ABSTRACT—The Blue Snakeskin (BSS) and Red Snakeskin (RSS) varieties are popular strains commercially cultured in Singapore. The blue-black tail color of BSS guppies is determined by a dominant X-linked gene (*Blt*) and the silvery snakeskin pattern on the body of males is under the control of a Y-linked gene (*Ssb*). The Y-linked snakeskin tail pattern gene (*Sst*) though present in BSS males is masked by the blue-black tail color gene (*Blt*). The putative genotypes for males and females of the BSS variety are $X_{Blt}Y_{Ssb,Sst}$ and $X_{Blt}X_{Blt}$, respectively. The red tail color of the RSS variety is due to an X-linked dominant gene (*Rdt*). The snakeskin body pattern of RSS males is under the control of the Y-linked *Ssb* gene while the black reticulations on the tail is due to interaction between the snakeskin tail pattern gene (*Sst*) and the red tail gene (*Rdt*). The proposed genotypes for males and females of the RSS variety are $X_{Rdt}Y_{Ssb,Sst}$ and $X_{Rdt}X_{Rdt}$, respectively. An estimate of 0.9% crossover frequency was obtained between the Y-linked *Ssb* and *Sst* genes and a 2.7% crossover rate of the *Blt* gene from the Xto the Y-chromosome.

INTRODUCTION

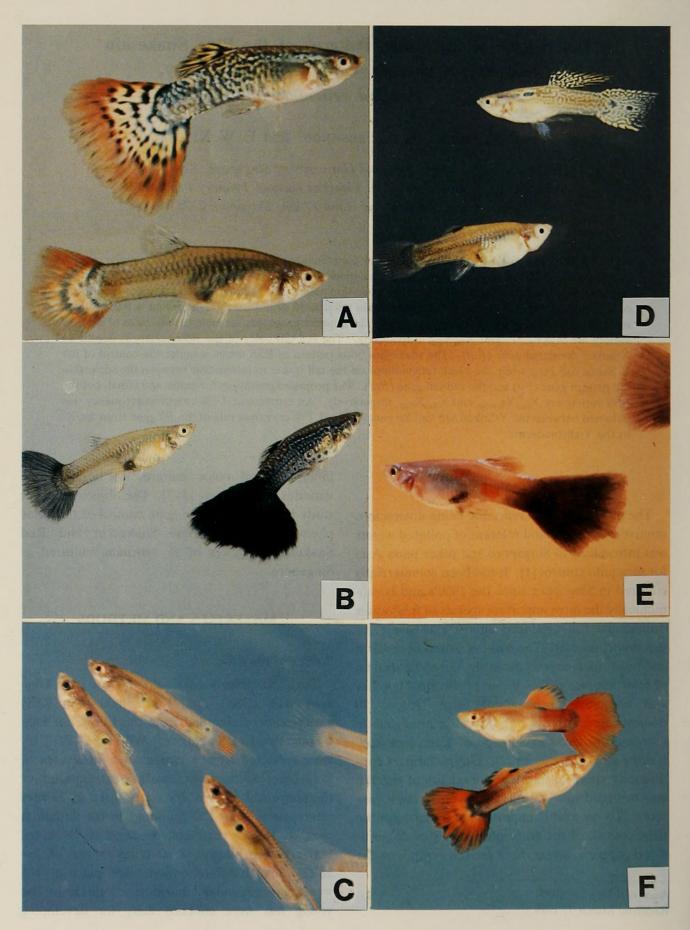

The guppy, Poecilia reticulata being a voracious omnivorous feeder and tolerant of polluted waters was introduced to Singapore and other parts Asia for mosquito control [1]. It has been commercially cultured in Singapore since the 1950's and is economically the most important species of freshwater ornamental fish produced almost exclusively for the export market. The wide variation of brilliant and beautiful colors on the body, tail and dorsal fin of male guppies makes it one of the most popular and ubiquitous ornamental fish. About 30 domesticated varieties of guppies are produced on monoculture farms in Singapore. Each farm specialises in 8-12 varieties [2]. Guppy farmers continuously strive to improve the quality of the fish and to breed new varieties with novel color patterns. To do so it is important to understand the gene control of the color phenotypes of domesticated guppies. So far there are few reports on the

Accepted July 27, 1989 Received March 7, 1989 inheritance of color patterns of domesticated varieties of the guppy [3-7]. The objective of this study is to elucidate the gene control of the color phenotype of the Blue Snakeskin and Red Snakeskin varieties of *P. reticulata* cultured in Singapore.

MATERIALS AND METHODS

Source of the fish

Two- to three-weeks old fry of the Blue Snakeskin (BSS) and Red Snakeskin (RSS) varieties were obtained from the Lim Chin Lam Guppy Farm in Singapore. Wild-type (WT) fry were collected from a stream in a rural area of Singapore. Since virgin females were required for the reciprocal crosses, fry were raised in 33 liter clear plastic tanks (20 fish/tank) in the aquarium area of the Department of Zoology, National University of Singapore, at temperatures of 26– 28°C. Sexual differentiation takes place at 4–6 weeks of age under laboratory conditions. The young fish were checked daily for developing

420

males which are recognized by the modification of the anal fin into the gonopodium. Males when spotted were immediately removed and raised separately from females.

Description of the varieties

Adult males and females of the BSS and RSS varieties have total length of 4–5 cm. Adult RSS males have iridescent snakeskin-like reticulations on the olive-brown body and an orange-red colored tail with black reticulations (Fig. 1A). BSS males are also characterized by silvery snakeskin-like pattern on the body but the tails are blue-black in color (Fig. 1B). Both RSS and BSS females lack the snakeskin patterns. RSS females have the normal wild-type olive brown body coloration with tinges of red and opaque white on the tail. BSS females have the WT body coloration and partial expression of the blue-black tail color.

Wild-type guppies are smaller than the domesticated varieties, with marked size differences between males and females. Adult WT females are 3.0-3.5 cm long while adult males are about 2 cm long. WT males have highly polymorphic color patterns, consisting of spots or patches of various colors on the body, tail and sometimes the dorsal fin while the females lack color patterns (Fig. 1C).

Reciprocal crosses

The inheritance of the color phenotypes of the BSS and RSS varieties were elucidated by performing single-pair reciprocal crosses between each of them and the wild-type stock, using 3month old sexually mature virgin fish. The pairs were kept in eight liter breeding tanks. The following notations were used for the crosses:

Cross 1A: BSS male×WT female, Cross 1B: WT male×BSS female Cross 2A: RSS male×WT female, Cross 2B: WT male×RSS female Broods were usually produced 4–6 weeks after mating. F_2 broods were obtained from single-pair matings between full-sib F_1 fish. Phenotypic proportions among the F_1 and F_2 progeny were subjected to chi-square tests.

Twenty adult females of the BSS and RSS parental stocks and all the F_1 and F_2 female progeny that were not required for breeding were fed with the androgen, methyl testosterone, to express any inherent color genes [8, 9].

RESULTS

Androgen treatment of BSS and RSS females

When androgen treated the tail color of BSS females deepened to a dark blue no snakeskin pattern was manifested on the body. Androgen treated RSS females developed red color on the tail but not the iridescent snakeskin body pattern or the black reticulations on the tail. These results showed that the BSS and RSS females carried the genes for the blue tail color and red tail color, respectively, but not the genes determining the snakeskin pattern.

Cross between the BSS variety and WT stock

Twelve matings between BSS males and WT females (Cross 1A) gave a total of 120 male and 150 female F_1 progeny (Table 1). The F_1 males had the hyaline tail color of WT guppies and a delicate, silvery snakeskin pattern on the body and tail (Fig. 1D). We called the color phenotype of these F_1 males wild-type snakeskin (WTSS). The F_1 females had blue tinges on the tail which on androgen treatment deepened in color but no snakeskin pattern developed the body or tail. These females were cinsidered to have the blue tail phenotype (BT). Since only the male progeny inherited the snakeskin pattern from the BSS male

parent, it showed Y-linkage of the genes determining the snakeskin pattern. The presence of snakeskin reticulations on the tail of F1 males showed that the BSS male parents were carrying the gene for snakeskin tail pattern which was masked by the blue-black tail color. The snakeskin body and tail patterns of another guppy variety, the Green Snakeskin, are controlled by two closely linked genes (Ssb and Sst) on the Y-chromosome [10]. Absence of the blue tail color of the BSS male parents in F_1 males and presence in all F_1 females gave evidence of X-linkage and dominance of the gene determining the blue tail coloration which has been designated as Blt [11]. The recessive allele, Blt^+ , present in WT guppies gives the hyaline tail color.

The F₂ generation of Cross 1A cinsisted of BSS males, WTSS males, BT females and WT females with observed numbers conforming to the 1:1:1:1 expected ratio (Table 1). These results gave evidence that the putative color genotype of BSS males is $X_{Blt}Y_{Ssb,Sst}$ and that for WTSS males is $X_{Blt}+Y_{Ssb,Sst}$. A genetic model is proposed to show segregation of the color genes in Cross 1A (Fig. 2).

However, there were two exceptional F_2 males with WT body color and snakeskin pattern on the tail giving further evidence that the snakeskin body and tail patterns are determined by two Y-linked genes, *Ssb* and *Sst*, respectively. The absence of the expected snakeskin body pattern in these two males is probably due to crossing-over of the *Ssb* gene from the Y- to the X-chromosome. The crossover frequency between the *Ssb* and *Sst* genes calculated from the F_2 offspring of Cross 1A is 0.9%, two crossovers out of a total of 212 F_2 individuals.

Twelve matings of the reciprocal cross (Cross 1B) between WT males and BSS females gave 12 F_1 broods consisting of 97 males and 108 females, all with blue tails (BT phenotype) and without any snakeskin pattern (Fig. 1E). With the exception of five females with the WT phenotype, the F_2 progeny of this cross segregated into BT males, WT males and BT females according to the 1:1:2 hypothetical ratio. Thus the F_1 and F_2 results gave evidence that the BSS parental females were homozygous for the X-linked dominant blue tail gene (*Blt*) with the genotype being $X_{Blt}X_{Blt}$. Figure 2 shows the proposed genetic model for the segregation of color genes in Cross 1B.

The occurrence of five exceptional F_2 females of Cross 1B, with hyaline tails instead of the expected blue tail color of the typical F_2 females could be due to crossing over of the X-linked *Blt* gene to the Y-chromosome in the F_1 male parents of these individuals. Since there were five crossover females out of a total of 183 F_2 females of Cross 1B, the crossover frequency of the *Blt* gene from the X- to the Y-chromosome in the F_1 females of this cross is 2.7%. Crossovers among the F_2 males cannot be detected (Fig. 2).

* Exceptional mating between a RSS $\stackrel{\circ}{\rightarrow}$ producing three exceptional broods, giving evidence that the RSS female parent was heterozygous for the *Ssb* and *Sst* genes.

Cross between the RSS variety and WT stock

Six matings between RSS males and WT females (Cross 2A) produced 12 F_1 broods (Table 2). The 117 F_1 males had hyaline tails and iridescent snakeskin pattern on the body and tail (WTSS phenotype) like the F_1 males of Cross 1A. The 135 F_1 females showed pink tinges on the tail which deepened to red after androgen treatment (RT phenotype). The pooled F_1 data conformed to the 1 WTSS male: 1 RT female. Thus, results showed that the RSS parental males carried the dominant X-linked red tail gene (designated as Rdt) which they passed to their daughters and the Y-linked snakeskin body (*Ssb*) and snakeskin tail (*Sst*) genes which were transmitted to their sons. The recessive tail color allele, Rdt^+ gives the hyaline tail color. The F₂ progeny of this cross segregated into

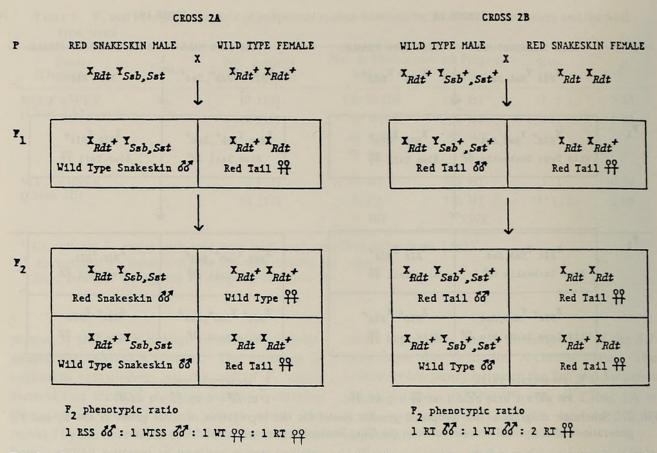

FIG. 3. Schematic diagram of the proposed genetic model for the segregation of color genes in the F_1 and F_2 generations of reciprocal crosses between the Red Snakeskin variety and wild-type guppies.

four phenotypic classes: red snakeskin males (RSS), wild-type snakeskin males (WTSS), red tail females (RT) and WT females with observed numbers conforming to the expected 1:1:1:1 ratio. The putative genotype of RSS males is $X_{Rdt}Y_{Ssb,Sst}$ and that for WTSS males is $X_{Rdt}+Y_{Ssb,Sst}$. A genetic model is proposed to show the segregation of color genes in Cross 2A (Fig. 3).

Five matings of the reciprocal cross of WT males with RSS females (Cross 2B) gave 10 typical F_1 broods consisting of red tail (RT) males and females with numbers conforming to the expected 1:1 segregation ratio (Fig. 1F). The phenotypes of the females were expressed after androgen treatment. The 12 F_2 broods consisted of 56 RT, 70 WT males and 140 RT females. These observed numbers fit an expected segregation ratio of 1:1:2 and provided evidence that the RSS parental females were homozygous for the X-linked dominant red tail gene, *Rdt* (X_{*Rdt*}X_{*Rdt*} genotype). A single atypical mating of Cross 2B gave three exceptional F_1 broods consisting of four phenotypic classes: expected RT males, unexpected WTSS males, expected RT females and unexpected WTSS females. The observed numbers segregated according to the hypothetical 1:1:1:1ratio (Table 2). These results give evidence that the exceptional RSS female parent of this mating carried the *Ssb* and *Sst* genes on one of the X-chromosomes.

DISCUSSION

The blue-black tail color of the BSS variety is found to be controlled by the X-linked *Blt* gene and the red tail color of RSS guppies by the X-linked *Rdt* gene. There is similar evidence of X-linkage of the blue tail and red tail color tail genes present in the domesticated Blue Tail variety and Red Tail variety, respectively [6]. Fernando *et*

424

al. [11] also reported Y-linkage of these genes in domesticated varieties from one farm in Singapore. In this study 2.7% of crossing over of the *Blt* gene from the X- to the Y-chromosome was found, while no crossovers were observed for the *Rdt* gene. Crossing over of genes from the X- to the Y-chromosome and vice versa in the guppy was first documented by Winge [12] and the crossover data have been used to map the sex chromosomes [3, 5, 13, 14]

In male guppies with wild-type hyaline tails (Blt+and Rdt+) the snakeskin tail pattern gene (Sst) is expressed as iridescent delicate reticulations. The Sst gene in males carrying the red tail gene (Rdt) is manifested as black reticulations on the orange-red tail. However, in males carrying the Blt gene which gives the blue-black tail color, the Sst gene when present is completely masked. Outcrosses with WT females showed that the BSS male guppies are carrying the Sst gene.

The 0.9% recombination frequency between the Y-linked Ssb and Sst genes found among the F₂ progeny of Cross 1A is in close agreement with the 1% reported in another domesticated guppy variety, the Green Snakeskin [10]. No crossovers were found among the progeny of Cross 1A showing that the Ssb and Sst genes tend to behave as a supergene and are transmitted as a single unit on the Y-chromosome through the male line. The single RSS female parent of Cross 2B heterozygous for the Ssb and Sst genes, gave evidence that one or both these normally Y-linked genes could be found on the X-chromosome due to crossingover. Our results also showed that the Blt, Ssb and Sst genes are found on the homologous segments of the sex chromosomes. Currently experiments are being conducted to test for possible allelism of the blue tail (Blt) and red tail (Rdt) color genes.

ACKNOWLEDGMENTS

This work was supported by a grant from the National University of Singapore. We would like to thank Mr. K. J. Goh and Mr. H. K. Yip for photography of the guppies and Mrs. J. Mui for typing the tables.
