the decussating fibres of the diaphragm, and the strengthened circular fibres of the inferior end of the œsophagus, forms a kind of sphincter for this orifice which serves to prevent regurgitation from the stomach under ordinary condition.

The cardia is very deeply placed, and lies about four inches behind the sternal end of the seventh left costal cartilage, at a point one inch from its junction with the sternum. Posteriorly it corresponds to the level of the eleventh thoracic vertebra.

Owing to the fixation of the œsophagus by its passage through the diaphragm, and the close connexion between the stomach and the diaphragm, near the cardia where the peritoneum is absent, this is the most fixed part of the whole organ. The object of this immobility is evidently to maintain a clear passage for the food entering the stomach.

Pylorus.—The pyloric orifice or pylorus is the aperture by which the stomach communicates with the duodenum. It is placed at the extremity of the pyloric end of the stomach, and its position is indicated upon the surface of the stomach by a slight annular constriction which is most marked at the curvatures.

Its position is also indicated by an arrangement of blood-vessels at the pyloric ring, which is nearly constant. On the peritoneal surface a thick vein passes upwards from the lower side somewhat more than half-way on the anterior surface, and from the upper border a second vein reaches downwards in the same line, nearly, if not quite, meeting the first (W. J. Mayo).

The pyloric constriction marks the junction of stomach and duodenum, and here the various coats of these portions meet with one another. The peritoneal covering of the stomach is continued onwards on to the first part of the duodenum.

The muscular fibres have here a special arrangement, which is due to the presence of a mechanism for arresting the escape of food from the stomach before it has undergone digestion. The longitudinal fibres of the stomach (*stratum longitudinale*) are in part continued onwards into the longitudinal fibres of the duodenal coat, but many of them bend inwards into the thickened ring around the opening, where they spread out in diverging bundles, which interlace with the most superficial of the circular fibres, and some of them reach and terminate in the subjacent submucosa.

The circular muscular fibres of the stomach (*stratum circulare*) are not continuous directly with those of the duodenum. On the contrary, at the orifice they become very much increased in number, and they form a thick ring, or sphincter, which is separated from the circular muscular coat of the duodenum by a fibrous septum.

The length of this sphincteric ring is not easily estimated, for while it is sharply marked off from the duodenum there is no sharp line of demarcation on the gastric side. There the ring gradually merges into the circular muscular coat of the cylindrical pyloric canal.

When this canal is contracted, its wall is nearly as thick as the sphincteric ring.

The gastric mucous membrane (*tunica muscosa*) is continued into the mucous membrane of the duodenum at the distal margin of the sphincter. The junction cannot be recognised by superficial inspection. The gastric mucosa is considerably thickened where it covers the sphincter muscle. When examined post-mortem in the ordinary way, the aperture, viewed from the duodenal side, is somewhat oval in form. When seen from the opposite side, it presents an irregular or stellate appearance, owing to the fact that the rugæ of the gastric mucous membrane are continued up to the orifice.

The orifice is directed horizontally backwards, and to the right. When the stomach is full, however, it looks almost directly backwards, or even slightly to the left side.

The pylorus rests on the neck of the pancreas below and posteriorly, and is overlapped by the liver above and anteriorly. When the stomach is empty the pylorus is usually placed near (*i.e.* within $\frac{1}{2}$ inch, 12 mm. of) the median plane, below the left lobe or sometimes the quadrate lobe of the liver, and at the level of the first lumbar vertebra, or the fibro-cartilage between this and the second lumbar. During distention it is pushed over beneath the quadrate lobe for a variable distance, but very rarely more than $1\frac{1}{2}$ or 2 inches to the right of the median plane. Its average position can be marked on the surface of the body by the intersection of two lines; one drawn horizontally half-way between the top of the sternum and the pubic crest (Addison), the other drawn vertically a little way ($\frac{1}{2}$ inch, 12 mm.) to the right of the median plane.

During the earlier stages of gastric digestion the sphincter pylori is strongly contracted and the aperture firmly closed, but it opens intermittently to allow of the passage of properly digested portions of the food. As digestion advances the sphincter probably relaxes somewhat; but in hardened bodies a really patent pylorus is rarely or never found, which would seem to

FIG. 917.—LONGITUDINAL SECTION THROUGH THE PYLORIC CANAL AND COMMENCEMENT OF THE DUODENUM IN A NEW-BORN CHILD. (From Stiles.)

indicate that the pylorus is normally closed, or nearly so, and that its opening is an active rather than a passive condition, as in the case of the anal canal.

As regards its size, the pylorus is stated to be about $\frac{1}{2}$ inch (12.5 mm.) in diameter, but there is no doubt that this represents neither its full size nor its calibre when at rest. Foreign bodies with a diameter of $\frac{3}{4}$ to 1 inch have been known to pass through the pylorus without giving rise to trouble, even in children. On the other hand, when at rest, with an empty stomach and duodenum, the aperture is practically closed.

Curvatura Ventriculi Minor.—The lesser curvature is directed towards the liver, and corresponds to the line along which a double fold of peritoneum called the hepato-gastric ligament is attached to the stomach, between the pyloric and œsophageal orifices (Fig. 916). This fold connects the stomach and liver, and between its two layers the gastric vessels run along the curvature of the stomach.

While this border is on the whole concave, it consists of two portions which meet and form a sharp angle, called the *incisura angularis*, situated nearer the pyloric than the cardiac end, though its position varies with the condition of the stomach. The superior or left portion is nearly vertical, and continues the direction of the right margin of the œsophagus, while the inferior, distal, or right portion is more nearly horizontal, when viewed from the front. The depth and acuteness of the angle between these two segments varies with the degree of distension of the stomach. When the pyloric portion of the stomach is full, the distal portion of the lesser

curvature becomes distended, and this portion of the border becomes convex in outline.

The lesser curvature does not form a straight line along the surface of the stomach, for at the left end it turns forwards somewhat on to the anterior surface of the stomach, to the place where the cardiac orifice is situated. In length, the lesser curvature measures some 3 to 4 inches.

Curvatura Ventriculi Major.—The greater curvature of the stomach is usually over three times as long as the lesser curvature, and corresponds to a line drawn from the cardia over the summit of the fundus (Fig. 916), and then along the most projecting portion of the stomach as far as the pylorus. In general, it is directed to the left and forwards, but at its beginning, near the cardia, it of course looks in a different direction. The great curvature corresponds in the greater part of its length to the attachment of the gastro-splenic and gastro-colic ligaments, folds of peritoneum passing to the spleen and to the transverse colon respectively; and in close relation to it, between their layers, run the right and left gastro-epiploic vessels.

This border of the stomach, like the lesser curvature, does not present a uniformly curved outline. Towards the pylorus a notch is often found, called the *sulcus intermedius*. The portion to the right of this sulcus is known as the *pyloric canal*.

On the left side of this notch, the greater curvature bulges forwards, forming a chamber called the *antrum pylori*, and the projecting rounded prominence which it forms is, in some phases of digestion, marked off from the rest of the body of the stomach by a temporary indentation. Other indentations which are sometimes found on the greater curvature, or the body of the stomach, are probably due to temporary peristaltic waves of contraction.

Paries Anterior.—The anterior surface of the stomach is more convex and more extensive than the posterior. It lies, when the organ is distended, in contact with the inferior surface of the left lobe of the liver medially, the vault of the diaphragm laterally, and the anterior abdominal wall below (Fig. 916). When the stomach is empty, on the other hand, the transverse colon doubles up anteriorly to it, and separates this surface from the liver and diaphragm and abdominal wall.

Paries Posterior.—The posterior surface looks downwards and posteriorly. It is more flattened than the anterior, and is moulded by the structures upon which it rests.

Thus, to the left is a flattened area, passing on to the fundus, which is in contact with the diaphragm and the spleen. To the right of the fundus, the posterior surface is divisible into two horizontal areas, a superior and an inferior, separated by a slight ridge. The superior portion, nearly vertical, lies in contact with the left kidney and supra-renal gland and diaphragm, and the inferior portion, more horizontal, is in contact with the pancreas, transverse mesocolon, and transverse

FIG. 918.—ABDOMEN OF FEMALE, SHOWING DISPLACEMENTS RESULTING FROM TIGHT LACING.

The liver is much enlarged, and extends on the left side to the ribs, where it was folded back on itself for over an inch. The pyloric end of the stomach and the beginning of the duodenum are quite superficial below the liver, and all the viscera are displaced downwards. (From a photograph of a body hardened by injections of formalin.)

colon. These structures constitute the posterior wall of the bursa omentalis of the peritoneal cavity.

Between the two surfaces, the wall comes into contact with the splenic artery as it runs along the superior border of the pancreas.

The different portions into which the stomach may be divided are as follows:—

FIG. 919.—THE VISCERA AND VESSELS ON THE POSTERIOR ABDOMINAL WALL.

The stomach, liver, and most of the intestines have been removed. The peritoneum has been preserved on the right kidney, and also the fossa for the caudate lobe. In taking out the liver, the vena cava was left behind. The stomach bed is well shown. (From a body hardened by chromic acid injections.)

Fundus Ventriculi.—The fundus is that portion of the stomach which lies above a horizontal plane drawn through the oesophageal opening. It is rounded or dome-shaped. This shape seldom alters, whatever the condition of the stomach may be. It is usually filled with gas.

Corpus Ventriculi.—The body of the stomach extends from the fundus to

the incisura angularis on the lesser curvature, and to the notch on the greater curvature already described. It forms a rounded chamber, capable of great distension, but when the stomach is empty it contracts to a narrow tube-like structure. As the stomach is seldom completely empty, the body usually tapers from the fundus to the proximal end of the pyloric portion.

Pars Pylorica.—The pyloric portion of the stomach extends from the incisura angularis in the lesser curvature, and a variable and inconstant notch on the greater curvature, as far as to the pyloric orifice.

It differs from the body of the stomach in being more tubular in shape, and possessing thicker walls.

It has been divided anatomically into two portions, the pyloric canal and the antrum pyloricum respectively.

The pyloric canal is a short more or less tubular portion rather more than an inch in length, extending from the sulcus intermedius on the greater curvature to the pyloric constriction. The proximal portion, called the pyloric antrum,

FIG. 920.—TRANSVERSE SECTION OF THE TRUNK AT THE LEVEL OF THE FIRST LUMBAR VERTEBRÆ. Showing relations of stomach, pancreas, kidneys, etc. From a subject ten years old.

is more expanded. It is not clearly demarcated from the body of the stomach by any constant line of division on the greater curvature. On the lesser curvature it extends from the incisura angularis to the pyloric canal, and it is occasionally pouched outwards on the side of the greater curvature so as to form a chamber or pouch, the “camera princeps” of His.

RELATIONS AND CONNEXIONS OF THE STOMACH.

When the stomach has been removed, after the body has been hardened, a chamber or recess is exposed, known as the stomach chamber. It is (Figs. 920 and 921) a space in the upper and left portion of the abdominal cavity which is completely occupied by the stomach when that organ is distended, but into which the transverse colon also passes, doubling up in front of the stomach, when it is empty.

The chamber presents an arched roof, an irregularly sloping floor, and an anterior wall. The roof is formed partly by the visceral surface of the left lobe of the liver, and in the rest of

its extent by the left cupola of the diaphragm, which arches gradually downwards behind and on the left to meet the floor.

The floor or "*stomach bed*" (Fig. 921) is a sloping shelf on which the posterior surface of the stomach rests, and by which it is supported. The bed is formed posteriorly by the superior pole of the left kidney (with the supra-renal gland) and the gastric surface of the spleen; anterior to this, by the wide anterior surface of the pancreas; and more anteriorly still, by the transverse mesocolon running forwards above the small intestine, from the anterior edge of the pancreas to the transverse colon (Fig. 921), which completes the floor anteriorly.

Finally, the *anterior wall* of the stomach chamber is formed by the abdominal wall, between the ribs on the left and the liver on the right side.

This chamber is completely filled by the stomach, when that organ is distended. When, on the other hand, the stomach is empty and contracted, it still rests on the floor, or stomach bed, but occupies only the inferior portion of the chamber, whilst the rest of the space is filled by the transverse colon, which turns gradually upwards as the stomach retracts, and finally comes to lie both above and in front of that organ and immediately beneath the diaphragm—a fact to be remembered in clinical examinations of this region.

Peritoneal Relations.—The stomach is almost completely covered by

FIG. 921.—STOMACH CHAMBER VIEWED FROM THE FRONT AND FROM BELOW.

From the specimen figured in Fig. 912, after removal of the stomach.

peritoneum—the anterior surface being clothed by that of the general peritoneal sac, and the posterior surface by the anterior layer of the bursa omentalis (see p. 1162). From the small curvature the hepato-gastric ligament extends to the liver, whilst to the greater curvature the gastro-lienal and gastro-colic ligaments are attached. Finally, a small peritoneal fold, known as the *gastro-phrenic ligament*, is found running from the stomach up to the diaphragm along the left side of the esophagus.

A small irregularly triangular area (Fig. 919), about 2 inches wide and $1\frac{1}{2}$ inches from above downwards, during moderate distension of the stomach, on the inferior surface below and to the left of the cardia, is uncovered by peritoneum, and over it the organ is in direct contact with the diaphragm, occasionally also with the superior extremity of the left kidney and the supra-renal gland. From the left angle of this "uncovered area" the attachment of the gastro-lienal ligament starts; and at the right angle the *left gastric artery* passes on to the stomach.

The margins of this fold on the right enclose the left gastric artery, and constitute a fold called the *left gastro-pancreatic fold*.

The *right gastro-pancreatic fold* is a fold of peritoneum passing from the right extremity of

the superior part of the pancreas to the first part of the duodenum. It encloses the hepatic artery.

Size and Capacity of the Stomach.—Probably no organ in the body varies more in size within the limits of health than the stomach. Moreover, as its tissues change so rapidly after death, measurements made on softened and relaxed organs are not only worthless but quite misleading. Consequently it is difficult, perhaps impossible, to arrive at a correct estimate of its size and capacity.

The *length* of the stomach in the fully distended condition is about 10 to 11 inches (25 to 27·5 cm.), and its greatest *diameter* not more than 4 to 4½ inches (10 to 11·2 cm.); whilst its *capacity* in the average state rarely exceeds 40 ounces, or 1 quart.

FIG. 922.—THE COURSE OF THE LARGE INTESTINE. The jejunum and ileum have been removed.

The length has been estimated by different authorities at from 10 to 13½ inches (26 to 34 cm.); its diameter, from 3¼ to 6 inches (8 to 15 cm.); and its capacity from 1½ to 5 pints. The measurements of the capacity given by Dr. Sidney Martin are probably the most accurate: he states that the capacity varies between 9 and 59 oz., with an average of from 35 to 40, or a little over a litre.

The distance in a direct line from the cardiac to the pyloric orifice varies from 3 to 5 inches (7·5 to 12·5 cm.), and that from the cardia to the summit of the fundus from 2½ to 4 inches (6·2 to 10·0 cm.).

As regards the *weight*, the average of twelve wet specimens freed from their omenta was found to be 4¾ oz. (135 grms.), with a maximum of 7 oz. (198·45 grms.) and a minimum of 3½ oz. (99·22 grms.). Glendinning gives the weight as 4½ oz.

In the child at birth the stomach is scarcely as large as a small hen's egg, and its capacity is about 1 oz. (28·3 grms.). In shape it corresponds pretty closely to that of the adult, and the fundus is well developed. It is vertical in position.

Displaced Stomach (Fig. 918).—As a result of disease, or of constriction of the superior part of the abdomen, the stomach is occasionally displaced in position and distorted in shape, so that instead of running obliquely forwards, downwards, and to the right, it is placed nearly vertically along the left side of the vertebral column, in which direction it has a very considerable length. Its inferior part bends rather suddenly, and runs upwards

and to the right to join the pylorus, which is often placed quite superficially below the liver. As a result of the displacement, the left extremity of the pancreas is pushed downwards from the horizontal until it almost assumes a vertical position. The narrowing and inversion of the inferior margin of the thoracic framework at the same time constricts the stomach about its middle, and may lead to a bilocular condition.

Hour-glass or Bilocular Stomach.—This is a condition of the organ, by no means rare, in which the stomach is more or less completely separated into two divisions—a cardiac and a pyloric—the normal arrangement in certain rodents and other animals. As a rule the former division is the larger, but occasionally the two are nearly equal, or the pyloric portion may exceed the cardiac in size. Sometimes the condition is temporary, and the result of a vigorous contraction of the circular muscular fibres at the seat of constriction. In other cases it is

FIG. 923.

- A. Empty stomach in vertical position as defined by the X-rays.
- B. Filled stomach in vertical position as seen with the X-rays.
- C. Half-filled stomach in vertical position as seen with the X-rays.
- D. Half-filled stomach in horizontal position as seen with the X-rays.

permanent, and may be due to cicatricial contraction after gastric ulcer, or to some other pathological condition. The condition is more frequent in the female than the male, and is rarely found in the foetus or child.

Position of the Stomach.—*When empty*, or nearly so, the stomach lies in the left hypochondrium and left part of the epigastrium, with its fundus directed posteriorly towards the diaphragm, its long axis lying almost in a horizontal plane and its pyloric part running to the right to join the duodenum. In this state the whole organ is narrow and attenuated, particularly the pyloric part, which is contracted, and resembles a piece of thick-walled small intestine.

When distended, both the cardiac and pyloric parts become full and rounded (Fig. 923). It still lies within the hypochondriac and epigastric regions; but in exceptional cases, or in extreme distension, it may pass down below the subcostal plane and reach into the umbilical and left lumbar regions. As a result of the

general increase in length which takes place during distension, the pylorus is moved a variable distance to the right beneath the quadrate lobe of the liver, and at the same time the long axis of the whole organ becomes much more oblique, running forwards, downwards, and to the right. Finally there is developed a special dilatation of the pyloric part, known as the *antrum pylori*, which in extreme distension is carried so far to the right that it may even reach to the hypochondrium.

Shape and Position of the Stomach as seen by X-Ray Examination.—Examination of the stomach by means of X-rays after a “bismuth meal” has given important information about the shape and position of the stomach in the living, and about the changes which occur as the stomach fills and empties.

These examinations corroborate, in great part, the conclusions which have been arrived at by the study of formalin specimens so far as the shape of the stomach, and its division into parts, is concerned. In regard, however, to the position and direction of the stomach, X-rays show that the stomach in the living, and especially in the erect attitude, is more vertical than it is after death, and when the body is examined in the horizontal position. In the upright position, in fact, the long axis of the organ appears to be nearly vertical. The general shape and position of the stomach in the vertical position, moderately distended, is shown in Fig. 923. From this it will be seen that not only is the body of the stomach nearly vertical, but that the greater curvature reaches down to the umbilicus, and may descend even beyond it. The pyloric part is directed upwards, as well as backwards, and the pylorus is not usually the lowest point of the stomach.

The other anatomical features of the stomach described above are well brought out. Thus the fundus is a hemispherical dome, lying to the left of the terminal portion of the cesophagus, and continuous in outline with the body of the stomach. It usually contains gas, and appears translucent to X-rays. The body is of uniform outline, and the pyloric part is marked off from it by the incisura angularis, on the lesser curvature. Further, the pyloric part shows division into pyloric antrum and pyloric canal. The incisura angularis and sulcus intermedius are distinct.

The position of the stomach is greatly influenced by attitude and by the condition of the abdominal muscles. Contraction of the abdominal muscles can elevate the stomach from 5 to 13 cm., or 2 to 5 inches, and the change from the horizontal to the erect attitude alters the height of the inferior border from 2 to 10 cm. This sinking which occurs in the alteration from the horizontal to the erect attitude, accounts largely for the differences found between the stomach seen in the post-mortem room or on the operating table and the stomach displayed by means of X-rays. Thus, if the stomach figured on p. 1167 be considered fixed at the cardiac end, and somewhat fixed at the pylorus, and the pyloric antrum and greater curvature should sink downwards, the shape, as seen from the front, would closely resemble the X-ray appearances found often in the living.

The empty stomach is a contracted tubular organ, except at the fundus, where it appears to be always dilated. When food is taken, when the individual is standing or sitting, it runs down to the point where the gastric walls are in contact with one another. The distal portion of the stomach dilates for some distance, or at least as far as the pyloric canal.

As the stomach becomes filled the whole of the body of the organ becomes dilated, but the fundus and cardiac portion more particularly so, and these two latter regions act as a storehouse.

There is no definite division of this portion from the remainder of the stomach by a permanent sphincter, but the peristaltic waves of contraction begin about the middle of the organ, and form a fleeting constriction between the two parts.

As peristalsis goes on, the tubular pyloric part relaxes somewhat. The waves of peristalsis here become so deep as to divide this portion into chambers. The food substances are forced through the pylorus by successive waves of peristalsis, and in the form, usually, of jets which impinge against the posterior aspect of the duodenal wall.

Should there be undigested masses, the pyloric valve relaxes to allow them also to pass into the duodenum.

STRUCTURE OF THE STOMACH.

The stomach wall is composed of four coats—namely, from without inwards: (1) Tunica serosa, (2) tunica muscularis, (3) tela submucosa, and (4) tunica mucosa (Fig. 924).

Tunica Serosa.—This coat is formed of the peritoneum, the relations of which to the stomach have already been described. It is closely attached to the subjacent muscular coat, except near the curvatures, where the connexion is more lax; and it confers on the stomach its smooth and glistening appearance.

Tunica Muscularis.—The muscular coat, which is composed of unstriped muscle, is thinnest in the fundus and body, much thicker in the pyloric portion, and very highly developed at the pylorus. It is made up of three incomplete layers—an external, *stratum longitudinale*; a middle, *stratum circulare*; and an internal of oblique muscular fibres, *fibre oblique*.

The *stratum longitudinale* consists of longitudinal fibres, continuous with those of the œsophagus on the one hand, and those of the duodenum on the other (Fig. 926, A). They are most easily demonstrated on the lesser curvature, where they can be traced down from the right side of the œsophagus. Over the greater curvature and on the two surfaces they are present as an extremely thin and irregular sheet. Towards the pylorus the longitudinal fibres grow much thicker, and also much tougher and more closely united, and they take part in the formation of the **pyloric valve**.

FIG. 924.—TRANSVERSE SECTION THROUGH THE WALL OF A HUMAN STOMACH. $\times 250$.

A specially condensed band of these can be often made out both on the front and back at the antrum pylori, the form of which is said to be due to their presence. These bands are known as the **ligamenta pylori** (pyloric ligaments).

FIG. 925.—MUSCULAR COAT OF THE STOMACH, seen from within after removal of the mucous and submucous layers. The anterior half of the stomach is shown, viewed from behind (Cunningham).

The *stratum circulare* is composed mainly of circular fibres, continuous with the more superficial of the circular fibres at the lower end of the œsophagus (Fig. 925). They begin as a set of U-shaped bundles which loop over the lesser curvature at the right of

the cardia, and pass downwards and to the left on both surfaces. Further to the right these looped fibres are succeeded by circles which surround the organ completely. Traced towards the narrow end of the stomach, the circular bundles grow thicker, and at the pylorus they undergo a further increase, giving rise to the pyloric sphincter which surrounds the orifice as a thick muscular ring.

The *fibræ oblique*, forming the inner layer, consist of fibres which are arranged on the fundus and adjacent parts of the stomach, in much the same manner as those of the middle layer are on the body and pyloric part of the organ (Fig. 926, C). They are continuous above with the deeper circular fibres of the inferior end of the œsophagus, and form U-shaped bundles which loop over the stomach immediately to the left of the cardia, and run very obliquely downwards and to the right for a considerable distance on both surfaces of the organ. These looped fibres, as they pass to the left, gradually become less oblique, and finally form circles which surround the wide end of the stomach completely, even as far as the summit of the fundus. The oblique fibres can be most readily shown by removing the circular fibres on either surface below the cardia. When traced towards the right, they will be found to terminate by turning down and joining the fibres of the circular layer.

Tela Submucosa.—The submucous coat is a layer of strong but loose connective tissue, which lies between and unites the muscular and mucous coats (Fig. 924). It is more loosely attached to the muscular and more closely to the mucous coat, and it forms a bed in which the vessels and nerves break up before entering the mucous membrane.

Tunica Mucosa.—If examined in the fresh state soon after death, the mucous coat is of a reddish-gray colour and of moderate consistence. When examined some time after death, the colour turns to a darker gray, and the whole membrane becomes softer and more pulpy. It is thicker (over 2 mm.) and firmer in the pyloric than in the cardiac part, and is thinnest at the fundus, where it often shows signs of post-mortem digestion. When the stomach is empty all three outer coats, which are extensible, contract; whilst the inextensible mucous coat, as a result of its want of elasticity, is thrown into numerous prominent folds or *rugæ*, which project into the interior and, as it were, occupy the cavity of the contracted organ. These are, in general, longitudinal in direction, with numerous cross branches, and they are largest and most numerous along the greater curvature. They disappear when the stomach is distended.

When the surface of the mucous coat is examined in a *fresh* stomach, it is seen to

FIG. 926.—THE THREE LAYERS OF THE MUSCULAR COAT OF THE STOMACH. A, External or longitudinal layer; B, Middle or circular layer; C, Internal or oblique layer. *a*, Longitudinal fibres of œsophagus; *b*, Superficial circular fibres of œsophagus passing into circular fibres of stomach in B; *c*, Deep circular fibres of œsophagus passing into oblique fibres of stomach in C; *d*, Oblique fibres forming rings at the fundus; *e*, Submucosa.

be marked out into a number of small, slightly elevated, polygonal areas, *areae gastricae*, by numerous linear depressions; the mucous membrane is consequently said to be mamillated (Fig. 927, A). These little areas, which measure from 1 to 6 mm. in diameter, are beset with numerous small pits, *foveolæ gastricae*, about .2 mm. wide, which are the mouths of the gastric glands, and they are so closely placed that the amount of surface separating them is reduced (particularly in the pyloric portion, where the gland mouths are widest) to a series of elevated ridges, *plicæ villosæ*, resembling villi on section. Although the gland mouths cannot be seen with the naked eye, a very slight magnification is sufficient to show them clearly; it is also possible to see the gland tubes leading off from the bottom of each (Fig. 927, B).

Minute Structure of the Mucous Coat.—In structure the mucous coat consists of an epithelial covering composed of long columnar cells, and of numerous tubular glands, *glandulæ gastricae*, which are prolonged out-

wards from this surface, and which are enclosed in a delicate connective tissue stroma, with some small lymph nodules, *noduli lymphatici gastrici*. The bases of the glands reach outwards to the lamina muscularis mucosæ, a layer consisting of an external longitudinal and an internal circular layer of plain muscle fibres.

Glandulæ Gastricae.—These consist of a duct terminating in one or more secreting tubules. The duct is lined with columnar epithelial cells, similar to those which cover the surface of the mucous membrane. Three varieties of glands are found in different regions of the stomach, and are named from their position—

(1) **Cardiac Glands.**—These glands are situated close to the œsophageal opening. The duct terminates in a single long tubule, which is lined with short columnar granular cells.

(2) **Fundus Glands.**—In these glands the duct terminates in one or more tubules, lined with polyhedral cells, termed the *chief* or *central* cells. At intervals, between this layer of cells and the basement membrane, are placed larger spheroidal cells, which stain more deeply as a rule, termed the *parietal* or *oxyntic* cells. These glands are found in the fundus and body of the stomach.

FIG. 927.—MUCOUS MEMBRANE OF THE STOMACH. A, Natural size; B, Magnified 25 diameters. In A the rugæ and the mamillated surface are shown. In B the gland mouths (*foveolæ gastricae*), with the gland tubes leading off from some of them, and the ridges separating the mouths (*plicæ villosæ*) are seen.

(3) **Pyloric glands** are found in the pyloric portion of the stomach. These consist of a short duct, terminated in a group of short but tortuous gland tubules. These tubules are lined with short columnar or polyhedral cells, similar to the central cells of the fundus glands.

Blood-vessels.—The arteries of the stomach are all derived ultimately from the *cœliac artery*. The *gastric artery* arises from this trunk direct. Having reached the lesser curvature and given off an œsophageal branch, it divides into two large branches, which run, one on each side of the organ, along this curvature, and join below with two similarly-disposed arteries derived from the *right gastric* branch of the hepatic. From the two arches thus formed, four or five large branches pass to each surface of the stomach, and soon pierce the muscular coat. Along the greater curvature several smaller branches reach the stomach from the *right* and *left gastro-epiploic arteries*, which are branches respectively of the gastro-duodenal and the splenic, and run in the gastro-colic ligament close to its attachment to the stomach. Finally, four or five *aa. gastricae breves*, branches of the splenic, are distributed to the fundus of the stomach, which they reach by passing forwards between the layers of the gastro-lienal ligament. At first the arteries lie beneath the peritoneum; very soon, however, they pierce the muscular coat, which they supply, and, reaching the submucosa, break up to form a close network of vessels. From these arise numerous small branches, which enter the mucous membrane and form capillary plexuses around the glands as far as the surface.

The veins begin in the capillary plexuses around the glands; uniting, they form a network in the submucosa, from which arise branches that pierce the muscular coat, and finally end in the following veins: the *right gastro-epiploic*, which joins the superior mesenteric; the *left gastro-epiploic*, and four or five veins corresponding to the *aa. gastricae breves*, which join the splenic; the *v. coronaria ventriculi*, which runs along the lesser curvature from right to left, and joins

the portal vein. These veins contain numerous valves which, though competent to prevent the return of blood in the child, are rarely so in the adult.

The lymph vessels of the stomach arise in an extensive plexus in the mucous membrane around the gastric glands. They then join a plexus of vessels in the tela submucosa, from which some vessels pass at intervals to join another plexus of vessels, subserous in position; piercing the muscular coats obliquely in their course. The efferent vessels pass mainly from the subserous plexus, and are arranged in three main groups, which pass in different directions, and drain three different areas of the stomach wall.

One set of vessels is connected mainly with the whole of the lesser curvature, from fundus to pylorus, and the adjacent half or two-thirds of the anterior and posterior surfaces of the stomach. These vessels pass to the superior gastric glands, along the lesser curvature, and, in company with the left gastric artery, to the celiac glands.

The second set of vessels drains an area which includes the greater curvature below the fundus, and the adjacent portions of the anterior and posterior surfaces of the stomach. These vessels pass with the right gastro-epiploic artery to some inferior gastric glands which lie below and behind the pylorus, and thence they pass with the hepatic artery to the celiac glands.

The third set of vessels drains the region of the fundus. The vessels from this area pass in the gastro-lienal ligament to the spleen, where they are connected with some splenic glands, and pass onwards, along the superior border of the pancreas, to the celiac glands also.

The superior and inferior gastric glands and the splenic glands are the first glands interposed in the course of the lymph vessels. The celiac glands form the second set.

The nerves are derived from the two *vagus nerves* and from the *ganglia celiaca* of the sympathetic. The vagi nerves pass through the diaphragm with the œsophagus, the left lying on its anterior, the right on its posterior aspect; in this way they reach the anterior and posterior surfaces of the stomach respectively. Here they unite with the sympathetic fibres from the celiac plexus, which pass to the stomach with the branches of the celiac artery. The nerve fibres, which are chiefly non-medullated, form two gangliated plexuses, those of the myenteric plexus and the submucous plexus, in the muscular and submucous coats respectively.

The development of the stomach is described with that of the intestines on p. 47.

INTESTINUM TENUE.

The **small intestine** is the portion of the digestive tube which is placed between the stomach and the beginning of the large intestine. It commences at the pylorus, where it is continuous with the stomach, and ends at the valvula coli by joining the large intestine. It occupies the greater portion of the abdominal cavity below the liver and stomach (Fig. 913), and is found in the umbilical, hypogastric, and both lumbar regions; also, but to a less extent, in the other regions of the abdomen, and in the pelvic cavity.

In *length*, the small intestine usually measures over 20 feet. According to Treves, it is 22½ ft. in the male, 23 in the female, whilst Jonnesco gives the average length at 24 ft. 7 ins., or 7½ metres. In form it is cylindrical, with a *diameter* varying from nearly two inches (47 mm.) in the duodenum to a little over an inch (27 mm.) at the end of the ileum; there is thus a gradual diminution in its size from the pylorus to the valvula coli.

The small intestine is relatively longer in the child than in the adult; at birth it is to the total height of the child as 7 to 1, whilst in the adult the proportion is as 4 to 1. Notwithstanding Treves' results, it is generally held that the small gut is relatively longer in the male than the female.

While the former figures, 20 to 22 feet, represent the entire length of the intestine in its most extended form, after death, when muscular tonus has disappeared, it is probable that during life the length is not so great. The muscular coats, both longitudinal and circular, are more or less contracted, and probably the total length during life may be estimated as 15 to 17 feet.

In formalin-hardened bodies the small bowel rarely measures more than 12 or 13 feet in length. Similarly its diameter is often reduced in places to ½ or ¾ inch (12·5 to 18·7 mm.), although the greater part of the gut may retain its usual width: these narrow parts have apparently been fixed in a state of contraction.

The small intestine is divided more or less arbitrarily into three parts (Fig. 873)—namely, the **duodenum**, constituting the first eleven inches, distinctly marked off from the rest by its fixation and the absence of a mesentery; the **intestinum jejunum** ("empty intestine") which comprises the upper two-fifths, and the **intestinum ileum** ("twisted intestine") the lower three-fifths of the remainder. The two latter parts pass imperceptibly into one another, and the line of division drawn between them is entirely artificial; however, if typical parts of the two—namely, the beginning of the jejunum and the end of the ileum—are selected, they differ so

much in size and in the appearance presented by their lining mucous membrane, that they can be distinguished from one another without difficulty.

Both the jejunum and ileum are irregularly disposed in the form of crowded loops or coils (Fig. 913) which are connected to the posterior abdominal wall by a great fan-shaped fold of peritoneum, containing their vessels and nerves, and known as the mesentery. Hence the name of *intestinum tenue mesenteriale* is applied to them. The mesentery is of such a length that the coils are able to move about freely in the abdominal cavity, and consequently the position occupied by any portion of the tube, with the exception of the beginning of the jejunum and the ending of the ileum, can never be stated with certainty. Nevertheless, it may be said that, in general, the jejunum occupies the superior and left portions of the cavity below the stomach, the ileum the inferior and right divisions, its terminal part almost always lying in the pelvis, just before it joins the large gut.

According to Mall, the most usual arrangement is to find the proximal coils of the jejunum on the left side, and high up. Then the tube crosses the vertebral column below the duodenum, and a few coils are placed on the right side. It then crosses to the left side again, and several coils are formed, some of which may descend into the pelvis. Thence it passes again to the

FIG. 928.—A PORTION OF SMALL INTESTINE, WITH MESENTERY AND VESSELS.

The peritoneal coat has been removed from the right half, and the two layers of the muscular coat exposed.

right side, where it is coiled up, and then finally descends into the pelvis. The terminal portion almost always lies in the pelvis, just before it ascends to join the large intestine.

As the coats of the large and small intestine agree in many particulars, it will be convenient to describe the general structure of the intestines here. Subsequently, any peculiarities of structure in particular regions will be described with the corresponding division of the tube.

STRUCTURE OF THE INTESTINES.

The wall of the intestines, like that of the stomach, is made up of four coats, which are named from without inwards—*tunica serosa*, *tunica muscularis*, *tela submucosa*, and *tunica mucosa* (Figs. 928 and 929).

1. **Tunica Serosa.**—This is formed of peritoneum, and confers on the intestines their smooth and glossy appearance. It varies in the extent to which it clothes the different divisions of the tube, giving the duodenum, the ascending, descending, and iliac colons, and the rectum only a partial covering; whilst it clothes the jejunum and ileum, the cæcum, the transverse and the pelvic colons completely. The detailed arrangement of this coat will be given with the description of each division of the intestinal tube.

2. **Tunica Muscularis.**—This consists of unstriped muscle arranged in two layers

—an outer *stratum longitudinale*, in which the fibres run longitudinally, and an inner *stratum circulare*, in which they are circularly disposed. The muscular coat is thicker in the duodenum than in any other part of the small intestine, and it gradually diminishes in thickness until the end of the ileum is reached. On the other hand, in the large intestine, it is thickest in the rectum and thinner towards the beginning of the colon.

The *stratum longitudinale* of this coat is much thinner than the underlying *stratum circulare*. In the small intestines it forms a complete sheet, continuous all round the gut (Fig. 928), but thickest at its free margin; whilst in the large intestine it is divided up into three longitudinal bands known as the *teniæ coli*, which will be more fully described in connexion with the colon.

The *stratum circulare*, much thicker than the longitudinal layer, is composed of bundles of muscular fibres arranged circularly round the tube (Fig. 929), and forming in all parts a continuous sheet. Unlike the longitudinal fibres, those of the circular layer take part in the formation of the valves of the pylorus and colon.

3. Tela Submucosa.—This is a loose but strong layer of areolar tissue connecting the muscular and mucous coats, on which chiefly depends the strength of the intestinal wall. In addition to forming a bed in which the vessels break up before entering the mucous coat, it contains the *glandulæ duodenales* (*Brunneri*) (Fig. 929), and, in both small and large intestines, the bases of the solitary lymph nodules lie in it (Fig. 929).

4. Tunica Mucosa.—The mucous membrane constitutes the inner coat of the intestine. It is everywhere composed (Fig. 929) of the following parts:—(1) A layer of striated, columnar, epithelial cells, resting on (2) a basement membrane. Outside this lies (3) a layer of retiform tissue, containing a considerable number of scattered lymph cells. This layer is limited towards the tela submucosa by (4) an extremely thin sheet of unstriated muscle, the *lamina muscularis mucosæ*, which is not visible to the naked eye. The mucous membrane is very vascular, particularly in the small intestine. It is thicker in the duodenum than in the jejunum, and thicker in this latter than in the ileum.

Throughout both the small and large intestines the substance of the mucous membrane is closely beset with innumerable (small microscopic) tubular glands, known as the *glandulæ intestinales*

[*Lieberkühni*] (O.T. glands or follicles). In shape they are minute straight tubes, like diminutive test-tubes. Their mouths open on the free surface of the mucous membrane: their closed ends lie in the deeper part of the mucous coat, and their cavities are lined with columnar epithelium. They open on the surface between the bases of the villi of the small intestine, and in the large gut their orifices are found all over the surface of the non-villous mucous membrane.

FIG. 929.—DIAGRAM to show the structure of the large intestine, the duodenum, and the jejunum.

Certain special developments of the mucous coat, found in particular regions of the intestinal tube, must next be considered: these are the (1) villi intestinales; (2) plicæ circulares [*Kerkringi*] (O.T. *valvulae conniventes*); (3) noduli lymphatici solitarii (O.T. solitary glands); and (4) noduli lymphatici aggregati [*Peyer*] (O.T. *Peyer*'s patches).

Villi Intestinales.—If the mucous membrane of any part of the small in-

testine is examined, it is seen to present a soft, velvety, or fleecy appearance (Fig. 930, B); this is due to the presence of an enormous number of minute processes, known as villi, which cover its surface.

They are minute cylindrical or finger-like projections of the tunica mucosa

(Fig. 929) about $\frac{1}{30}$ th or $\frac{1}{40}$ th of an inch ($\frac{1}{12}$ to $\frac{1}{16}$ mm.) in height, and barely visible to the naked eye, which are closely set all over the surface of the lining membrane of the small intestine. Beginning at the edge of the pyloric valve, they are broad but short in the duodenum, and grow narrower as they are followed down through the intestine to the valvula coli, at the edge of which

FIG. 930.—PLICÆ CIRCULARES (natural size).

A, as seen in a portion of jejunum which has been filled with alcohol and hardened ;
B, a portion of fresh intestine spread out under water.

they cease. They are found, not only on the general surface of the mucous membrane, but also upon the plicae circulares, and, while they are not present over the solitary lymph nodules, they are found in the intervals between the individual nodules of the aggregated nodules.

They play an important part in the absorption of the products of digestion which takes place in the small intestine.

Plicae Circulares [Kerkringi].—When the intestine is empty and contracted, its mucous membrane is thrown into effaceable folds or rugae, which disappear on distension. But in addition to these, there are found in certain portions of the small intestine a series of large, permanent transverse folds, which are not effaceable; these are known as plicae circulares (Fig. 930). These are usually more or less crescentic in shape, and resemble a series of closely placed shelves running transversely around the gut. They rarely form more than two-thirds of a circle; sometimes, however, they present a circular or even a spiral arrangement, the spiral extending little more than once round the tube, as a rule. Occasionally they bifurcate at one or both ends; sometimes, too, short irregularly directed branches pass off from them. They are usually about 2 to 3 inches (5 to 7.5 cm.) in length, and their breadth, that is their projection into the cavity, may be as much as $\frac{1}{3}$ rd of an inch (8 mm.), whilst in thickness, as seen when cut across, they measure about $\frac{1}{8}$ th inch (3 mm.).

They are composed of two layers of the tunica mucosa, with a prolongation from the tela submucosa between, to bind the two together. They are covered with villi, and are permeated by intestinal glands. Their use is to increase the amount of surface available for secretion and absorption.

Plicae circulares are not found in the upper part of the duodenum. They begin at a distance varying from 1 to 2 inches (2.5 to 5 cm.) from the pylorus. At first they are small, irregular, and scattered; but they are larger lower down, and at the opening of the bile duct (4 inches from the pylorus) they are distinct and prominent. In the rest of the duodenum, and in the superior half of the jejunum, they are highly developed, being large, broad, and closely set. In the inferior half of the jejunum they become gradually smaller and fewer. Passing down into the ileum, they

become still smaller and more irregular, and, as a rule, they practically cease a little below the middle of the ileum.

Often patches of *plicæ circulares*, much reduced in size, can be traced to within a short distance of the *valvula coli*. According to Sappey, Luschka, and others, they usually reach to within two or three feet of the end of the ileum.

Noduli Lymphatici Solitarii.—The solitary lymph nodules are minute masses of lymph tissue, opaque and of a whitish colour, found projecting on the surface of the mucous membrane throughout the whole length of both the small and large intestines.

Isolated lymph cells are found in abundance scattered through the connective-tissue layer of the intestinal mucous membrane generally; in places these cells are gathered together to form little nodules, supported by a framework of retiform tissue, and surrounded by a lymph space which communicates below with the lymph vessels of the *tela submucosa*. Such a collection of lymph cells constitutes a solitary nodule. They are usually of a rounded or oval shape (Fig. 931), the wide end resting in the *tela submucosa*, the nodule itself piercing the *lamina muscularis mucosæ*, and the narrow end projecting slightly above the general surface of the mucous membrane. In size they vary from $\frac{1}{10}$ th to $\frac{1}{8}$ th of an inch ($\cdot 6$ to $3\cdot 0$ mm.), but their average bulk is about that of a small grain of sago, to which they bear some resemblance.

As already mentioned, they are present throughout the small and large intestines, being particularly abundant in the vermiform process and cæcum. In the small intestine they are found on the *plicæ circulares*, as well as upon the general surface of the mucous membrane between them.

Noduli Lymphatici Aggregati.—These lymph nodules (O.T. Peyer's patches) consist of a large number of minute lymph nodules grouped closely together so as to form a slightly elevated area, usually of an oblong form, on the surface of the mucous membrane (Fig. 931). In length they vary from half an inch (12 mm.) or less to three or four inches (100 mm.), and in width they commonly measure from a third to half an inch (8 to 12 mm.). Their number is variable, but in the average condition about 30 or 40 are found. They are best marked in young subjects, where they form considerable elevations above the general surface, and may be as many as 45 in number. After middle life they atrophy, and in old age, although usually to be found, they are indistinct, occasionally being marked by little more than a dark discoloration of the mucous membrane. They are invariably situated along the surface of the intestine opposite the line of mesenteric attachment, with their long axis corresponding to that of the bowel. Consequently, in order to display them, the tube must be slit up along its attached or mesenteric border.

These aggregated nodules are entirely confined to the small intestine, being largest and most numerous in the ileum, particularly in its inferior part, where they usually assume an oblong shape; in the inferior half of the jejunum they are small, circular, and few in number; in its superior part they are rare; and, although their presence has been noted in the inferior portion of the duodenum, they may be said to be absent, as a general rule, from this division of the intestine.

The *plicæ circulares* stop at the margins of the aggregated nodules, and are not continued across them; but villi are found on the surface of the aggregated nodules, in the intervals between the individual lymph nodules.

FIG. 931. — NODULI LYMPHATICI AGGREGATI and SOLITARI, from intestine of child two years old (natural size).

Near the lower border are seen a few small patches made up of two or three lymph nodules; they are marked "intermediate form."

The chief bowel lesion in typhoid fever is found in these aggregated and in the solitary nodules.

When the surface of one of these nodules from a child's intestine (in which these structures are particularly well developed) is carefully examined, it is seen to be made up, not of a series of separate, rounded nodules grouped together, but rather of a number of wavy, irregular, and branching ridges connected with one another by cross branches (Fig. 981), the whole recalling in miniature the appearance of a raised map of a very mountainous district in which the chief chains run irregular courses, and are joined to one another by connecting ridges.

Small patches, intermediate in form between solitary and aggregated nodules, and consisting of two or three lymph nodules, are also usually present.

DUODENUM.

The **duodenum**, the portion of the digestive tube which immediately succeeds the stomach, is the first part of the small intestine, and differs from the rest of that tube in having for the greater part no mesentery, and hence it is closely fixed to the posterior abdominal wall. The ducts of the liver and pancreas open into it, and some special glands are found in its wall, known as the *duodenal glands of Brunner*.

Shape and Divisions.—The duodenum begins at the pylorus, about the level of the first lumbar vertebra, and ends at the left side of the first or second lumbar vertebra (Fig. 932). Between these two points it pursues an irregular course, which has some resemblance to the outline of a horse-shoe. It is made up of three main parts, namely:—(1) The **pars superior**, which begins at the pylorus, passes posteriorly and to the right beneath the liver, and ends at the neck of the gall-bladder by turning down forming the *flexura superior* and joining (2) the **pars descendens**. This begins at the neck of the gall-bladder, runs down on the posterior abdominal wall, on the right of the vertebral column, behind the transverse colon (Fig. 932), and ends opposite the third or fourth lumbar vertebra. There it turns to the left, and passes into (3) the **pars inferior**. This portion at first runs more or less transversely to the left, across the vena cava, aorta, and vertebral column (*pars horizontalis*), and then ascends as far as the inferior surface of the pancreas (*pars ascendens*). There, at the level of the first or second lumbar vertebra, it bends abruptly forwards, forming the **duodeno-jejunal flexure** (Fig. 932), and passes into the jejunum. The junction of the pars descendens and pars inferior constitutes the *flexura inferior*.

Taking the whole of the duodenum together, it forms an irregular horseshoe-shaped curve, with the opening directed upwards and to the left, and the ends reaching to within about two inches of one another. Within the concavity of the curve the head of the pancreas is placed.

The incomplete ring which the duodenum makes does not all lie in the same plane; for, whilst its greater part is placed in a frontal plane, the superior part, and the commencement and termination of the inferior part, lie more in a sagittal plane (Fig. 932).

Position and Size.—As a rule, a little more than half of the duodenum lies in the epigastrium; the remainder—namely, about the inferior third of the descending portion and the adjoining two-thirds of the inferior portion—are placed in the umbilical region. With the exception of the terminal ascending portion of the third part, the whole of the duodenum lies to the right of the median plane.

Its length is usually about 11 inches (27·5 cm.), its first portion being the shortest and its third portion the longest. Its diameter varies considerably, and may be stated to average about $1\frac{1}{2}$ inches when empty, but it may be as much as two inches when distended.

Relations. Pars Superior.—The superior part (O.T. first portion) begins at the pylorus opposite the first lumbar vertebra. From this it runs to the right, and then *posteriorly*, beneath the liver, when the stomach is empty, but directly backwards when it is full; and ends at the neck of the gall-bladder by turning inferiorly and passing into the descending part. Its length varies from about $1\frac{1}{2}$ to 2 inches (3·7 to 5·0 cm.), and is said to be greater when the stomach is empty than when distended.

Its relations are as follows:—It forms the inferior boundary of the foramen epiploicum, and above this foramen it is in relation to the caudate process of the liver, while the quadrate lobe of the liver hangs downwards over it and to the right. The hepatic artery is in contact for a short distance with the superior border. Below, it rests on the head and neck of the pancreas. The portal vein, gastro-duodenal artery, and the bile-duct lie in contact with it on the left

FIG 932.—THE VISCERA AND VESSELS ON THE POSTERIOR ABDOMINAL WALL.

The stomach, liver, and most of the intestines have been removed. The peritoneum has been preserved on the right kidney, and the fossa for the caudate lobe. In taking out the liver, the vena cava was left behind. The stomach bed is well shown. (From a body hardened by injection of chromic acid.)

side, and behind them the duodenum comes into contact with the right aspect of the inferior vena cava. The superior pancreatico-duodenal and the right gastro-epiploic vessels pass forwards below its inferior margin.

Its *peritoneal relations* are similar to those of the pyloric end of the stomach for about an inch. It is therefore at first invested by peritoneum on the right and left aspects, and the peritoneum passes upwards from its superior border as the right portion of the lesser omentum, forming the *hepato-duodenal ligament*, while from its inferior border the descending folds of the

peritoneum pass downwards. The peritoneum is reflected from off the left surface on to the pancreas and abdominal wall, forming a fold known as the *right gastro-pancreatic fold*, while the peritoneal covering of the right side is continued onwards along the whole of this part of the duodenum.

Pars Descendens.—The descending part (O.T. second portion) begins at the neck of the gall-bladder, passes down behind the transverse colon, and ends at the right side of the third or fourth lumbar vertebra. In length it measures $3\frac{1}{2}$ or 4 inches (8·7 to 10 cm.).

Its relations are as follows:—It lies on the right of the vertebral column and the inferior vena cava, from the first to the third or fourth lumbar vertebra, and is anterior to the pelvis

FIG. 933.—THE PERITONEAL RELATIONS OF THE DUODENUM, PANCREAS, SPLEEN, KIDNEYS, ETC.

From a body hardened by injections of formalin. In removing the liver, stomach, and intestines the lines of the peritoneal reflections were carefully preserved. The peritoneum is coloured blue.

of the right kidney, the right renal vessels, and ureter, and also to a varying extent the front of the right kidney itself; while, below the level of these structures, it rests upon the *psoas major* muscle.

The lateral aspect is in contact with the sloping inferior surfaces of the liver in its superior part, and with the right flexure of the colon below.

Peritoneal Relations.—The anterior aspect is covered by peritoneum, except about its middle, where the root of the transverse mesocolon crosses the duodenum. Occasionally, and not infrequently, the transverse colon has no mesentery, but is itself in direct contact with the wall of the duodenum. In other cases, the colon is in contact with the peritoneal surface of the duodenum, below the line of reflection of the transverse mesocolon.

The head of the pancreas is in contact with its concave left margin, and occasionally overlaps it anteriorly and posteriorly; and along the margin of the pancreas, both anteriorly and posteriorly, are branches of the superior and inferior pancreatico-duodenal vessels, the veins often forming a dense network on the posterior aspect.

The bile-duct, after passing down behind the superior part of the duodenum, descends between the head of the pancreas and the descending part, nearly as far as its middle; here it is joined by the pancreatic duct, and the two, piercing the wall of the duodenum obliquely, open by a common orifice on its inner aspect, about 3 to 4 inches (8·7 to 10 cm.) beyond the pylorus.

Pars Inferior.—The inferior part (O.T. third portion) begins at the right side of the third or fourth lumbar vertebra. It is described in two parts, *pars horizontalis*, transverse in direction, and *pars ascendens*, and it shows that arrangement in Fig. 933.

The *pars horizontalis* runs more or less transversely to the left across the inferior vena cava (Fig. 933) for one or two inches, and the *pars ascendens* passes very obliquely, or even vertically, upwards in front of the aorta and left psoas major muscle. Finally, having reached the inferior surface of the pancreas, it bends forwards, and passes into the jejunum.

Anteriorly, it is crossed (about the junction of its two divisions) by the superior mesenteric vessels, and also by the root of the mesentery (Fig. 933). On each side of this it is covered by coils of small intestine. *Posteriorly*, the *pars horizontalis* lies over the vena cava inferior; the *pars ascendens* on the aorta, the left renal vein and occasionally also the artery, and the left psoas major muscle, all of which separate it from the vertebral column. *Above*, it is closely applied in its whole extent to the head of the pancreas. The *left side* of the *pars ascendens*, which is free, lies in contact with some coils of the small intestine.

Peritoneal Relations.—The inferior part of the duodenum is covered by peritoneum on its anterior surface throughout, except where it is crossed by the superior mesenteric vessels and the root of the mesentery which contains them (Fig. 933). In addition, its ascending part is also clothed by this membrane on its left side.

The attachment of the root of the mesentery begins above quite close to the duodeno-jejunal flexure, on the front of the duodenum; from this it runs down on the anterior aspect of the ascending part, and finally leaves the duodenum about the union of the two divisions of its third portion.

Duodenal Fossæ.—In the neighbourhood of the *pars ascendens* are found three well-known fossæ of the peritoneum which are of some surgical interest; these are the superior and inferior duodenal and the paraduodenal fossæ (Fig. 934). Other rarer forms are occasionally present.

When the ascending part of the duodenum is drawn over to the right, and the angle between its left side and the posterior abdominal wall examined, one or two triangular folds of peritoneum will generally be found crossing over this angle from the duodenum to the abdominal wall. Each fold has one edge attached to the duodenum, another to the parietal peritoneum at the left of the duodenum, whilst the third is free, and bounds the opening of a small pouch which lies behind the fold, the *recessus duodeno-jejunalis*. Of these folds, the *upper* is termed the *plica duodeno-jejunalis*, and it is situated near the termination of the duodenum, with its apex directed up and its free margin down. It sometimes contains between its two layers the termination of the inferior mesenteric vein. Behind it lies a prolongation from the *recessus duodeno-jejunalis* termed the **superior duodenal fossa**. Its opening looks downwards, and will usually admit the tip of a finger (Fig. 934). The second, known as the *plica duodeno-mesocolica*, is placed lower down, at the side of the same part of the duodenum. Its free border is directed upwards, as is the mouth of the **inferior duodenal fossa**, which lies behind it. This latter is larger and more constant than the superior duodenal fossa, and is present in 75 per cent of bodies, whilst the superior is present in 50 per cent (Jonnesco).

Paraduodenal Fossa (fossa of Landzert).—This fossa, which is best seen in the

FIG. 934.—THE DUODENAL FOSSÆ AND FOLDS.

The transverse colon and mesocolon have been thrown up, and the mesentery has been turned to the right and cut. The paraduodenal fossa (of Landzert) is situated to the medial side of the inferior mesenteric vein, between it and the terminal part of the duodenum. It is not shown in the illustration.

infant, is placed some distance to the left of the ascending part of the duodenum. It is produced by the inferior mesenteric vein raising up a fold of peritoneum, as it runs medially along the side of the fossa, and then above it (see Fig. 934, where the vein, but not the fossa, is shown). It is limited below by a special fold (the mesenterico-mesocolic fold). According to Moynihan, this is the only fossa to the left of the duodenum capable of developing into the sac of a hernia; and when this occurs, the inferior mesenteric vein always lies in the anterior margin of the orifice of the sac (accompanied for some distance by the ascending branch of the left colic artery).

FIG. 935.—THE PAPILLA DUODENI IN THE INTERIOR OF THE DUODENUM.

portion is covered; for the peritoneum forms a fold running in behind this portion, in addition to covering its left side and half its anterior aspect.

Interior of Duodenum.—No *plicæ circulares* are found in the duodenum for an inch or two beyond the pylorus. They then begin; at first as low, scattered, and irregular folds; further down, they gradually become larger, more regular and more numerous; and by the time the middle of the descending part is reached they have attained a considerable development. In the inferior part of the duodenum the folds are large, prominent, and closely set.

On the inner aspect of the descending portion, about its middle—namely, $3\frac{1}{2}$ or 4 inches (8·7 to 10 cm.) beyond the pylorus—is seen a prominent papilla, on which the bile and pancreatic ducts open by a common orifice (Fig. 935). This is known as the *papilla duodeni* (Santorini).

The *papilla duodeni* is placed beneath, and protected by, a prominent, hood-like *plica circularis*, which is situated immediately above it. From its lower margin a firm ridge of the mucous membrane, the *plica longitudinalis duodeni*, descends for a considerable distance, and acts as a frenum, which fixes the papilla and directs its apex somewhat downwards (Fig. 935). The papilla is prominent, and nipple or dome-shaped, and at its summit is placed the small orifice, which will usually admit the point of a pencil; the whole bears a close resemblance to the nozzle of a perfume-spray.

Nearly an inch higher up, and invariably on the ventral side of the papilla (sometimes as much as $\frac{1}{2}$ to $\frac{3}{4}$ inch distant), is seen a second and smaller papilla, the *caruncula minor* of Santorini, at the point of which is placed the very small orifice of the accessory pancreatic duct. This second papilla seems to be constantly present, although sometimes so small that it may easily escape detection unless carefully sought for. When well developed, it may have a hood-like *plica circularis* and a little frenulum, like those of the bile papilla.

Structure of the Duodenum.—The *tunica serosa*, which is incomplete, has already been described in detail, in connexion with each part of the duodenum.

The *tunica muscularis* is well developed, and is pierced by the bile and pancreatic ducts, but otherwise calls for no special description.

The *tela submucosa* differs from that of the rest of the small intestine, in that it contains, especially in the superior half of the duodenum, the *glandulæ duodenales* [Brunneri]. These are small acino-tubular glands, closely resembling the pyloric glands of the stomach, which lie in the submucous coat, and send their ducts through the *muscularis mucosæ* to open on the surface between the *glandulæ intestinales*, or sometimes into these glands themselves (Fig. 929). They can be exposed by removing the peritoneal and muscular coats, and also some of the submucosa, when they appear as little round or flattened masses of a reddish-gray colour, varying in size from $\frac{1}{50}$ th to $\frac{1}{12}$ th of an inch in diameter (·5 to 2·0 mm.). They form an almost continuous layer as far as the opening of the bile duct; beyond this they diminish progressively, and completely disappear near the duodeno-jejunal flexure.

The *tunica mucosa*, which is thicker in the duodenum than in any other part of the small intestine, is covered throughout with broad short villi.

Various Forms of Duodenum.—Three different types of duodenum have been described—(1) The annular, in which the curves separating the various parts are open, and the two extremities come fairly close to one another. (2) The U-shaped, in which the horizontal part of the inferior part is very long, and the ascending part nearly vertical; and (3) the V-shaped duodenum, in which the horizontal portion of the inferior part is very short or absent.

Vessels and Nerves.—The duodenum receives its blood from the superior and inferior pancreatico-duodenal arteries, branches of the gastro-duodenal and superior mesenteric arteries respectively. The blood is returned by the corresponding veins, the superior of which opens into the superior mesenteric, and the inferior into the beginning of the portal vein.

The lymph vessels of the duodenum follow for the most part the course of the blood-vessels.

From the anterior surface, lymph vessels pass along the course of the inferior pancreatico-duodenal artery, and communicate with lymph glands found along the course of that vessel. Thence they pass to the inferior celiac glands, beside the origin of the superior mesenteric artery.

The vessels from the posterior aspect accompany the superior pancreatico-duodenal artery, communicate with the inferior gastric glands, and terminate in the celiac glands.

The nerves come from the solar plexus of the sympathetic.

Flexura Duodenojejunalis.—When the ascending part of the duodenum reaches the inferior surface of the pancreas, at a point opposite the left side of the first or second lumbar vertebra, it turns abruptly forwards, downwards, and to the left, and passes into the jejunum. This abrupt bend is known as the **duodeno-jejunal flexure**. Unlike the rest of the duodenum, which is subject to considerable variations in position in different individuals, the duodeno-jejunal flexure is fixed by a thin band of unstriped muscle, which is attached above to the strong connective tissue around the celiac artery, as well as to the left crus of the diaphragm. This band passes posterior to the pancreas, and inferiorly it joins the muscular coat of the duodenum at the flexure. It is known as the **m. suspensorius duodeni** (O.T. muscle of Treitz).

The duodeno-jejunal flexure is occasionally directed to the right, and it lies at a variable distance from the root of the transverse mesocolon. When the attachment of the transverse mesocolon is low, the duodeno-jejunal flexure is in contact with it.

Duodenal Pouches or Diverticula.—Occasional diverticula are found passing from the duodenal wall in different directions. Such diverticula may be hernial protrusions of the mucous and submucous coats through the muscular wall, termed false diverticula, or they may be “true” diverticula, in which all the coats are represented.

They are usually situated on the aspect of the duodenum which is in contact with the pancreas, and frequently in the neighbourhood of the orifice of the bile duct.

Some of these appear to be due to the pressure from the interior of the duodenum, while others, and the majority of the true diverticula, are rather congenital in origin, and are probably associated with the diverticula which give rise to the liver and pancreas.

HEPAR.

The **liver** is the large glandular organ which secretes the fluid called bile (fel). It occupies the superior and mainly the right portion of the abdominal cavity, and lies immediately below the diaphragm.

Its secretion is conveyed away from it by the hepatic ducts and the bile-duct to the duodenum. With the bile duct there is connected a pear-shaped diverticulum, the gall-bladder (vesica fellea), which lies in contact with the liver, and which serves apparently for the temporary storage of bile.

In addition to secreting bile, the liver plays an important part in the metabolism of both the carbohydrate and nitrogenous materials absorbed from the intestine which are conveyed to it by the portal vein, and it also has to do with the production and the destruction of some of the blood-cells.

Physical Characters.—The liver is a large irregularly shaped mass, of a reddish-brown colour, soft and pliant to the touch, somewhat readily lacerated, and highly vascular.

It is of uniform consistence throughout, and little of its internal structure can be made out by naked-eye examination. If, however, a torn surface be examined, the liver tissue is seen to be somewhat granular. Under the investing peritoneum the surface is somewhat mottled.

This mottled or granular appearance is due to the lobules (**lobuli hepatis**) of

which the liver is composed. Each lobule is a small irregular or polygonal area, measuring from $\frac{1}{25}$ th to $\frac{1}{12}$ th of an inch in diameter, or 1 to 2 mm., with a partial covering of fine connective tissue, forming a delicate stroma.

In the adult, the liver weighs from 3 to $3\frac{1}{4}$ pounds, or about $\frac{1}{40}$ th of the body weight, and it is somewhat heavier in the male than in the female, its weight in the former being from 50 to 55 ounces and in the latter 43 to 48 ounces. The ratio to the body weight is the same in both sexes. In the foetus and child it is relatively very large and heavy. At birth it occupies the greater part of the abdominal cavity, and constitutes from $\frac{1}{20}$ th to $\frac{1}{18}$ th of the body weight. In the young foetus the ratio is even larger.

The average size of the liver may be briefly expressed as follows:—It measures in the transverse direction about seven inches (17.5 cm.); in the vertical, six to seven inches (15 to 17.5 cm.); and in the antero-posterior, on the right side where greatest, about six inches (15 cm.). Its

FIG. 936.—LIVER VIEWED FROM THE FRONT.

greatest width, measured obliquely from side to side along the inferior or visceral surface, is ten inches (25 cm.).

The liver is capable of being greatly distended by fluid forced into its blood-vessels. Its surface then becomes tense, and the consistence of the whole organ becomes much firmer.

Shape.—If the liver is hardened *in situ* and then removed from the body, it will be found to present a form which is fairly constant, but which is modified by the shape and size of the adjacent viscera, and hence shows minor variations in different individuals.

If the liver has not been hardened, it does not retain, after removal, the shape and form which it had when it lay in the abdomen, but tends to collapse into a flattened cake-like mass.

The description of the shape, surfaces, and borders given below is drawn from examination of specimens hardened *in situ*.

The liver possesses three principal surfaces, a superior, a posterior, and an inferior, known as the *facies superior*, *posterior*, and *inferior*.

The *facies superior* is in contact chiefly with the rounded vault of the abdominal cavity, and hence it is uniformly rounded and convex.

The *facies posterior*, directed backwards, is in contact with the structures

forming the superior portion of the posterior abdominal wall. It is deeply indented by the projecting vertebral column, and it is flat in the vertical axis.

The *facies inferior* is directed obliquely downwards and posteriorly, is in contact with a number of the abdominal viscera, especially the right kidney, stomach, duodenum, and colon, and its general configuration is influenced to a marked degree by the shape and position of these organs.

This surface is sometimes termed the visceral, in contrast to the other two surfaces which constitute the parietal surface of the organ.

The parietal and visceral surfaces are marked off from one another by the **inferior margin of the liver**. *Posteriorly*, this margin is indistinctly marked and corresponds to the inferior edge of the posterior area, or back, of the parietal surface: it is in contact with the right kidney, and runs along the course of the eleventh rib. *At the right side* the margin is stout but distinct, and usually corresponds to, or projects a little way below, the inferior border of the thoracic

FIG. 937.—THE LIVER VIEWED FROM BEHIND.

framework. *Anteriorly*, the border is thin and sharp, and passes obliquely upwards from the right to the left side behind the anterior abdominal wall. This portion forms the **margo anterior**. Its direction corresponds to a line drawn from a point half an inch (12 mm.) below the margin of the ribs (tip of tenth costal cartilage) on the right side to a point an inch below the nipple on the left. It extends down in the median plane to a point half-way between the body of the sternum and the umbilicus. This portion of the lower border usually, but not invariably, presents one or two notches. The **incisura umbilicalis**, the more constant of the two (Fig. 936), is situated at the anterior end of a cleft on the inferior surface, known as the **fossa sagittalis sinistra** (see p. 1191), and corresponds to the inferior part of the attachment of the ligamentum teres hepatis. It is usually placed from one to two inches (2.5 to 5.0 cm.) to the right of the median plane. The second notch, less frequently present, corresponds to the fundus of the gall-bladder, and is called the **incisura vesicæ felleæ**.

At its left extremity the margo anterior turns posteriorly around the edge of the left lobe, and ends at a groove on the posterior surface, in which the œsophagus lies, termed the **impressio œsophagea**.

The division between the superior surface and the posterior surface is not marked by a border of any prominence, but by an indefinite margin which runs transversely from side to side.

The superior surface may be further divided into three areas, a superior, an anterior, and a right, following the general direction of these portions of the surface, but they are not clearly marked off from one another by borders.

Their arrangement is as follows:—

The **superior area** of the **superior surface** lies in contact with the roof of the abdomen; it is convex on each side, and depressed near the median plane. The two convexities, of which the right is the more prominent, fit into the two cupolæ of the diaphragm; whilst the central depression, *depressio cardiaca*, corresponds to the position of the heart. This area (with the exception of a small triangle at its posterior part, between the separating layers of the ligamentum falciforme) is completely covered by peritoneum, and on it the division of the liver into right and left lobes is indicated by the attachment of the ligamentum falciforme.

The **anterior area** of the **superior surface** is triangular in shape, and after death is usually flattened, owing to the falling in of the anterior abdominal wall. In part it lies in contact with the diaphragm, which separates it from the rib-cartilages on each side, but at the subcostal triangle it comes into direct relation with the anterior wall of the abdomen, for a distance usually of two or three inches below the xiphi-sternal articulation. It has a complete peritoneal covering, and gives attachment, as far down as the umbilical notch at the inferior border, to the ligamentum falciforme, which connects it to the anterior abdominal wall.

The anterior passes gradually into the upper and right areas, but it is distinctly separated from the visceral surface by the sharp margo anterior of the organ. The umbilical notch is often continued upwards for some distance on the surface as a slit-like fissure.

The **right area** of the **superior surface** is convex and extensive, and lies in contact with the diaphragm, which separates it from the inner surface of the lower ribs, and also above from the inferior margin of the lung and pleura. Though sharply marked off by the margo anterior from the visceral surface, it passes without distinct limits into the other areas of the parietal surface. It is completely covered by peritoneum.

The superior surface is smooth and shows no fissures, but the line of attachment of the ligamentum falciforme is taken as dividing the liver on this surface into a right and a left lobe.

Upon the posterior surface and inferior surface there are several clefts or depressions upon the surface of the liver, termed fossæ or fissures, which further subdivide the surfaces into lobes.

These fossæ, it should be noted, do not indicate any deep division of the liver into separate parts, but are only indentations upon the surface.

Porta Hepatis.—(1) The gate of the liver (O.T. portal or transverse fissure) is the equivalent in the liver of the hilus of other glands. It is a slit-like depression, where the vessels enter the gland, and whence the ducts emerge.

It is placed on the inferior surface, runs transversely from right to left, and measures about 2 to 2½ inches in length. It is bounded anteriorly and posteriorly by prominent margins, and through it the hepatic artery, vena portæ, and plexus hepaticus of nerves enter the liver, and the hepatic ducts and many of the lymph vessels leave. To the anterior and posterior margins of the fissure are attached layers of peritoneum which constitute part of the lesser omentum.

The various structures found in the porta hepatis are arranged in the following way. The vena portæ lies posteriorly, and divides, in the fissure, into right and left branches, which run to right and left. The neck of the gall-bladder, with the cystic duct coming from it, lies at the right extremity of the fissure, and there the cystic duct bends downwards between the layer of the hepato-duodenal ligament.

The right and left bile ducts lie at their respective ends of the porta hepatis, and converge towards each other at the right extremity and lie anterior to the corresponding branches of the hepatic artery, and to the right side of the main vessel at their junction in the hepato-duodenal ligament. The nerves mainly invest the arteries, and the lymph vessels lie in the connective tissue which invests all these structures.

Two or three lymph glands are occasionally found in the porta hepatis, especially at the right end, near the neck of the gall-bladder, and when enlarged, they may press upon the ducts, and interfere with the passage of the bile.

The intervals between the vessels and other structures are filled in by loose connective tissue, which is continued inwards with the vessels as the fibrous capsule of Glisson.

When the porta hepatis is opened up, it is found to extend on the left as far as to the fossa venæ umbilicalis.

(2) **Fossa Venæ Umbilicalis** (O.T. **Umbilical Fissure**).—This is a deep crevice-like fissure, situated in the inferior surface, running from before backwards, parallel to the gall-bladder, but about 1 to $1\frac{1}{2}$ inches to its left side. It begins in front at the margo anterior, which it intersects, and runs backwards to the left extremity of the porta hepatis. Within this fissure lies a rounded cord-like structure, the *ligamentum teres hepatis*, the remains of the left umbilical vein of the foetus. The fissure is often crossed by a bridge of liver tissue, the *pons hepatis*, which may even extend for the whole length of the fissure, and conceal the round ligament from view.

(3) **Fossa Ductus Venosi** (O.T. **Fissure of the Ductus Venosus**).—At the posterior termination of the fossa venæ umbilicalis the ligamentum teres is usually attached to the left branch of the portal vein. Beyond that point it is continued backwards as a fine fibrous band, the *lig. venosum* (Arantii), which runs onwards to join the vena cava inferior. This fibrous cord lies in a groove on the posterior aspect of the liver, called the *fossa of the ductus venosus*.

The umbilical vein and the ductus venosus in the foetus serve to convey the blood back from the placenta to the inferior vena cava.

The umbilical fossa and the fossa for the ductus venosus together form a continuous fossa on the inferior and posterior surfaces which divide them into a right and left lobe. This fossa is known as the *fossa sagittalis sinistra*, in contrast to the porta hepatis, and to the *fossa sagittalis dextra*, lying to the right of two fossæ which is made up of:

(4) **Fossa Vesicæ Felleæ**.—The fossa of the gall-bladder is a slight depression which begins (often as a notch) at or near the margo anterior of the liver, and runs backwards and to the left, as far as the porta hepatis (Fig. 938). Its surface is uncovered by peritoneum as a rule, and in it lies the gall-bladder—the two being united by areolar tissue.

(5) **Fossa Venæ Cavæ**.—The fossa of the vena cava is a deep groove, on the posterior surface, between the caudate and right lobes, in which the superior part of the vena cava inferior is embedded, immediately before it pierces the diaphragm.

The depressions for the gall-bladder and the vena cava are rightly called fossæ. In hardened specimens it will be seen that the fossa of the umbilical vein, the porta hepatis, and the fossa of the ductus venosus are really fissure or crevice-like.
